ABSTRACT

We present a complete library of synthetic spectra based on Kurucz's codes that covers the 2500–10 500 Å wavelength range at resolving powers $R_p = 20\,000$, 11 500 (\equiv GAIA), 8500 (\equiv RAVE), 2000 (\equiv SLOAN) and uniform dispersions of 1 and 10 Å/pix. The library maps the whole HR diagram, exploring 51 288 combinations of atmospheric parameters spanning the ranges: $3500 \leq T_{\text{eff}} \leq 47\,500$ K, $0.0 \leq \log g \leq 5.0$, $-2.5 \leq [M/H] \leq 0.5$, $[\alpha/\text{Fe}] = 0.0, +0.4$, $\xi = 1, 2, 4$ km s⁻¹, $0 \leq V_{\text{rot}} \leq 500$ km s⁻¹. The spectra are available both as absolute fluxes as well as continuum normalized. Performance tests and spectroscopic applications of the library are discussed, including automatic classification of data from spectroscopic surveys like RAVE, SLOAN, GAIA. The entire library of synthetic spectra is accessible via the web.

Key words. astronomical data bases: miscellaneous – stars: atmospheres – stars: fundamental parameters – surveys

1. Introduction

Large and complete synthetic spectral libraries of normal stars are of interest for many different applications, including (a) automatic analysis and classification of large volumes of data, like those collected by ongoing spectral surveys, (b) derivation of radial velocities via cross-correlation against best matching templates, (c) calibration of spectroscopic line/band classification criteria, and (d) calibration of photometric indexes. Tasks a–c require the synthetic spectra to match the absorption lines in observed spectra normalized to the local continuum, generally irrespective of how well the overall spectral energy distribution is reproduced. The goal of task d is instead to match the energy contained within photometric bands, irrespective of the performance on the individual absorption lines. Therefore, synthetic spectral libraries well suited for one task do not necessarily perform equally well on another. For example, within the Kurucz's synthetic spectra suite, the inclusion in the computations of the so-called “predicted lines” (hereafter PLs, Kurucz 1994) limits the range of applications. The PLs are calculated absorption lines due to transitions involving one and sometimes

two levels whose locations are predicted by atomic structure codes. Wavelengths for these lines may be uncertain by ≥ 10 Å, with large uncertainties also affecting their computed intensity. As a consequence the predicted lines may not correspond in position and size to the observable counterparts (cf. Bell et al. 1994; Castelli & Kurucz 2004). For all these reasons the predicted lines are not intended to be used for the analysis of high resolution spectra, but are an essential contribution to the total line blanketing in model atmospheres and spectral energy distribution computations. Very accurate line wavelengths and shapes are not needed for the statistical computations of the line opacity in model atmospheres or for the prediction of low resolution spectra.

Various libraries of synthetic spectra are becoming available, and they are summarized and compared in Table 1. These libraries widely differ in wavelength interval, spectral resolution, input model atmospheres and range of atmospheric parameters explored, so that their overlap is not significant.

As for other libraries in Table 1, our one is based on Kurucz's atmospheres, line-lists and computing software. The main goal of our spectral library is spectroscopic applications of the a and b types above, which imposes the exclusion of the PLs from computations and therefore does not claim accurate broad-band photometric performances particularly at lower temperatures. Other relevant characteristics of our library are the various resolutions and rotational velocities at which it is provided, its wide wavelength range, the adoption of improved model atmospheres based on the new opacity

[★] Figure 1 is only available in electronic form at the CDS via anonymous ftp to cdsarc.u-strasbg.fr (130.79.128.5) or via <http://cdsweb.u-strasbg.fr/cgi-bin/qcat?J/A+A/442/1127>; Table 1 is also available in electronic form at the CDS. The entire library of synthetic spectra is accessible via CDS, <http://archives.pd.astro.it/2500-10500/> or (for the 1 Å/pix version only) <http://gaia.esa.int/spectralib/spectralib1A/SpectralLib1a.cfm>

Table 1. Comparison of the principal characteristics of publically available libraries of synthetic spectra with resolution better than 5 Å. *N*: number of combinations of atmospheric parameters and rotational velocities. *new ODF*: use of the new opacity distribution functions. *TiO*: inclusion of the TiO line-list. *pred. lines*: inclusion of the “predicted lines”. The last three columns indicate if the spectra are provided for different values of enhancement of α -elements, micro-turbulence velocity and rotational velocity.

distribution functions (ODFs) by Castelli & Kurucz (2003), the use of the TiO line list of Schwenke (1998), the inclusion of α -element enhancement and different micro-turbulent velocities.

