Abstract. We present diffraction-limited bispectrum speckle interferometry observations of four well-known Herbig Ae/Be (HAeBe) stars, LkHα 198, Elias 1, HK Ori and V380 Ori. For two of these, LkHα 198 and Elias 1, we present the first unambiguous detection of close companions. The plane of the orbit of the new LkHα 198 companion appears to be significantly inclined to the plane of the circumprimary disk, as inferred from the orientation of the outflow. We show that the Elias 1 companion may be a convective star, and suggest that it could therefore be the true origin of the X-ray emission from this object. In the cases of HK Ori and V380 Ori, we present new measurements of the relative positions of already-known companions, indicating orbital motion. For HK Ori, photometric measurements of the brightness of the individual components in four bands allowed us to decompose the system spectral energy distribution (SED) into the two separate component SEDs. The primary exhibits a strong infrared excess which suggests the presence of circumstellar material, whereas the companion can be modelled as a naked photosphere. The infrared excess of HK Ori A was found to contribute around two thirds of the total emission from this component, suggesting that accretion power contributes significantly to the flux. Submillimetre constraints mean that the circumstellar disk cannot be particularly massive, whilst the near-infrared data indicates a high accretion rate. Either the disk lifetime is very short, or the disk must be seen in an outburst phase.

Key words. stars: circumstellar matter – stars: formation – stars: binaries – ISM: Herbig-Haro objects

1. Introduction

Herbig Ae/Be stars (HAeBes) are young intermediate-mass (2–8\,M\odot) pre-main-sequence stars first defined by Herbig (1960). According to his definition, HAeBes should have emission lines in their spectra, an early spectral type and be associated with dark cloud material as an indication of their youth. Despite the similarities between HAeBes and the lower-mass T Tauri stars, questions such as the existence of circumstellar disks, the multiplicity and clustering of the objects, the origin of X-ray emission (Zinnecker & Preibisch 1995), and the outflow activity are much less clarified in the case of HAeBes.

The frequency and properties of binary systems amongst all stars are of great importance in understanding the star formation process, since they can point to certain star formation scenarios and rule out or strongly constrain others.

The configuration of pre-main-sequence multiples is of special importance because the binary properties of the objects can be compared with their formation environment, for example whether in a T association or massive star forming region. There is also less scope for the system configuration to have been altered by stellar interactions or continuing accretion. The angular momentum of the binary can also be compared to that of circumstellar or circumbinary disks which may still exist at this stage. The coplanarity of the system orbit, the individual disks of the components and a possible circumbinary disk are all major constraints on viable formation mechanisms.

Numerous studies using a variety of techniques have established that the majority of low-mass young stars are members of binary systems (e.g. Ghez et al. 1993; Leinert et al. 1993; Simon et al. 1995). The T Tauri population in the nearby Taurus-Auriga T-association displays a factor of 2 higher binary fraction than that seen amongst main-sequence stars. At the high end of the stellar mass range, bispectrum speckle interferometry of the massive stars in the Orion nebula cluster revealed companions for 7 out of 13 target objects, which after correction for undetected systems was estimated to represent a binary frequency close to 100%, with an average

Article published by EDP Sciences and available at http://www.aanda.org or http://dx.doi.org/10.1051/0004-6361:20041135
of >1.5 companions per primary (Preibisch et al. 1999). This is about three times the multiplicity of low-mass stars, and may suggest an alternative formation scenario for the high mass objects. Studies aimed specifically at intermediate mass stars have been rare. Li et al. (1994) carried out an infrared imaging study of 16 sources and reported companions for nine of them, although of these many were widely separated and are probably not bound. Leinert et al. (1997, hereafter LRH97) studied a larger sample of 31 stars using a speckle interferometry technique in the near-infrared, and found that 31% of the systems were multiple with separations between 50 and 1300 AU. This was estimated to represent an excess binarity among HAeBe stars compared to main-sequence G dwarfs of a factor of two. Pirzkal et al. (1997) used a speckle shift and add technique to search for companions around 39 HAeBe stars. They detected 9 multiple systems, and estimated on statistical grounds that this implied a true binary frequency amongst HAeBes of at least 85%. A survey for spectroscopic binaries amongst HAeBe stars by Corporon & Lagrange (1999) found a binary frequency of 17%. For short periods (<100 days) the binary frequency was found to be 10%, compared to the frequency amongst WTTS spectroscopic binaries of 11 ± 4% (Mathieu 1992) or the frequency amongst main sequence solar-mass stars of 7 ± 2% (Duquennoy & Mayor 1991).

