### ABSTRACT

We present the results of the analysis of the hard band *XMM-Newton* spectra of the luminous,  $L_{2-10\text{ keV}} \sim 3.4 \times 10^{45}$  erg/s, radio-quiet quasar, E1821+643. Two emission features were observed in the 6–7 keV rest frame band, confirming previous *Chandra* detection of these structures. We interpret these features as two single emission lines, one consistent with the neutral Fe K $\alpha$  line at 6.4 keV and the other most likely due to FeXXVI. If related to the quasar, the high-energy emission line should originate in highly ionised matter, i.e. the accretion disc or the clouds of the emission line regions. Alternatively, it may be related to the intergalactic medium of the rich galaxy cluster in which E1821+643 is embedded. A composite broad emission line in combination with an absorption line model, however, also fits the data well. We discuss the possible physical interpretations of the origin of these features.

**Key words.** galaxies: general – galaxies: active – galaxies: nuclei – X-rays: individuals: E 1821+643

### 1. Introduction

The very luminous radio-quiet quasar E1821+643 ( $m_v = 14.1$ ,  $z = 0.297$ ) is embedded in a rich cluster of galaxies (Hutchings & Neff 1991). A *ROSAT* image of E1821+643 shows evidence of extended X-ray emission associated to the cluster (Hall et al. 1997), although the quasar dominates the X-ray emission. The core radius of the cluster is  $17''.6 \pm 0''.2$  ( $1'' = 4.4$  kpc, Fang et al. 2002). E1821+643 has been observed extensively in X-rays. The *ASCA* spectrum confirmed the presence of an emission line, first discovered by *Ginga* (Kii et al. 1991), consistent with an ionised state of iron (Yamashita et al. 1997). Recently, E1821+643 was observed with both the *High Energy Transmission Grating Spectrometer (HEGTS)* on board *Chandra*. The high-resolution spectra show that the emission line feature is complex and can be resolved in a double-peak structure. However, the origin of this feature is still not clear. Fang et al. (2002) argue that the feature is best explained by two emission lines, a neutral Fe K $\alpha$  line, and the other highly ionised, which could originate in a highly ionised layer above the accretion disc. On the other, Yaqoob & Serlemitsos (2005) reanalysed the data to conclude that the feature is a broad iron emission line with an absorption line superimposed on the red wing of the broad line. The absorption line could be due to the resonance absorption of highly ionised iron, either in inflowing matter or in an outflow that is strongly gravitationally redshifted and located very close to the accretion disc.

In this paper we analyse an *XMM-Newton* observation of E1821+643. The spectral analysis (Sect. 3) was performed in the 2–10 keV bandpass and focused on studying (Sect. 4)

of the double-peak structure that was also detected in the *XMM-Newton* spectrum.

### 2. Observations and data reduction

The *XMM-Newton* (Jansen et al. 2001) observation of E1821+643 (Obs-Id. 0110950501) was performed on October 16th, 2002. The *EPIC* observations were performed in the *large window (pn)* and *small window (MOS)* using the *thin filter* for all instruments. The raw data were processed with the standard *Science Analysis System, SAS*, v.6.5.0 (Gabriel et al. 2004). The most updated calibration files available in October 2005 were used to process the data. According to the *epaplot*<sup>1</sup> task, no significant pile-up was detected in any of the *EPIC* observations. We used *WebPIMMS v3.8a2* to evaluate the expected pile-up fraction for the measured count rate and spectral shape of E1821+643 (see next section) and obtained a pile-up fraction smaller than 0.1%. This agrees with the values in the *XMM-Newton User's Handbook* (Sect. 3.7.1.3)<sup>2</sup>. The *EPIC* event lists were filtered to ignore periods of high background flaring according to the method described in Piconcelli et al. (2004). Due to the telemetry band, the *pn* scientific buffer was full several times during the observation with a result of losing time. The exposures after the filtering are 1.62, 4.52, and 4.57 ks for *pn*, *MOS-1*, and *MOS-2*, respectively.

<sup>1</sup> The *SAS* task *epaplot* utilises the relative ratios of single- and double-pixel events that deviate from standard values in cases of pile-up.