2. The spectra

The whole grid of spectra in our library was computed using the SYNTH code by Kurucz (Kurucz & Avrett 1981; Kurucz 1993), running under the VMS operating system on a Digital Alpha workstation in Asiago. We adopted as input model atmospheres the ODFNEW models (<http://wwwuser.oat.ts.astro.it/castelli/grids/>; Castelli & Kurucz 2003). They differ from the NOVER models (<http://kurucz.harvard.edu/grids.html>; Castelli et al. 1997) in the adoption of new ODFs, replacement of the solar abundances from Anders & Grevesse (1989) with those from Grevesse & Sauval (1998), and improvements in the molecular opacities including the adoption of the molecular line-lists of TiO by Schwenke (1998, as distributed

by Kurucz 1999a) and of H₂O by Partridge & Schwenke (1997, as distributed by Kurucz 1999b). For the combination of atmospheric parameters for which no ODFNEW models were available at the time of writing, we adopted the corresponding NOVER input model atmospheres. We plan to update the library from NOVER to ODFNEW models as more of the latter will become available and to post the result on the library web page (see below). Both the NOVER and the ODFNEW models were computed with the overshooting option for the mixing-length convection switched off, while Kurucz (K) atmospheric models (also available from <http://kurucz.harvard.edu/grids.html>) were computed with the overshooting option switched on. Several papers have demonstrated that for stars with active convection ($T_{\text{eff}} < 9000 \text{ K}$) the no-overshooting convection treatment provides better agreement with the observations than the overshooting case does (Castelli et al. 1997; Smalley & Kupka 1997; Gardiner et al. 1999; Smalley et al. 2002). The no-overshooting models used by us were computed for the mixing-length parameter to the scale height of 1.25. This value allows to fit the observed solar irradiance, while a lower value, like that of 0.5 suggested by Smalley et al. (2002), does not. On the contrary, 0.5 seems to better fit the wings of H β , provided that the position of the continuum is known with an uncertainty smaller than 1%. In fact, a difference of 1% in the position of the solar continuum corresponds to the difference

Table 2. Range of atmospheric parameters explored by our synthetic spectral library.

Temperature (K)	$3500 \leq T_{\text{eff}} \leq 47\,500$	steps of 250 K for $T_{\text{eff}} \leq 10\,000$ K; proportionally larger for higher T_{eff}
Gravity (cgs units)	$0.0 \leq \log g \leq 5.0$	
Metallicity	$-2.5 \leq [M/H] \leq +0.5$	
Rotation velocity (km s^{-1})	$0 \leq V_{\text{rot}} \leq 500$	0, 2, 5, 10, 15, 20, 30, 40, 50, 75, 100 for $T_{\text{eff}} \leq 6000$ K 0, 10, 20, 30, 40, 50, 75, 100, 150, 200, 250, 300, 400, 500 for $T_{\text{eff}} > 6000$ K
Enhancement	$[\alpha/\text{Fe}] = 0.0, +0.4$	$[\alpha/\text{Fe}] = +0.4$ for $[M/H] = -0.5, -1.0, -1.5$
Micro-turbulent velocity (km s^{-1})	$\xi = 1, 2, 4$	1 and 4 km s^{-1} for $[\alpha/\text{Fe}] = +0.4$
ODFs	new	old where new ones not yet available
Predicted lines	excluded	

between 0.5 and 1.25 of the mixing-length parameter (Castelli et al. 1997). Generally, it is very difficult to determine the location of the continuum across the wings of the Balmer lines, especially in Echelle spectra which are notoriously severely affected by the blaze function.

In computing the synthetic spectra we used the Kurucz atomic and molecular line-lists (Kurucz 1992). The effects of several molecules were taken into account, including C_2 , CN, CO, CH, NH, SiH, SiO, MgH and OH. The TiO molecular lines (from Schwenke 1998) were included in the computation when $T_{\text{eff}} \leq 5000$ K. The synthetic spectra are calculated and made available both as fluxes for unit wavelength and as normalized intensities. The latter have a different meaning from the normalization to the continuum of the observational spectroscopy, where the location of the continuum is taken to be represented by the regions away from absorption lines or bands. In synthetic spectra, a continuum-normalized spectrum is obtained by dividing the absolute fluxed spectrum by its *calculated* continuum. Noticeable differences are limited to the head of the Paschen and Balmer series of hydrogen, and to the coolest stars dominated by molecular bands.