In this paper, we present bispectrum speckle interferometry at multiple epochs of four HAeBe systems. For two of these, LkHα 198 and Elias 1, our diffraction-limited images show unambiguously for the first time that they have close binary companions. For the known binary HK Ori, we separate the SEDs of the two companions and by considering the different colours show that the brighter object possesses a circumstellar disk which the secondary lacks. For V380 Ori, we are able to show relative motion compared to the position measured by LRH97.

2. Observations and data reduction

The optical observations of HK Ori were made with the 2.2 m ESO/MPG telescope on March 8, 1995. The speckle interferograms were recorded through interference filters with central wavelength/bandwidth of 550 nm/60 nm and 656 nm/60 nm. The detector used for the visible observations was an image intensifier (gain 500 000) coupled optically to a fast CCD camera (512² pixels/frame, frame rate 4 frames/s). All the other speckle interferograms were recorded with the SAO 6 m telescope in Russia between 1995 and 2003. The detector of our speckle camera at SAO was either a Rockwell HAWAII array (1998-2003; only one 512 × 512 Quadrant was used) or a 256 × 256 PICNIC array detector (1996 and 1997). The visible data sets consist of about 700 to 1400 speckle interferograms each with an exposure time of 50 msec. The infrared data sets consist of between 400 and 3200 speckle interferograms each with an exposure time of between 150 and 250 msec.

The object power spectra were determined with the speckle interferometry method (Labeyrie 1970). Speckle interferograms of unresolved single stars were recorded just before and after the object and served as references to determine the speckle transfer function. Diffraction-limited images were reconstructed using the bispectrum speckle interferometry method (Weigelt 1977; Weigelt & Wirnitzer 1983; Lohmann et al. 1983; Hofmann & Weigelt 1986).

For HK Ori, photometric calibration in the $K'$-band was carried out by observing the photometric standard stars HD 18881 and Gl 105.5, chosen from Elias et al. (1982), on October 19, 1997. For the photometric calibration in the H-band the photometric standard star HD 40335 and the star HD 31648 were observed on October 22 and 19, 1997. The photometric calibration in the visible is based on our speckle observations of NX Pup from March 10, 1995 (Schöller et al. 1996). Simultaneously to our observations of NX Pup, CCD photometry of the unresolved pair NX Pup A/B was carried out at the Danish 1.5m telescope at La Silla. Observations of standard stars taken from the list by Landolt (1992) allowed for the absolute photometric calibration.

3. Results

Each of the observed visibility functions clearly showed a pattern suggestive of a binary system. The separation and position angle of the system were measured directly from the two dimensional visibility function. Maps of the objects were made and the flux ratios were also measured. The recovered parameters for the various systems are listed in Table 1. Below, we discuss each object individually.

3.1. LkHα 198

LkHα 198 (SIMBAD coordinates: $\alpha = 00^h 11^m 25.97^s$, $\delta = +58^\circ 49' 29.1''$, J2000) is a well-studied HAeBe located in the dark cloud Lynds 1265 at a distance of about 600 pc. It is associated with another well-known HAeBe star, V376 Cas, which lies approximately 35° to the north. A schematic picture of the complex environment around these two sources is given in the paper by Koresko et al. (1997). We reproduce a previously unpublished HST image from the archives in Fig. 1, which shows the inner 15'' × 15'' of the system. Other images of the inner region of the system are shown in Koresko et al. (1997), Fukagawa et al. (2002) and Perrin et al. (2004).

Lagage et al. (1993) detected an embedded source (LkHα 198 B) 6'' north of LkHα 198 in 10 $\mu$m images which is also visible at 2.2 $\mu$m (Li et al. 1994) and in the 1.1 $\mu$m HST image shown here. A deeply embedded protostar (LkHα 198 MM) was found about 19'' to the northwest by Sandell & Weintraub (1994) using the JCMT at 800 $\mu$m. This object dominates in the millimetre and submillimetre but is not visible at all at shorter wavelengths. The most striking extended feature in the optical is a large bubble-like elliptical loop extending some 40'' to the southeast at a position angle of approximately 135° (Corcoran et al. 1995). Coronagraphic imaging in the near-infrared by Fukagawa et al. (2002) showed in more detail the close environment of LkHα 198. Their image showed the primary extended along a roughly north-south axis (PA = 15°). This elongation was also reported by Koresko et al. (1997), and is visible in the HST image in Fig. 1, but here the issue is complicated by the presence of a diffraction spike along the same axis.
Table 1. Summary of the observations. For each observation, the epoch and observing wavelength is shown, together with the recovered binary separation (in both mas and AU for the assumed distance), position angle (measured anticlockwise from north), and flux ratio (typical uncertainty 10–20%). Where photometric calibration was performed, the individual magnitudes of the components are also given.