### 3. Spectral analysis

We extracted the spectra of a circular region centred on the maximum emission of the source and with 20'' and 25'' radii for the *pn* and *MOS* detectors, respectively. The background spectra were extracted from circular regions of 50'' and 15'' radius and located 2'2 and 1' for *pn* and *MOS*, respectively, i.e. outside the galaxy cluster. In order to apply the modified  $\chi^2$  minimization technique (Kendall et al. 1973), the source *EPIC* spectra were grouped such that each bin contains at least 20 counts. The *MOS-1* and *MOS-2* spectra were combined to obtain a single spectrum with higher signal-to-noise and the *pn* and *MOS* spectra were analysed simultaneously. The count rates of the spectra in the whole energy band (0.1–10 keV) are 8 and 2 c/s for *pn* and the *MOS1* and *MOS2* combined spectra, respectively. The spectral analysis was performed using the XSPEC v.12.2.0 (Arnaud 1996). Unless otherwise indicated, all parameters are given in the E1821+643 rest frame. The quoted errors for the fit parameters refer to the 90% confidence level (i.e.  $\Delta\chi^2 = 2.71$ ; Avni 1976). We assumed a flat  $\Lambda$ CDM cosmology with  $(\Omega_M, \Omega_\Lambda) = (0.3, 0.7)$  and a value for the Hubble constant of 70 km s $^{-1}$  (Bennett et al. 2003).

#### 3.1. High-energy continuum emission

The spectral analysis was performed in the 2–10 keV band. The Galactic absorption ( $N_{\text{H}}^{\text{GAL}} = 3.8 \times 10^{20}$  cm $^{-2}$ , Dickey & Lockman 1990) was included in all the models assuming the photoelectric cross section of Morrison & MacCammon (1983). A simple power law with a photon index of  $1.87 \pm 0.07$  provides an acceptable fit to the data with  $\chi^2 = 149$  for 177 d.o.f. (degrees of freedom). The addition of any absorption above the Galactic value does not improve the  $\chi^2$ . However, residuals are present in the 4.5–5.5 keV range in the observers frame (5.8–7.1 keV in the quasar rest frame). We therefore excluded this energy range in order to better determine the continuum emission. We found a power-law photon index of  $\Gamma = 1.92^{+0.09}_{-0.08}$  properly fits the data ( $\chi^2 = 112$  for 146 d.o.f.; model A). This value of the photon index is consistent with the mean value  $\sim 1.9$  observed for a large sample of radio-quiet quasars (Piconcelli et al. 2005).

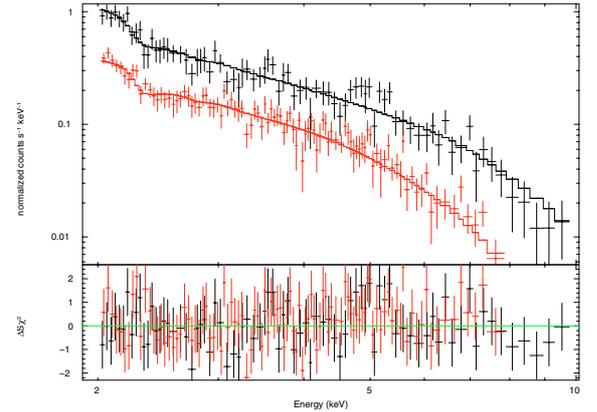

Figure 1 shows the residuals from extrapolating the previous fit in the 4.5–5.5 keV band, which was previously ignored. The deviations in the 4.5–5.5 keV reveal a double-peaked structure. We also present (Fig. 2) the *pn* spectrum binned with at least 10 counts-per-channel, which shows the double-peaked structure more clearly, partially lost in the 20 counts per channel binned spectrum in which just a single point marks the decrease in the flux between the two lines. In the 5–6 keV, i.e. in the band-pass where the residuals are observed, the effective area of *pn* is 2.5 times larger than in the *MOS* detectors. As the *MOS* spectra do not significantly improve the statistics, we excluded them in the following fits for simplicity.