3. The library

The spectra in our library covers from 2500 to 10 500 Å and were calculated at a resolving power $R_p = \lambda/\Delta\lambda = 500\,000$ and then degraded by Gaussian convolution to lower resolving powers and properly re-sampled to the Nyquist criterion (the FWHM of the PSF being 2 pixels), to limit the data volume and therefore facilitate the distribution.

The highest resolving power for our library is $R_p = 20\,000$, which is typical of moderately high resolution Echelle observations, such as the spectral database of real stars of Munari & Tomasella (1999) and Marrese et al. (2003). The library is also provided at the resolving powers of the SLOAN survey $R_p = 2000$ (York et al. 2000), of the RAVE survey $R_p = 8500$ (Steinmetz 2003, Munari et al. 2005) and of the Gaia space mission $R_p = 11\,500$ (Katz et al. 2004, Wilkinson et al. 2005). The present library is also made available at the uniform dispersions of 1 and 10 Å/pix (again with the FWHM of the PSF being 2 pixels). The latter two are intended to be of assistance in classification of medium and low resolution grating spectra obtained in single dispersion mode (as with conventional B&C spectrographs or EFOSC-like imager/spectrographs).

Each spectrum is provided for a range of rotational velocities, as detailed in Table 1, spanning 14 values between 0 and

Table 3. Naming scheme for the spectra contained in the library.

example: T04000G45M05V015K2ANWNVNR20F.asc		
characters		meaning
1–6	T04000	T_{eff} (K)
7–9	G45	$10 \times \log g$ (cgs units)
10	M	sign for metallicity: M = “–”, P = “+”
11–12	05	$10 \times [M/H]$
13–16	V015	rotational velocity (km s^{-1})
17–18	K2	microturbulent velocity (km s^{-1})
19	A	$[\alpha/\text{Fe}]$ enhancement: S = 0.0, A = +0.4
20–21	NW	NW = new ODF models, OD = old ODF models
22–23	NV	no overshooting
24–26	R20	R20 = resolving power 20 000; RVS = resolving power 11 500 (GAIA); RAV = resolving power 8500 (RAVE); SLN = resolving power 2000 (SLOAN); D01 = 1 Å/pix dispersion; D10 = 10 Å/pix dispersion
27	F	F = fluxed spectrum ($\text{erg cm}^{-2} \text{s}^{-1} \text{Å}^{-1}$) N = normalized spectrum

500 km s^{-1} for stars hotter than 6000 K and 11 values between 0 and 100 km s^{-1} for cooler ones.

The explored combinations of parameters in Table 2 give rise to 51 228 spectra, each provided in six different combinations of resolving power and sampling, and two flux varieties (absolute units and normalized intensities). The total number of individual spectra contained in this library is therefore $51\,228 \times 6 \times 2 = 615\,456$. The spectra are provided as gzipped ASCII files containing only the flux column, the common wavelength column being given separately only once for each of the six resolutions. The adopted scheme for the naming of files is outlined in Table 3.

All spectra in the library can be directly accessed and retrieved through the dedicated web page <http://archives.pd.astro.it/2500-10500/>. The version of the library at 1 Å/pix is accessible also via ESA’s web site <http://gaia.esa.int/spectralib/>, where browsing facilities based on Virtual Observatory tools are provided. A distribution via DVDs will be possible in special cases (to be arranged directly at munari@pd.astro.it).

4. Test applications

To evaluate the spectroscopic and photometric performances of our library we have carried out several tests. They support the use of the library in spectroscopic applications (our main goal), while caution should be applied in the photometric use at lower temperatures and/or shorter wavelengths. It is worth noticing that significant discrepancies affect the comparison of available libraries with observational data over blue wavelengths and low temperatures.

4.1. Eclipsing binaries

A heavily demanding spectroscopic application of our library has been carried out by Siviero et al. (2004) and Marrese et al. (2005) in investigation of double-lined solar type eclipsing binaries, as a source for (i) best matching templates in cross-correlation determination of radial velocities and (ii) a reference grid in χ^2 analysis of atmospheric properties of binary components. They used the $R_p = 20\,000$ version of the library.