</table>

Numerous HH objects are found around LkHα 198 (see e.g. Corcoran et al. 1995; Molinari et al. 1993; Goodrich 1993). Corcoran et al. (1995) found knots of SII emission tracing both sides of a jet from LkHα 198 at a position angle of around 160°. A further knot of emission was seen along the same axis on the opposite side of LkHα 198 at position angle 340°. These objects have been designated HH 164. Spectra of these emission knots revealed that they have a low radial velocity, and therefore suggest that the jet lies close to the plane of the sky. Another knot seems to trace the southeast part of a jet apparently originating from the companion LkHα 198 B along the axis of the loop. This knot, together with [SII] emission at the loop apex, has been designated HH 161. The trail of nebulosity that can be seen extending eastwards from the previously-known companion LkHα 198 B may be the northern edge of an outflow cavity caused by the flow from this source driving HH 161. Nebulosity is also seen extending east from the main object. This region contains "streamer"-like structure with the same position angle as HH 161 and this might indicate interaction of the outflow from LkHα 198 B with material surrounding the primary. Aspin & Reipurth (2000) discovered a further HH object, HH 461, with a faint bowshock morphology, along the axis of the LkHα 198 jet some 80° to the southeast. McGroarty & Ray (2003) identified two further bowshock-shaped structures, designated HH 801 and HH 802, which lie along the line of HH 164 with a total separation of 2.3 pc.

A region of polarization perpendicular to the centrosymmetric pattern was seen within the central 0.5. This was taken to be the signature of a central, unresolved disk. Perrin et al (2004) used laser guide star adaptive optics to obtain very high quality near-infrared J, H and K_s band polarimetry of the central part of the LkHα 198 system. They saw a polarized biconical nebula aligned almost exactly north-south, with a dark unpolarized central region. This biconical nebula, which can be interpreted as scattering from an evacuated bipolar cavity caused by an outflow, is consistent with LkHα 198 being the source of the outflow HH164, but the axis is apparently misaligned by approximately 20°.

Our speckle observations of LkHα 198 span seven years, from 1996.75 to 2003.78. The two dimensional visibilities show clear signatures of binarity, and the position of the companion, which we designate LkHα 198 A2, relative to the primary (LkHα 198 A1) changes significantly over the period of the observations. The track of the secondary relative to the primary is shown in Fig. 2. The trajectory shows signs of curvature to the east, indicating that we are seeing a segment of an orbit, although it appears a straight line trajectory cannot be excluded. A map of the system reconstructed from the 1999 observations, is also shown in Fig. 2.

3.1.1. Orbital motion

With only seven points, spanning a short segment of the apparent orbit, it is not possible to determine the true orbit with any certainty. Nevertheless, we make some preliminary orbital fits and explore the constraints which can be imposed on the motion.
The exact configuration of the orbit is particularly interesting in the case of LkHα 198 because of the complex environment of the system. The outflow has a low radial velocity, suggesting that it lies in the plane of the sky and that the inner disk should be seen nearly edge-on. This is also the impression given by the polarization maps of Perrin et al. (2004). Long-term photometric monitoring by Mel’nikov (1997) shows that LkHα 198 lacks the strong photometric variations which define UXOR sources, despite the supposed edge-on viewing angle of any disk. According to the prevailing theories of UXOR variability, in which the deep photometric minima are caused by obscuration by clumps in a disk, this makes the object something of an anomaly. The presence of the companion and the details of the orbit are interesting in the context of the complex environment, and we therefore make a more detailed discussion of the orbit than would be justified for an isolated system with such a short known orbital segment.

We made a number of fits to the observed relative motion of the LkHα 198 companion. The fits were made numerically by running a 2-body code multiple times and minimizing the resulting deviations from the points. Conventional orbital parameters for the best fit, such as the major axis, eccentricity and so on, can be recovered from a full simulation of the best-fit orbit.

The mass of the primary was estimated by Hillenbrand et al. (1992) to be 1.6 $M_\odot$ based on the luminosity estimated from the dereddened V magnitude and a spectral type of A5. However, Natta et al. (1992) estimated the luminosity to be 250 $L_\odot$ from far infrared measurements, which by comparison with pre-main-sequence tracks from Palla & Stahler (1993), suggests a mass of 3.5–4 $M_\odot$, if the bulk of this luminosity can be assumed to originate from the primary. If half this luminosity arises from accretion power, the estimated primary mass would fall to 3.0–3.5 $M_\odot$. For an orbit calculation, to the mass of the primary must be added the mass of any compact circumstellar structure such as a disk. Leinert et al.’s (1991) estimate of the mass of the immediate circumstellar material was only 0.01 $M_\odot$, and so we neglect the possible mass of circumprimary...
... inclination of which is listed in Table 2 for comparison with the model orbits. Interestingly, the orientation of the axis of the projected orbit \( d \) is approximately aligned with the direction of the HH 164 jet.