#### 3.2. The iron complex

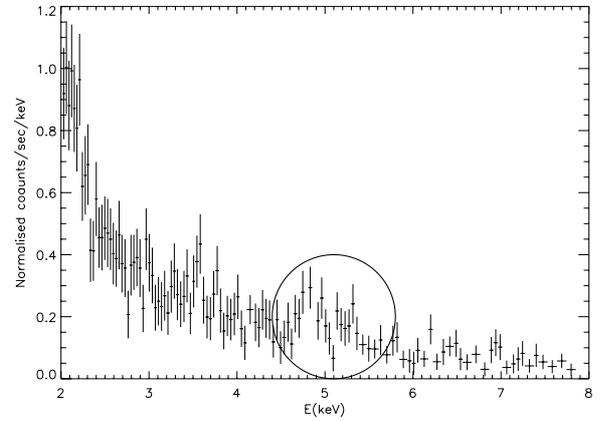

In order to explain this double feature, we tested several models, which are described in the following. Table 1 shows these models, the values of the fitting parameters, and the goodness of each fit. All these fits were performed using as the underlying continuum model a power law with the photon index fixed to  $\Gamma = 1.92$  (model A<sub>PN</sub>).

##### Two Gaussian emission lines

The addition of a single Gaussian line fit ( $\chi^2 = 53$  for 76 d.o.f.) results in an improvement with respect to the single

**Fig. 1.** The upper panel shows the simple power-law model fitted to the *EPIC* data, excluding the 4.5–5.5 keV band (observed energy). The lower panel shows the residuals of the fitted model to the data where important residuals are present in the vicinity of 5 keV (observed energy).

**Fig. 2.** The *pn* spectrum binned to have at least 10 counts per energy channel. The plot shows the presence of a double-peaked structure located in the vicinity of 5 keV (observed energy).

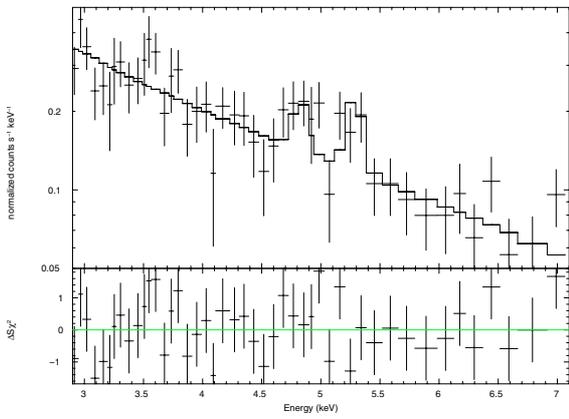

power-law model (model A<sub>PN</sub>) with a significance level of >99% according to the *F-test*. This single Gaussian line is centred at  $6.28^{+0.4}_{-0.11}$  keV (rest frame) with  $\sigma = 130^{+400}_{-90}$  eV. The inclusion of a second Gaussian line further improves the fit, at a confidence level of  $\sim 98\%$  according to the *F-test*. This double-Gaussian line model (model B) provides the simplest model to account for the residuals. The lines are located at  $6.27^{+0.18}_{-0.14}$  keV and  $6.8^{+0.12}_{-0.14}$  keV with  $EW = 120^{+20}_{-50}$  eV and  $EW = 200^{+200}_{-130}$  eV, respectively. The widths of the lines have been fixed to 0.01 keV; the fit does not improve by leaving the widths of the lines free. Figure 3 shows this model, together with the data and the residuals.

##### Relativistic disc line

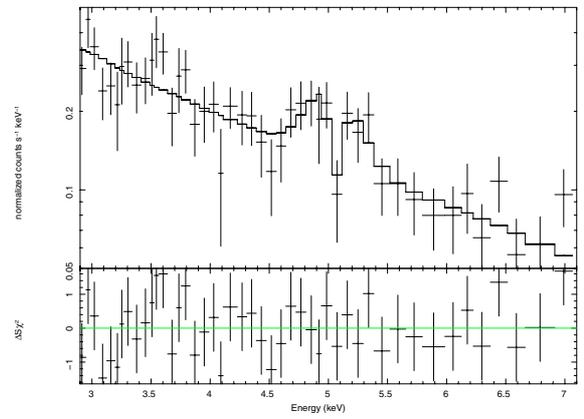

We also fitted the data considering a relativistic-disc-line model (*diskline* XSPEC model Fabian et al. 1989). We fixed the disc inclination to 30° (Porquet & Reeves 2003) and the inner and outer disc radii to the standard values of  $6r_g$  and  $100r_g$  ( $r_g = GM/c^2$ ), respectively. The fit does not significantly improve when the disc inclination and inner and outer disc radii are left free to vary. Moreover, the values of the parameters end up being unbounded. The fit (model C,  $\chi^2 = 55$  for 77 d.o.f.) improves the fit with respect to model A<sub>PN</sub> with a significance of 98% according to the *F-test*. Even if still acceptable, the fit is worse than the one obtained with the two emission Gaussian lines. The line energy is  $6.68^{+0.12}_{-0.15}$  keV, which is incompatible