The availability of a wide and complete range of rotational velocities for all the spectra in our library always allowed them to select the best template even with binaries characterized by high rotation, a key ingredient to reach absolute precisions better than 1 km s^{-1} in individual radial velocities even on modest S/N spectra.

The derivation of atmospheric parameters via χ^2 fitting to the library converged independently to the same values as derived geometrically by the orbital solution. The χ^2 and orbital determinations provide the same gravities within 0.03 dex, the same rotational velocities within 4 km s^{-1} and the same difference in temperature between the two components within 42 K (0.6%). The metallicity was indirectly derived by the orbital solution via matching with theoretical isochrone tracks on the temperature-luminosity plane. The values derived in this way are confirmed within 0.06 dex by direct χ^2 analysis. Given the significant rotation exhibited by components of binaries (generally synchronous with orbital motion) the wide range of rotational velocities covered by our library proved once again to be essential to obtain accurate χ^2 results.

The above results would have been significantly degraded if we had used a library computed with inclusion of the PLs. To support this assertion we have re-run exactly the same χ^2 fits of Siviero et al. (2004) and Marrese et al. (2005) using an identical grid of synthetic spectra, this time computed with the inclusion of PLs. In the case of V570 Per the use of spectra with PLs pushes the χ^2 fit away from the geometrical solution by $\Delta T_{\text{eff}} = 109\text{ K}$ and $\Delta[M/H] = 0.16$, and by $\Delta T_{\text{eff}} = 98\text{ K}$, $\Delta \log g = 0.10$ and $\Delta[M/H] = 0.11$ for V432 Aur (average values for the components of the given binary). The differences are always in the sense that inclusion of PLs pushes the χ^2 fit away from the correct one by going toward cooler temperatures and lower metallicities. This is an expected, systematic trend. In fact, the inclusion of PLs causes the continuum in synthetic spectra to become fainter (cf. bottom panel of Fig. 2), causing a reduction in the contrast between strong absorption lines (those dominating the outcome of the χ^2 fit) and the adjacent continuum. To re-establish the proper contrast, the χ^2 fits a

Fig. 2. The effect of α -enhancement, micro-turbulent velocity ξ , new vs old ODFs, and inclusion of “predicted lines” are illustrated by sample spectra. To increase readability all spectra have been broadened to a rotational velocity of 20 km s^{-1} . In each panel the bottom part highlights the difference between the plotted spectra (always in the sense *solid – dotted* lines).

cooler temperature. Also fitting a lower metallicity helps to re-establish the proper contrast. PLs are mainly a forest of weak, optically thin lines that respond much faster to a small change in metallicity than the stronger absorption lines which are much closer to optically thick conditions than PLs.

We observed also a reduction in the accuracy of the radial velocities, which is however more difficult to quantify. It appears as a systematic shift (toward shorter or longer wavelengths) dependent on the actual wavelength interval and the orbital phase. This is caused by the beating in the cross-correlation between the pattern of PLs and the observed absorption lines which is a function of both λ and radial velocity separation between the binary components. The presence of these locally different systematic shifts becomes evident only when radial velocities from various wavelength intervals on the same spectrum are inter-compared (like those provided by individual orders in an Echelle spectrum). The overall effect is an increase of the scatter of individual measurements, different in amount from spectrum to spectrum.

This concerns the analysis performed on wavelength regions dominated by weak PLs, as in the example on the bottom panel of Fig. 2. There are however limited wavelength intervals where PLs much stronger than usual are stochastically clustered together. The result of a χ^2 fit performed on any such interval would provide unrealistic results. One such interval is illustrated in Fig. 3, where the observed spectra of V432 Aur and V570 Per are taken from Siviero et al. (2004) and Marrese et al. (2005). While the fit with synthetic spectra computed without PLs provide – for the values of the atmospheric parameters derived by the geometrical orbital solution – an almost perfect match to the observed spectra, the same spectra computed with inclusion of PLs bear no resemblance at all to the observed spectrum. It is evident that the photometric calibration of a color-index that includes a narrow band centered on such a wavelength interval would provide unrealistic results if carried out on synthetic libraries computed with PLs.

4.2. RAVE spectra

We are engaged in the data analysis of the RAVE spectroscopic survey of the galactic Halo (Steinmetz 2003; Munari et al. 2005) with the 6dF fiber positioner and spectrograph at the UK-Schmidt at the Anglo-Australian Observatory. The survey is carried out at high S/N over the 8420–8780 Å interval at $R_p = 8500$ resolving power.