### 3.2. Elias 1

Elias 1, also known as V892 Tau \((\alpha = 04^\text{h}18^\text{m}40.60^\text{s}, \delta = +28^\circ19'16.7'', J2000)\) is located in the Taurus-Auriga complex at a distance of approximately 140 pc (Elias 1978). Its spectral type was estimated as A6 with \( A_V = 3.9 \) mag and luminosity of around 38 \( L_\odot \) (Berrilli et al. 1992), but other authors have assigned earlier spectral types of A0 (Elias 1978) or B9 (Strom & Strom 1994). Elias 1 was classed as a type II HAeBe star by Hillenbrand et al. (1992), having a very flat or even rising SED with a total mass of 6.5 \( M_\odot \), the escape velocity is approximately 17 km s\(^{-1}\), so that the true velocity can be substantially larger than the apparent velocity on the plane of the sky, and the orbit can be significantly inclined to the line of sight.

In Fig. 3, we show four fitted orbits for various assumed system parameters. The orbital parameters and fit \( \chi^2 \) values for these are listed in Table 2. The top left panel shows the fit for a system with masses 1.6/1.0 \( M_\odot \), and low values for the initial value (i.e., before the fitting procedure) of the initial radial position and velocity. This leads to a quite eccentric orbit almost in the plane of the sky. In the top right panel, we show a fitted orbit with the same low values for the initial radial position and velocity, for a system with masses 4/2.5 \( M_\odot \). The lower left panel shows a fit for system with 4/2.5 \( M_\odot \), for which the initial radial offset and velocity were chosen to attempt to produce a near-circular orbit. In fact, the eventual fit has an eccentricity of about 0.3. Finally, a fit was made with a very large initial radial velocity. The intention of this was to incline the fit as highly as possible to the plane of the sky, so that it is as close as possible to coplanar with the supposed edge-on disk at the heart of the system. The inclination of this fit to the plane of the sky was approximately 70\(^\circ\). This fit is shown in the lower right panel of Fig. 3. Finally, a fit was made with the secondary set a long way back from the plane of the sky, and only the north-south and east-west motion varied. This produces the best-fit straight-line motion, the \( \chi^2 \) of which is listed in Table 2 for comparison with the bound fits.

#### 3.1.2. Results of orbit fitting

Although the straight line has the highest \( \chi^2 \) (because it can’t account for the apparent curvature), there is no significant difference between the quality of the various fits. The most edge-on orbit fits which could be made had an inclination of approximately 20\(^\circ\) to the plane of the sky, and the long axis of the projected orbit was tilted by at least 20\(^\circ\) to the east-west direction. This contrasts with the Perrin et al. (2004) image which shows a disk-like structure aligned almost exactly north-south, and the jet velocity measurements of Corcoran et al. (1995) which show low velocities for the jet material and therefore suggest that the jet lies very close to the plane of the sky. Unfortunately, without tangential velocity measurements, it is not possible to put firm limits on the inclination of the jet for comparison with the model orbits. Interestingly, the orientation of the axis of the projected orbit \( d \) is approximately aligned with the direction of the HH 164 jet.
Fig. 3. Orbit fits to the motion of the LkHα 198 companion for various choices of initial parameters. The main panel of each plot shows the fitted orbit projected on the plane of the sky. North is up and east to the left. The measured data points are plotted as open squares and the corresponding points in the fit are plotted with open triangles. A dash-dotted line marks the major axis, and a solid line marks the line of nodes (i.e., the line of intersection between the orbital plane and the plane of the sky). The ascending and descending nodes are labelled “a” and “d”. In the inset at upper right in each figure, we show the segment of the orbit with the data points on a larger scale. The data points are shown with errorbars, and the fitted points are again plotted as open triangles. The first and last points are labelled with the observing epoch. In the inset at lower right, we show the projection in a plane perpendicular to the plane of the sky. North is up and the radial direction (pointing away from the observer) is to the left. The coordinate systems are indicated in each panel of the top left-hand plot. a) Fit for an assumed primary mass of 1.6 $M_\odot$ and secondary mass 1.0 $M_\odot$. The initial guess for the fit involves a low velocity in the $R$ direction and a small displacement from the plane of the sky. As a result, the fitted orbit lies close to the plane of the sky. b) The same low starting values for $R$ position and velocity, but for an assumed primary mass of 4.0 $M_\odot$ and secondary mass 2.5 $M_\odot$. c) A fit with an assumed primary mass of 4.0 $M_\odot$ and secondary mass 2.5 $M_\odot$, with starting conditions chosen to produce a near-circular orbit. d) This fit has masses of 4 and 2.5 $M_\odot$ and a high initial radial velocity, which is intended to produce an orbital plane as highly inclined as possible to the plane of the sky.

in the NIR to FIR. This suggests the presence of a possible envelope as well as a circumstellar disk, or possibly a flared disk. The polarization is 4.7% (Yudin 2000).