**Table 1.** Different models, parameters, and goodness of the fits applied to the *XMM-Newton* spectrum of *E 1821+643*. **Model A:** single power-law model fitted to the *EPIC* data excluding the 4.5–5.5 keV band. Models for the the feature around 5 keV applied to the *pn* spectrum with the photon index fixed to the value of model A: Model B: two emission lines. Model C: disc line model. Model D: broad Gaussian emission line with an absorption line. Model E: single Gaussian line combined with a Raymond-Smith thermal plasma component. The label *f* indicates that the parameter has been fixed to the indicated value.

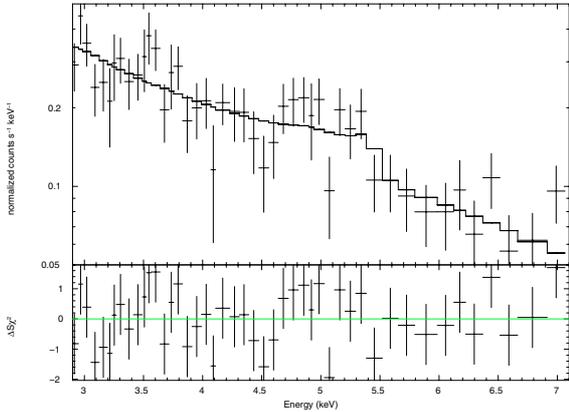

Model	$\Gamma$	Iron line 1				Iron line 2/Abs. Line				R-S	Goodness
		$E$	$\sigma$	$I$	$EW$	$E$	$\sigma$	$I$	$EW$

**Fig. 3.** The upper panel shows the *pn* spectrum and the best-fit model, a power law, and two emission lines. The lower panel shows the residuals in terms of sigma of the fitted model to the data.

**Fig. 5.** The upper panel shows the *pn* spectrum and a model consisting of a broad emission line and an absorption Gaussian line. The lower panel shows the residuals of the fitted model to the data.

**Fig. 4.** The upper panel shows the *pn* spectrum and the model consisting of a power law and a relativistic disc line. The lower panel shows the residuals of the fitted model to the data.

with the neutral iron (>FeXX). Moreover, fixing the energy of the line to 6.4 keV resulted in only a negligible improvement with respect to a single power-law fit. Figure 4 shows the model, the observed spectrum, and the residuals.

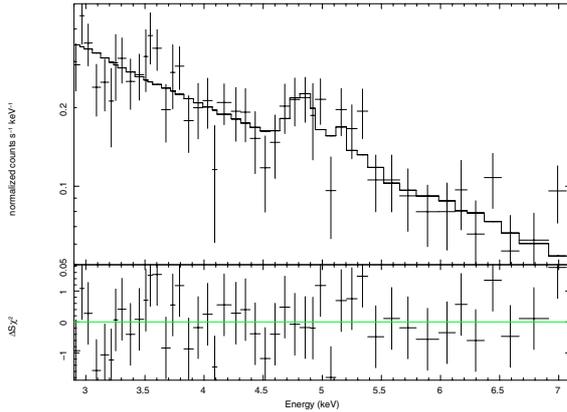

#### Broad emission line plus absorption Gaussian line

According to Yaqoob & Serlemitsos (2005), the preferable model for the HEG spectrum of *E 1821+643* includes a broad emission line and a Gaussian absorption line to fit the residuals around 5 keV. We also applied this model (model D) to *pn* data.