Two low galactic latitude calibration fields rich in HD stars (1607m492 and 1716m425) have been re-observed three times during the survey. Spectral classification of these stars is taken from the Michigan Project (Houk 1978). To test the performance of our library, we have χ^2 fitted the spectra of these HD stars against our library of synthetic spectra in its $R_p = 8500$ version. The results are presented in Fig. 4. The right panels illustrate the accuracy of the achieved fits by overplotting observed and synthetic spectra for the sample cases of a Sun analogue and of a A-type star. The T_{eff} and $\log g$ values derived by the χ^2 fit well match those expected from the G2V and A7IV classifications following the calibration by

Fig. 3. The observed spectra (solid thick lines) of two eclipsing binaries compared with synthetic ones computed without (solid thin line) and with (dotted line) inclusion of so-called “predicted lines”. The synthetic spectra are computed for the atmospheric parameters (T_{eff} , $\log g$) and co-rotational rotational velocity as derived from the accurate orbital solutions of Siviero et al. (2004, for V432 Aur) and Marrese et al. (2005, for V570 Per) and their chemical abundance analysis. The spectra of the two components are shifted at the appropriate radial velocity and combined following the light-ratio at these wavelengths as derived in the orbital solution. The synthetic spectra computed *without* the “predicted lines” offer a much better representation of the observed ones, and the effect of the inclusion of “predicted lines” becomes worst with increasing metallicity.

Straizys & Kuriliene (1981). For the whole sample of HD stars observed in the two calibration fields, the left panels of Fig. 4 compare the T_{eff} and $\log g$ values derived by the χ^2 fitting with those expected on the basis of the spectral classification and the Straizys & Kuriliene (1981) calibration. The results in Fig. 4 show an agreement within 3% for T_{eff} and better than 0.25 dex in $\log g$, the dispersion being almost entirely accountable for by the natural width in both T_{eff} and $\log g$ of a spectral sub-type and a luminosity class in the MK classification scheme.

4.3. The distance to the Pleiades

The present library, in the 1 Å/pix version, was used in differential broad-band photometric applications by Munari et al. (2004) while deriving a precise distance to the Pleiades via orbital solution of the eclipsing binary member star HD 23642, whose spectral type is A2V.

Fig. 4. The use of our synthetic spectral library at resolving power $R_p = 8500$ to classify RAVE spectra. The left panels show the results of χ^2 fitting in gravity and temperature of spectra of HD stars from RAVE fields 1607m492 and 1716m425, with spectral types from the Michigan Project (Houk 1978) and calibration into T_{eff} and $\log g$ by Straizys & Kuriliene (1981). The dotted lines represent margins for $\pm 3\%$ in T_{eff} and ± 0.25 dex in gravity. The error bars on each point represent the spread in the results of χ^2 fitting of three different spectra of the same object secured on different nights. On the right panels, examples of a match between observed and synthetic spectra are provided for two HD stars from the same RAVE fields. The results of the χ^2 fitting for the two spectra are given for T_{eff} , $\log g$ and metallicity.

Magnitudes in ten different photometric systems were found in the literature for this star, and they were used to derive temperature, gravity and reddening of both components of the binary via calibration on our spectral libraries of the color indexes of each photometric system. The zero point of colors was fixed to 0.00 for a Vega model characterized by $T_{\text{eff}} = 9400$, $\log g = 3.9$, $[M/H] = -0.5$ and $\xi = 0.0$ km s $^{-1}$ downloaded from Kurucz’s web site.

The photometric results on atmospheric and reddening parameters so derived for both components of HD 23642 were confirmed by high resolution spectroscopy and the orbital solution. The successful photometric application of the library was made possible by the proximity in the parameter space of HD 23642 and the calibrator Vega.

4.4. Broad-band photometric tests

To test the broad-band photometric performances of our library we have investigated the reproduction of observed colors along the Main Sequence (MS). The results are shown in Figs. 5 and 6, where the T_{eff} and $\log g$ of stars along the main sequence

were adopted from Straizys & Kuriliene (1981). We stopped at M2V as the MS faint end, because later types are characterized by T_{eff} cooler than the 3500 K limit of our library (cf. Table 4). We included for comparison all the other libraries from Table 1 for which data are actually accessible and are characterized by a wavelength coverage wide enough to cover at least three consecutive photometric bands. Caution is necessary when considering the results from Martins et al. (2005) library, whose red limit is placed at 7000 Å where the V band still has 1% transmission and reaches 0.0 only at 7400 Å. The effect of missing this far red wing of the V transmission profile has effects on colors of cooler stars by making their $B - V$ color marginally bluer.