A T Tauri type companion lies approximately 4″ to the northeast (LRH97). Kataza & Maihara (1991) obtained one-dimensional speckle interferograms at $K$ and $L$, with position angles of zero and ninety degrees. They also obtained one-dimensional speckle interferograms at $L'$ with PA = 45°, showing the object was resolved in this direction. The object was found to be resolved in the east-west direction, but unresolved in the north-south direction. The preferred interpretation was a flattened halo associated with a circumstellar accretion disk
Table 2. Parameters of the various fitted orbits shown in Fig. 3. The parameters shown are the mass of the primary, mass of the secondary, major axis length, eccentricity, period, position angle of the ascending node (measured anticlockwise from north in the plane of the sky), inclination between the orbital plane and the plane of the sky, and the longitude of periastron, defined as the angle between the ascending node and the periastron measured in the plane of the true orbit and taken in the direction of the secondary’s motion. All the orbits appear prograde on the sky. The last line, labelled “Straight Line”, shows the $\chi^2$ for the best straight-line fit.

and extending some 40 AU in $K$ or 100 AU in $L$. Haas et al. (1997) later obtained 1-D specklegrams at $J$, $H$, $K$ and $L$ with a larger 3.5 m telescope. Their specklegrams were also oriented north-south and east-west. Mostly on the basis of the relative halo brightness at $J$ and $H$, they rejected the disk hypothesis of Kataza & Maihara (1991) and argued instead for a bipolar nebula with east-west orientation. They also considered a possible binary interpretation, noting that a binary with position angle $45^\circ$ or $135^\circ$, separation <0.1 and brightness ratio 0.08 at $K$ or 0.2 at $L$ was not ruled out by their data.

Elias 1 is unusual for HAeBe stars in being an X-ray source (Zinnecker & Preibisch 1994). Giardino et al. (2004) observed a strong X-ray flare from the system, and also smaller X-ray variations which could be identified as originating on Elias 1 and not the companion Elias 1 NE. Spectral fits with a two temperature model suggested a hot component of around $kT \approx 2–3$ keV. The time variability, and the hot plasma temperature, point to magnetically confined plasma in the neighbourhood of the star. Elias 1 is also a radio source, although its rising spectrum, though steep, is consistent with thermal emission from a wind (Skinner et al. 1993).

Our data show that Elias 1 is a close binary with a separation of approximately 50 mas and position angle approximately $50^\circ$ (Fig. 4). Furthermore, the relative position of the secondary with respect to the primary has changed in the seven years between the two observation epochs. The positions and flux ratios are given in Table 1 and are shown in Fig. 5.

The binarity of Elias 1 is important for the interpretation of the X-ray flux observed from this object. HAeBe stars should lack the convective zone necessary to drive a conventional dynamo. Novel dynamo mechanisms have been developed to explain HAeBe activity, such as the differential rotation dynamo model of Tout & Pringle (1995). Also, it has been suggested that deuterium burning in a shell outside a radiative core powers a surface convective layer (Palla & Stahler 1990). Such models are of course not necessary if a low-mass companion is in fact the source of the X-ray emission. The spectral type of A6 and luminosity of Elias 1 suggest, from comparison with tracks (Palla & Stahler 1993), that its mass is of order $2–2.5 M_{\odot}$. The flux ratio of the system suggests a companion mass of 1.5–2 $M_{\odot}$, which lies close to the boundary between fully radiative and partially convective stars. Therefore, it is possible that the companion has a normal convection-generated magnetic field and corona and is the source of the X-ray emission.

3.3. HK Ori

3.3.1. The data

HK Ori ($\alpha = 05^h31^m28^s04, \delta = +12^\circ09'10''3", J2000$) is an A5 type star with $A_V = 1.2$. It was found to be a binary by LRH97, who designated the brighter NIR component to the southwest A and the fainter northeastern component B. LRH97 found a binary separation of $(0.34 \pm 0.02)'$ and position angle $(41.7 \pm 0.5)^\circ$. Contour maps of the system in bands V, $H$ and $K$ are shown in Fig. 6, together with 3-d plots illustrating the brightness ratio. The track of component B with respect to component A is shown in Fig. 7. Our data points trace a path from southeast to northwest. The radial position of LRH97 is broadly...
consistent with our measured positions, but the azimuthal position is not in agreement with the position suggested for epoch 1992.12 from our data.