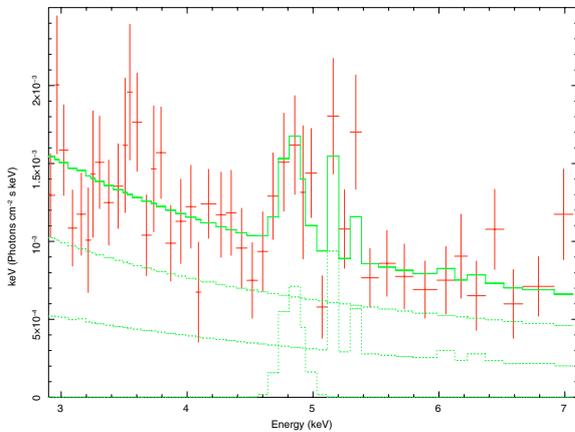

The residuals can be properly fit with this model ( $\chi^2 = 45$  for 73 d.o.f.). The broad ( $\sigma = 240 \pm 110$  eV) emission line was found at  $6.53^{+0.11}_{-0.12}$  keV and the absorption line at  $6.57^{+0.05}_{-0.07}$  keV with a  $\sigma < 180$  eV. Both lines are centred at the same energy,  $\sim 6.5$  keV, which corresponds to where the flux decreases between the two emission features. Figure 5 shows this model, together with the data and the residuals. A similar result is obtained when, instead of a single Gaussian line, a *diskline* model is considered for the broad emission line.

#### 3.2.1. A possible contamination from the surrounding galaxy cluster?

*E 1821+643* is known to be embedded in a very rich galaxy cluster. Although the X-ray images of *E 1821+643* are clearly dominated by the emission of the point-like source, *ROSAT* (Hall et al. 1997), and *Chandra* (Fang et al. 2002) images show evidence of extended emission associated with the cluster. We therefore investigate the possibility that the cluster emission could significantly contaminate the *E 1821+643* spectrum. We then tested a model consisting of a power law accounting for the AGN continuum emission, a Gaussian emission line for the lower energy feature, i.e.  $6.27 \pm 0.11$  keV, consistent with neutral iron combined with a Raymond-Smith thermal plasma (Raymond & Smith 1977) attributed to the galaxy cluster emission. We fixed the metal abundance to the typical value for hot clusters, i.e.  $0.3 Z_{\odot}$  (Ettori 2005 and references therein). This value is also consistent with the cluster abundance measured by

**Fig. 6.** The upper panel shows the *pn* spectrum and the model consisting of a single emission line ( $E = 6.27 \pm 0.11$  keV) and the Raymond-Smith thermal emission. The lower panel shows the residuals of the fitted model to the data.

**Fig. 7.** The figure shows the unfolded *pn* spectrum and the models consisting of a single emission line and the Raymond-Smith emission in units of  $Ef(E)$  and the contribution of the various additive components.

Fang et al. (2002) using *Chandra* data ( $Z = 0.35 \pm 0.08 Z_{\odot}$ ). The fit ( $\chi^2 = 50$  for 74 d.o.f.) improves with respect to the single power law with a single-Gaussian line model, but the improvement is not significant according to the F-test, which gives a probability of only 85%. Figures 6 and 7 show the fitted model, the data and the residuals to the fit, and the contribution of the several components. The temperature of the Raymond-Smith plasma ( $T = 8^{+13}_{-7}$  keV) is appropriated for rich clusters (Kaastra et al. 2004), even if too poorly constrained for deriving any conclusion in this respect. The line parameters are consistent with the values found for the single-Gaussian emission line and also with the best-fit parameters of the low-energy emission line in model B. The measured luminosity associated to the thermal plasma component in the 2–10 keV band is  $1.1^{+1.2}_{-0.2} \times 10^{45}$  erg/s, which corresponds to  $30 \pm 6\%$  of the total luminosity in this band.

### 3.3. Flux, luminosity and variability

Assuming that the best-fit model is the two Gaussian line model (model B), the *E 1821+643* flux observed in the 2–10 keV band is  $1.24^{+0.04}_{-0.05} \times 10^{-11}$  erg s $^{-1}$  cm $^{-2}$ . The corresponding unabsorbed luminosity in the same band is  $3.44^{+0.13}_{-0.09} \times 10^{45}$  erg/s. Similar results are found when the other models are applied.