To assist in the interpretation of the result of the photometric tests we have also recomputed the spectra of our library that define the MS, this time with inclusion of PLs (these spectra are available on the library web page). In Figs. 5 and 6 by “NOVER 1221 pt” and “ODFNEW 1221 pt” we mean the flux distributions that are predicted directly from the model atmosphere code, not to be confused with the spectra generated by the spectral synthesis code.

Fig. 5. Comparison of synthetic colors along the Main Sequence truncated at M2V. The observed empirical Main Sequence of Fitzgerald (1970) serves as a comparison. The adopted band transmission profiles are those of Buser (1978).

Table 4. Comparison between different calibrations for colors and temperatures of late type main sequence stars. *a*: Bessell (1990); *b*: Bessell (1995); *c*: Straizys (1992); *d*: Bertone et al. (2004) using Kurucz spectra; *e*: Bertone et al. (2004) using Phoenix spectra; *f*: Drilling & Landolt (2000); *g*: Straizys & Kuriliene (1981).

	$R_C - I_C$ color			T_{eff} (K)				
	(a)	(b)	(c)	(b)	(d)	(e)	(f)	(g)
K5V	0.63	0.62	0.55	4350	4480	4630	4410	4395
M0V	0.85	0.91	0.89	3900	4010	3990	3840	3900
M2V	1.08	1.16	1.11	3600		3720	3520	3550
M4V	1.36	1.63	1.42	3130		3450		3250

Figure 5 illustrates the behaviour on classical 2-color diagrams. Our library performs similarly to the others on the $U - B$, $B - V$ plane for colors bluer than 0.7 in $B - V$. For redder colors, the synthetic MS has $U - B$ colors too blue by some hundredths of a magnitude. The inclusion of PLs in the computation brings the synthetic MS in close agreement with the observed one and very close to the ODFNEW 1221 pt flux

Fig. 6. The behaviour of photometric colors along the Main Sequence for individual spectral types. The same data of Fig. 5 are used. The adopted band transmission profiles for R_C and I_C are those of Bessell (1990).

distributions. The effect of adopting the ODFNEW model atmospheres affects the lowest temperatures where the synthetic spectra (with and without PLs, as well as the 1221 pt flux distributions) fail to match the very red colors observed in real stars, with the synthetic MS displaying a small upward hook.

Figure 6 illustrates the data in a different format and expanded scale. The difference in the single color between real stars and synthetic spectra are plotted as function of the spectral type along the MS. This diagram highlights better the scatter between observed colors and those from synthetic spectra, particularly in $U - B$. It shows that, in all colors, significant departures of our library from observations are limited to spectral types cooler than K4V ($T_{\text{eff}} < 4500$ K).

Having already proved the satisfactory spectroscopic performance of our library, we refrain from discussing any further its broad-band photometric performances and that of the other libraries listed in Table 1, which is clearly beyond the scope of this paper. Figures 5 and 6 should not be considered as the ultimate comparison of the photometric performances of the available synthetic libraries, even if we placed all libraries on the same reference system, using the same $UBVR_CI_C$ band

profiles and the same $T_{\text{eff}}/\log g$ conversion to spectral type for all of them. Even if different reconstruction of the $UBVR_{\text{C}}I_{\text{C}}$ band profiles or $T_{\text{eff}}/\log g$ conversion would have been used, the spread among different synthetic libraries and with respect to observed colors would have remained. Table 4 shows the widely different T_{eff} calibration that have been published for the cooler spectral types along the MS considered in Figs. 5 and 6.

Acknowledgements. Support to R.S. by MIUR COFIN2001 program is acknowledged. We would like to thank S. Ansari for managing the library access via the ESA web portal within the framework of GAIA support activities, A. Baruffolo and S. Pastore for library access via the web server of the Astron. Obs. of Padova, and M. Fiorucci for useful support with treatment of RAVE data. The careful scrutiny and stimulating comments by the anonymous referee were deeply appreciated.