Following LRH97, we can use our flux measurements to disentangle the SEDs of the individual components of HK Ori. LRH97 used observations at wavelengths of \( \lambda \) (0.917 \( \mu \)m), \( J \), \( H \), and \( K \), and had to rely on flux ratios alone. We have data at four different wavelengths, 550 nm (\( V \)), 656 nm (\( R \)), as well as \( H \) and \( K \). The optical points were not available to LRH97, and we are therefore able to separate the SEDs of the components over a significantly wider wavelength range. Furthermore, our data is photometrically calibrated (except for the 2003 point which we do not use in this analysis). There remains the problem that our measurements are not simultaneous. However, independent measurements in October, 1997 show that the \( V \)-magnitude was the same as during our earlier observations in 1995 (\( V = 11.7 \pm 0.1 \) derived from speckle observations in 1995, \( V = 11.6 \pm 0.1 \) in 1997, Mel’nikov priv. communication). This indicates that the system was in a comparable state at both epochs and that it is therefore valid to combine our data into one SED.

In Fig. 8 we present the separated SED (along with various models described in Sect. 3.3.2). SEDs for the whole system were taken from Hillenbrand et al. (1992) and Berrilli et al. (1992). An upper limit at 1.3 mm was taken from Henning et al. (1997). The error bars for \( U \), \( B \) and \( V \) reflect the measured variability as reported by Eiroa et al. (2002) in the \( V \)-band. For \( R \) through \( K \) the measurement uncertainty was used (typically of order 10%), and for wavelengths longer than 2.2 \( \mu \)m, an assumed 10% uncertainty was adopted.

The SEDs of the individual components A and B are constructed from points measured by us at \( V \), \( R \), \( H \), and \( K \), and points measured by LRH97 at \( I \), \( J \), \( H \) and \( K \). Our points are calibrated as described in Sect. 2. LRH97 obtained flux ratios but not absolute fluxes. We therefore normalised their values against the total flux given by Hillenbrand et al. (1992). In the case of LRH97’s \( I \) point, the Cousins system flux of the composite SED was converted to a supposed Johnson system \( I \) flux using the information given in Bessell (1983).

All fluxes were corrected for the effect of interstellar reddening. The visual extinction, \( A_V = 1.2 \) was determined by Hillenbrand et al. (1992) from the \((B-V)\) excess. The extinction law given by Cardelli et al (1989) was used to estimate the wavelength dependency of the extinction, with the assumption that \( R_V = 3.1 \).

The SED is clearly dominated by component A (which we designate the primary) at longer wavelengths. The brightness ratio moves towards unity in the very near-infrared (\( I \) and \( J \) bands). LRH97 considered one possible scenario in which the brightest infrared component, A, might in fact be a low-mass IR companion, and the fainter component the primary. This conjecture was apparently confirmed by Baines et al. (2004) who used a spectroastrometry technique to show that the southwestern component dominates the emission at \( H \alpha \). Their data also suggested that the northeastern component might be the brightest optical source in the system. However, our data points at 550 nm and 656 nm now exclude this possibility, and show clearly that the brighter IR component to the southwest also dominates in the optical (see top panel of Fig. 7). Variability of the T Tauri source is a possible but not convincing explanation for this discrepancy, since the photometrically calibrated flux of component A matches the composite SED published in Hillenbrand et al. (1992), whereas the flux of component B does not.

The infrared colours of the two components are very different. The brightest component has \( H - K = 2.12 \), whereas component B has \( H - K = 1.10 \). The implication is that component A possesses significantly more circumstellar material than component B, which resembles a naked photosphere of around 4000 K. The positions of the two objects are shown in a colour–colour diagram in Fig. 9. Comparing this figure to colour–colour diagrams of young stars, for example Fig. 15 of Hillenbrand et al. (1992), it is clear that the primary (component A, to the southwest) occupies a typical position for an intermediate mass young star, whilst the companion (component B, to the northeast) occupies a position typical for a T Tauri star.

We have fitted a 4000 K photosphere, corresponding to a mid-K spectral type, to the SED of component B. This fit represents the SED of component B very well, with the possible exception of the \( B \)-band point. Where no resolved points were available, we have subtracted this fit to determine points for A. In practice, this model subtraction makes little difference to
most of the fluxes measured for the composite system, and this method is nearly equivalent to assuming that component A contributes essentially all the flux at $U$, $B$ and in the mid-infrared.

3.3.2. Modelling strategy

Component A is responsible for most of the IR-excess of the system and presents a “double-bumped” SED. The first bump peaks around 400 nm and is produced by the central A-type star. The second one, peaking around 3 $\mu$m, is a signature of the presence of circumstellar matter and is usually interpreted as emerging from an accretion disk (e.g. Hillenbrand et al. 1992).