No sign of short-term variability (i.e. during the observation) has been detected. On the contrary, when compared with previous observations, a moderate flux variation has been measured. In particular, the highest flux measured in the 2–10 keV band corresponds to the oldest observation, performed by *ASCA* (June 1993), with a value of  $(1.7\text{--}1.8) \times 10^{-11}$  erg s $^{-1}$  cm $^{-2}$ . The *Chandra* observations were performed 3 weeks apart in January and February of 2001, and the measured fluxes were  $1.1 \times 10^{-11}$  erg s $^{-1}$  cm $^{-2}$  and  $1.2 \times 10^{-11}$  erg s $^{-1}$  cm $^{-2}$ , respectively. These values are within the same order of magnitude of our result,  $(1.2\text{--}1.3) \times 10^{-11}$  erg s $^{-1}$  cm $^{-2}$ , from the *XMM-Newton* observation performed in October 2002.

## 4. Discussion

Giving the short net *pn* exposure (only 1.62 ks), resulting from high background and telemetry bandwidth limitations, the signal to noise of the *EPIC* spectra does not allow us to discriminate among the possible models applied (see Sect. 3) to account for the double-peaked feature in the 6–7 keV rest frame band. However, it is remarkable that even with such a short exposure time, some interesting results can be still established.

According to the results described in Sect. 3, the model consisting of a power law and two narrow Gaussian emission lines centred at  $6.27^{+0.18}_{-0.14}$  keV and  $6.85^{+0.12}_{-0.14}$  keV provides the simplest description of the observed spectrum. The two Gaussian emission-line model provides acceptable fits to the spectra of previous *Chandra* and *ASCA* observations.

The centroid of the lower energy line ( $6.27^{+0.18}_{-0.14}$  keV) measured in the *pn* spectrum is compatible within the errors with the *Chandra* grating result ( $6.35^{+0.03}_{-0.05}$  keV) obtained by Yaqoob & Serlemitsos (2005). This energy is consistent with neutral iron. A narrow emission line centred at  $\sim 6.4$  keV is observed in most *XMM-Newton* spectra of radio-quiet quasars (Jiménez-Bailón et al. 2005). The most likely origin of this feature is material located in the outer parts of the accretion disc, the molecular torus and/or the Broad Line Region. The value of the *EW* of this line ( $120^{+20}_{-50}$  eV) also closely matches with the average values found for low-luminosity (Yaqoob & Padmanabhan 2004) and high-luminosity (Jiménez-Bailón et al. 2005) radio-quiet AGN. It is worth noting that, given the high luminosity of *E 1821+643* ( $L_{2\text{--}10\text{keV}} \sim 3.4 \times 10^{45}$  erg/s), this finding is at odds with the so-called X-ray Baldwin effect, i.e. the decrement of the *EW* as a function of luminosity, as suggested by Jiménez-Bailón et al. (2005), in which no clear correlation between these two quantities is observed for a large sample of radio-quiet QSO.

The higher energy line has an *EW* of  $200^{+200}_{-130}$  eV and its centroid energy,  $6.85^{+0.12}_{-0.14}$  keV, which is consistent with the FeXXV and FeXXVI lines. These line parameters are fully consistent with those derived from previous *Chandra* grating observations (Fang et al. 2002 and Yaqoob & Serlemitsos 2005). This line should originate in hot matter. Therefore, we considered two possible scenarios for the origin of this feature: i) the quasar itself or ii) the contamination from the galaxy cluster where *E 1821+643* is embedded. In the former case, the feature can be interpreted as the result of the illumination of extended ionised matter, i.e. the emission line regions or the inner walls of the torus. It is also possible that the ionised line could originate in the accretion disc. In this case, the emission feature could correspond to either a narrow emission line originated in an ionised layer on the disc surface or the blue horn of a relativistically-broadened iron line. The intensities of both emission lines measured by *Chandra* are systematically lower than

our *XMM-Newton* values, although due to the large uncertainties, *XMM-Newton* and *Chandra* measurements are compatible within errors. A *diskline* model produced a statistically acceptable fit ( $\chi^2 = 55$  for 77 d.o.f.) to the double-peaked iron complex in the *pn* spectrum of *E 1821+643*. The line energy was found at  $6.68^{+0.12}_{-0.15}$  keV, so compatible with an origin from ionised matter ( $\geq$ FeXXI).