Let us emphasise that the NIR- and MIR-excesses are unusually strong for a Herbig star, with a flux intensity $AF_\lambda$ peaking as high as the stellar photosphere (see Fig. 8) while it is one order of magnitude smaller in most HAeBes (see Fig. 1 in
A long accreting disk should not strongly accrete. The separate optical positions from 1995 and separate $H$ and $K$ positions for epoch 1997.8 have each been averaged to produce one position for each date. The solid line is a circle of radius 155 AU for an assumed distance of 460 pc centred on the primary.

Natta et al. (2001). Making a simple three blackbody fit, we estimate that the circumstellar flux accounts for fully two thirds of the observed flux from component A. The low visual extinction ($A_V = 1.2$) hints that the star is not significantly shadowed by circumstellar material, so that the circumstellar matter actually emits twice as much flux as the star in the observer’s direction. Higher values of $A_V$ for the photosphere can be considered if the extinction law is taken to be non-standard ($R_V = 5$ leads to $A_V = 3$ for the measured $E(B - V)$), but we feel this is unlikely since the the derived extinction is in agreement with the extinction from interstellar matter measured for nearby Herbig-Haro objects (Goodrich et al. 1993). Though the reprocessing of stellar light is widely accepted to be the main source of energy in typical HAeBes (Chiang & Goldreich 1997; Natta et al. 2001; Dullemond et al. 2001), it seems unable to account for so high a IR-excess: an optically thin envelope would reprocess only a fraction $\tau < 1$ of the stellar light, and an optically thick disk $\tau = 0.05-0.5$, where $h$ is the thickness of the disk, and $r$ the distance to the star. So, we follow Hillenbrand et al. (1992) in their assumption that viscous heating (i.e. accretion luminosity) is responsible for most of the observed flux. We use a generalised version of the Chiang & Goldreich (1997) model by Lachaume et al. (2003), that includes viscous dissipation in addition to stellar irradiation, to fit the SED. Our approach has the advantage of not excluding a priori the hypothesis of an irradiated disk.

The fitted parameters are summarised in Table 3, and the SED data and fit are displayed in Fig. 8. The large IR excess at $\lambda > 2 \, \mu m$ cannot be explained with irradiation only (dash-dotted line in Fig. 8) and requires a high accretion rate $\dot{M} = 2.5 \times 10^{-6} \, M_\odot \, yr^{-1}$ (solid line). The depression in the SED around 1 $\mu m$ suggests that the inner, hot regions of the disk should be depleted. which our model backs: the inner rim of the disk is located at $31 \, R_\odot = 20 \, R_* = 0.15 \, AU$ from the star.

On one hand, the accretion rate and outer disk truncation radius are in good agreement with those derived by Hillenbrand et al. (1992). This could be expected, since these parameters are sensitive to the mid- and far-IR SED that was not affected by our resolving the binary. On the other hand, the visible and NIR SED for component A significantly differs from that of the total system, so that our estimates for the stellar photosphere (derived from the visible photometry) and the inner truncation (sensitive to the depression at 1 $\mu m$) are quite different from their values.

### 3.3.3. Disk properties

The model was computed with the viscosity coefficient $\alpha = 2 \times 10^{-2}$ (see Shakura & Sunyaev 1973), but choosing any $\alpha$ above $10^{-3}$ does not greatly affect the quality of the fit. The upper limit at 1.3 mm constrains the amount of material at larger radii, and the mass of the disk is limited to about 0.06 $M_\odot$. Combined with the high accretion rate, this estimate leads to a lifetime of the disk between a few $10^4$ and a few $10^5$ years, i.e. less than the typical age of HAeBe stars. On one hand, the lifetime may be extended by replenishing of the disk with material from some wider reservoir. The scenario of a circumbinary disk is unlikely, since material with high angular momentum should accrete on to the secondary instead of the primary, at least in a coplanar system. This favors the hypothesis of mass infall from a spherically symmetric envelope. This envelope should however comprise at least a few solar masses, implying a significant reddening, which is not observed. On the other hand, HK Ori could be in a transitory high-accretion state of an otherwise “quiescent”, passive accretion disk.

More concerning is the presence of a large central gap ($20 \, R_*$) in an intensively accreting disk. As pointed out by Hartmann et al. (1993), a strongly accreting disk should not present such a gap: the gap is either understood as a drop in optical thickness beyond the dust sublimation radius, or as a cleared region due to stellar magnetic fields which drive the matter into accretion streams or into an outflow. However, the large amount of material in this disk would ensure that the gas remains optically thick, whilst the field strength required to truncate the disk at $20 \, R_*$ would be of order tens of kilogauss. Though these arguments plead for a moderately accreting disk, we were not able to find a mechanism other than accretion that could account for the very large IR-excess. In particular, the reprocessing of the stellar light leads to IR fluxes of up to a few tens of percent of that of the star. As previous simulations by Chiang & Goldreich (1997) and Dullemond et al. (2001) suggest.

#### 3.4. V380 Ori

V380 Ori ($\alpha = 05^h36^m25.43^s$, $\delta = -06^\circ42'57.7''$, J2000) is a B9 star in the Orion complex at a distance of 460 pc. It was classified as a group I source by Hillenbrand et al. (1992), meaning that its SED can be fitted by a geometrically thin, optically thick accretion disk.
The system was resolved as a $\sim 150$ mas binary by LRH97. They attempted to divide the SED of the system into the contributions of the two components. As with HK Ori, they considered two models; one in which the brightest source in the IR continues to dominate in the optical, and one in which the brighter IR source is an “IR companion” which is less bright in the optical. Millan-Gabet et al. (2001) used long-baseline interferometry to resolve V380 Ori A. Their uniform ring model fit had an inner radius of 2.5 mas, corresponding to just over 1 AU.

In Fig. 10 we show a contour plot of the V380 Ori system, and a plot of the position we obtained for the secondary in 2003, together with the position obtained by LRH97.

Based on the data presented, it would appear that there has been orbital movement of the V380 Ori system. The relative position of the secondary has changed by about 26 AU. This apparent shift has been largely in a tangential sense, as can be seen by comparison with the circle segment shown in the figure.

The flux ratio at $K'$ is measured by us to be 0.266 $\pm$ 0.008, whereas LRH97 obtained 0.35 $\pm$ 0.08. These values are almost compatible with each other to within 1$\sigma$. Unfortunately, unlike in the case of HK Ori, we have no optical observation and so cannot resolve the ambiguity considered by these authors in the SEDs.

4. Conclusions

We have used bispectrum speckle interferometry to resolve for the first time the binary companions to the HAeBe stars...
Fig. 9. \((H-K)\) vs. \((J-H)\) colour–colour diagram showing the positions of the primary and secondary in the HK Ori system. Component A is shown with a circular point and component B with a triangle. The colours have been corrected for the effects of interstellar reddening. The main sequence (from Bessell & Brett 1988) and the direction of interstellar reddening are also shown.

Table 3. Fitted parameters for HK Ori. A disk mass of 0.06 \(M_\odot\) is derived from these parameters. The parameters obtained by Hillenbrand et al. (1992) are given in italic when available.

LkH\(\alpha\) 198 and Elias 1. We also resolved the known binaries HK Ori and V380 Ori. In the case of LkH\(\alpha\) 198, the new object lies at a separation of approximately 60 mas, or 36 AU from the brighter component. Our observations comprise seven data points taken at intervals of approximately one year over a seven year time period. Motion of the secondary with respect to the primary is seen and the path is suggestive of an arc, although a straight line cannot be excluded. Because the companion may well have an important effect on the interesting and well-studied circumstellar environment of LkH\(\alpha\) 198, we have fitted several possible orbits to these points and shown that the plane of the orbit cannot be viewed exactly edge-on with an exactly east-west orientation. This may imply that the binary is not coplanar with the inferred disk powering the outflow. The flux ratio of the Elias 1 system indicates that the new companion has a mass of around 2 \(M_\odot\) and therefore may be a convective star. This opens the possibility that the X-ray emission of Elias 1 originates from the companion and is powered by conventional mechanisms. The SED of HK Ori was separated into the contributions of the primary and secondary components. The IR excess of HK Ori A was found to contribute around two thirds of the total emission from this component, suggesting that accretion power contributes significantly to the flux, in contrast to most HAeBe stars whose SEDs can often be well fitted with passive disks. We fitted an accretion disk model to the HK Ori A SED and determined the accretion rate and disk mass. From these parameters, the inferred disk lifetime is found to be quite short compared to the suspected age of HK Ori. It is possible that the disk could be replenished from a wider reservoir of material, but there are problems with such a picture; a spherical envelope should lead to extinction which is not observed, whilst in a coplanar system, accretion...
from a disk should proceed preferentially onto the secondary. Another explanation could be that the HK Ori disk is seen in an outburst phase. Such a phase need not affect the outer disk, so that the accretion rate may not be uniform throughout. Our relative positions for this system trace a path over the eight years of observations which may be the segment of an orbit. Future near-simultaneous multi-wavelength high-resolution observations will allow a more detailed picture of the disk. High-resolution observations in the mid-infrared could determine whether or not component B has a passive disk. Further observations of all four stars will be necessary to build up reliable orbit determinations. LkHα 198 in particular should be a fascinating subject for future study from this point of view, since the close binary companion may be responsible for much of the complexity in the circumstellar environment of this system.

Acknowledgements. We would like to thank the anonymous referee for constructive comments which have helped us to improve the manuscript.