We also investigated the possibility that the surrounding galaxy cluster could significantly contaminate the source spectrum. The *pn* extraction radius of 20'' includes the entire core of the cluster, i.e. 17''.6 (Fang et al. 2002). Therefore we added a Raymond-Smith thermal plasma component attributed to the diffuse cluster emission to the power-law with an emission-line ( $6.27 \pm 0.11$  keV) model. The metal abundance was fixed to the typical value of hot clusters, i.e.  $0.3 Z_{\odot}$ . The parameters (temperature and X-ray luminosity) derived for the Raymond-Smith component are consistent with the typical values of rich galaxy clusters. In particular, the temperature ( $kT \sim 8$  keV) is in the range found for hot galaxy clusters. The luminosity associated to the thermal component,  $L_X = 1.1^{+1.2}_{-0.2} \times 10^{45}$  erg/s, is consistent with the temperature-luminosity relationship for cluster cores,  $L_X \sim 5 \times 10^{42} (kT)^3$  erg/s (Ota et al. 2006). Fang et al. (2002) have found that the radial profile of the diffuse emission associated to the cluster can be modeled by a  $\beta$ -profile (Cavaliere & Fusco-Femiano 1976). Adopting their parameters, we find that in the 20'' *XMM-Newton* extraction region, around 50% of the total cluster emission would be included, corresponding to a luminosity of  $1.4 \times 10^{45}$  erg/s, which is fully consistent with our measurement. On the other hand, given the measured temperature of the Raymond-Smith component, a significant contribution from the FeXXV and FeXXVI K $\alpha$  lines is expected. In fact, the measured flux for these two emission lines is  $(1.8 \pm 1.7) \times 10^{-5}$  photons  $\text{cm}^{-2} \text{s}^{-1}$ . By comparing this value with the line flux of the  $6.85^{+0.12}_{-0.14}$  keV line inferred by model B (i.e.  $(2.6^{+1.6}_{-0.5}) \times 10^{-5}$  photons  $\text{cm}^{-2} \text{s}^{-1}$ ), the hot plasma emission can in principle account for the 6.8 keV emission feature. However, the large errors indicate that the contribution of the cluster to the high-energy emission line flux could be as low as of  $\sim 2\%$ . Interestingly, Fang et al. (2002) estimated the contribution of the cluster to be between 3% and 50% of the flux line, when only the HEG spectrum is considered, and between 30% and 100% for the combined, higher signal-to-noise, HEG and MEG spectra.

Finally, another possible origin for the double-peaked iron emission is a combination of a broad emission line and an absorption line. This scenario was suggested by Yaqoob & Serlemitsos (2005) who argue that the absorption line could be attributed to redshifted resonance absorption by highly ionised material, most likely an inflow. The high ionisation state of the iron is supported by the absence of soft X-ray absorption features (Yaqoob & Serlemitsos 2005; Mathur et al. 2003; Fang et al. 2002). Matt (1994) suggests for the first time the importance of the effect of resonant K $\alpha$  transitions due to iron ions that can absorb continuum photons in the  $\sim 6.4$ – $6.7$  keV band. Ruszkowski & Fabian (2000) computed the absorbing effect of ionised iron located in a rotating diffuse plasma that surrounds the accretion disc and the corona. The FeXXV and FeXXVI can resonantly absorb photons of the continuum and of the fluorescent K $\alpha$  emission line emitted from the primary source, i.e. the corona and the accretion disc. Some observational evidence of absorption lines due to ionised iron has been reported: e.g. Dadina et al. (2005) observed in *XMM-Newton* and *BeppoSAX* spectra of Mrk 509 red- and blue-shifted absorption lines due to ionised iron; the *XMM-Newton* spectrum of Q0056-363 shows evidence of a transient absorption line interpreted as redshifted ionised iron

(Matt et al. 2005); and recently, Markowitz et al. 2006 detected a blue-shifted absorption FeXXVI K $\alpha$  line in IC 4329A, suggesting the presence of an ionised outflow component. In our analysis, the absorption line was found at  $6.57^{+0.05}_{-0.07}$  keV, consistent with Fe states from XX to XXII. This value is largely incompatible with the one measured by Yaqoob & Serlemitsos (2005),  $6.228^{+0.018}_{-0.013}$  keV. Fixing the values of the parameters of both emission and absorption lines in our model to the ones obtained by Yaqoob & Serlemitsos (2005) leads to an unsatisfactory fit. However, Yaqoob & Serlemitsos (2005) indicate that the absorption line could be variable and therefore would not be observed at the same energy (or even unrepresent at all) in other observations. If this is the case, and assuming that the line is due to the K $\alpha$  transition from FeXXVI, then it would be redshifted with a velocity of  $17\,200^{+3000}_{-2600}$  km  $\text{s}^{-1}$ ,  $\sim 6\%$  of the speed of light.

## 5. Conclusions

In this paper, we have presented the analysis of the high-energy band of the *pn XMM-Newton* spectrum of the luminous,  $L_{2-10 \text{ keV}} = 3.44^{+0.13}_{-0.09} \times 10^{45}$  erg/s, radio-quiet quasar *E 1821+643*. The spectrum shows the presence of a double-peaked feature observed in the 6–7 keV quasar rest frame band. This structure was also detected in two *Chandra* observations performed with the HEG and LEG. Our analysis of the *XMM-Newton* data therefore confirms the results of previous observations and also provides new possible physical interpretations of the origin of these emission features.

Several models have been tested to fit the emission properties. The simplest model corresponds to a couple of Gaussian emission lines. According to our interpretations, the lower energy line is consistent with the narrow neutral Fe K $\alpha$  line. Within the errors, the calculated parameters of the emission lines are compatible with previous *Chandra* observations. Matter located in the outer parts of the accretion disc, the molecular torus, and/or the the Broad Line Region is likely to be responsible of the emission line.

On the other hand, the centroid of the higher energy line is compatible with the K $\alpha$  transition from FeXXV and FeXXVI and therefore it had to originate in matter that was hot enough. Assuming that the line originated in the quasar itself, the feature can be interpreted as a narrow emission line originated in a highly ionised atmosphere of the accretion disc, as the blue-shifted peak of a relativistic emission line or as narrow emission line caused by the illumination of extended photoionised matter, i.e. the emission line regions or the inner parts of the *torus*. The statistical analysis is slightly unfavourable to the relativistically broaden emission line. We have also considered the possibility that the higher energy line is due to contamination by the rich cluster in which the source is embedded. The measured temperature of the hot diffuse plasma attributed to the cluster,  $kT = 8^{+13}_{-7}$  keV, is high enough to produce an important FeXXVI emission line. The *XMM-Newton* data analysis has revealed for the first time that the predicted plasma emission attributed to the cluster could fully explain the measured flux of the high-energy emission feature.

The line complex may be also be interpreted as a broad Gaussian emission line, compatible with the neutral iron combined with an absorption line, observed at  $6.57^{+0.05}_{-0.07}$  keV. This model was first suggested by Yaqoob & Serlemitsos (2005) to explain the *Chandra* HEG data. If this model is correct, the centroid energy of the absorption line must be variable, changing from  $\sim 6.23$  keV in the HEG data to  $\sim 6.57$  keV in our

*XMM-Newton* spectrum, thus indicating a large variability of the physical properties (location, velocity...) of the absorbing matter.

Neither short-term variability, i.e. within the *XMM-Newton* observation, nor mid-term, i.e. less than 22 months, has been detected. Although a decrease in flux of the order of  $\sim 5 \times 10^{-12}$  erg s $^{-1}$  cm $^{-2}$  has been detected when comparing our observed flux (October 2002) with that measured by *ASCA* (June 1993).

Unfortunately, given the short net exposure time results on a low signal-to-noise spectrum, the *XMM-Newton* data prevented our making firm conclusions on the real nature of the double-peaked feature in *E 1821+643*. Long enough *XMM-Newton* observations of the source would be valuable for determining both the best among several tested models and the values of the parameters, in order to shed light on the nature of the X-ray *E 1821+643* emission.

*Acknowledgements.* The authors would like to thank the anonymous referee for the very useful comments, that significantly improved the paper. We also thank Nobert Scharfel for very useful discussions. EJ and MSL acknowledge funding from Spanish MEC grant AYA2004-08260-C03-03.
