ABSTRACT

Aims. We study the effect of the extreme environment in Hickson compact groups (HCGs) on the molecular gas mass, \( M_{\text{H}_2} \), and the star formation rate (SFR) of galaxies as a function of atomic hydrogen (HI) content and evolutionary phase of the group.

Methods. We selected a redshift-limited \((D < 100 \text{ Mpc})\) sample of 88 galaxies in 20 HCGs with available atomic hydrogen (HI) VLA maps, covering a wide range of HI deficiencies and evolutionary phases of the groups and containing at least one spiral galaxy. We observed the CO(1–0) and CO(2–1) lines with the IRAM 30 m telescope for 47 galaxies. Together with literature data, our sample contains CO(1–0) spectra for 86 galaxies. We derived the far-infrared (FIR) luminosity \((L_{\text{FIR}})\) from IRAS data and used it as a tracer of the SFR. We calculated the HI mass \((M_{\text{HI}})\), \(L_{\text{FIR}}\), and \(M_{\text{H}_2}\) deficiencies, based on the values expected from \(L_{\text{FIR}}\) and \(L_{\text{H}_2}\) in isolated galaxies from the AMIGA sample. We limited our statistical analysis to spiral galaxies, since the large number of upper limits did not allow drawing strong conclusions about \(M_{\text{HI}}\) and \(L_{\text{FIR}}\) in early-type galaxies.

Results. The mean deficiencies of \(L_{\text{FIR}}\) and \(M_{\text{HI}}\) of spiral galaxies in HCGs are close to 0, indicating that their average SFR and molecular gas content are similar to those of isolated galaxies. However, there are indications of an excess of \(M_{\text{HI}}\) (~50%) in spiral galaxies in HCGs, which can be interpreted, assuming that there is no systematic difference in the CO-to-\(\text{H}_2\) conversion factor, as either an enhanced molecular gas content or as a higher concentration of the molecular component towards the center in comparison to galaxies in lower density environments. In contrast, the mean \(M_{\text{HI}}\) of spiral galaxies in HCGs is only 12% of the expected value. The specific SFR (sSFR = SFR/stellar mass) tends to be lower for galaxies with higher \(M_{\text{HI}}\) or \(M_{\text{HI}}\) deficiency. This trend is not seen for the star formation efficiency \((\text{SFE} = \text{SFR}/M_{\text{HI}})\), which is very similar to isolated galaxies. We found tentative indications of an enhancement of \(M_{\text{HI}}\) in spiral galaxies in HCGs in an early evolutionary phase and a decrease in later phases. We suggest that this might be due to an enhancement of the conversion from atomic to molecular gas due to ongoing tidal interactions in an early evolutionary phase, followed by HI stripping and a decrease in the molecular gas content because of lack of replenishment.

Conclusions. The properties of \(M_{\text{HI}}\) and \(L_{\text{FIR}}\) in galaxies in HCGs are surprisingly similar to those of isolated galaxies, in spite of the much higher \(\text{Def}(M_{\text{HI}})\) of the former. The trends of the sSFR and \(\text{Def}(M_{\text{HI}})\) with \(\text{Def}(M_{\text{HI}})\) and the evolutionary state indicate, however, that the ongoing interaction might have some effect on the molecular gas and SFR.

Key words. ISM: molecules – galaxies: evolution – galaxies: ISM – galaxies: interactions – galaxies: star formation – galaxies: groups: general

1. Introduction

Hickson compact groups (HCGs) (Hickson 1982) are dense and relatively isolated groups of four to eight galaxies in the nearby universe. The combination of high galaxy density (Hickson 1982) and low-density environment coupled with low systemic velocity dispersions \(\langle\sigma\rangle \approx 200 \text{ km s}^{-1}\) (Hickson et al. 1992) make HCGs especially interesting systems for studying how gas content and star formation activity in galaxies are influenced by the environment.

The most remarkable effect of multiple and strong interactions between galaxies in HCGs involves an atomic gas (HI) deficiency. VLA measures of individual spiral galaxies in HCGs show they only have 24% of the atomic hydrogen (HI) mass, \(M_{\text{HI}}\), expected from their optical luminosities and morphological types (Verdes-Montenegro et al. 2001). The inferred deficiency becomes even greater if one assumes that many of the lenticular galaxies, which are overrepresented in HCGs, are stripped spirals. Verdes-Montenegro et al. (2001) propose an evolutionary sequence for HCGs in which the HI is continuously removed from the galaxies, finally leading to groups where most of the HI is located outside of the galaxies. However, not only are the individual galaxies in HCGs HI deficient, but also HCGs are so as a whole (Verdes-Montenegro et al. 2001). This leads to the still
open question of where the missing HI has gone and by which galaxies. Borthakur et al. (2010) find with new single-dish Green Bank Telescope (GBT) observations of HGCs an important diffuse, low-column density intragroup HI component, missed by VLA observations. Taking these components into account reduced, but did not completely eliminate, the HI-deficiency of the groups.

The effect of an extreme environment on molecular gas properties is controversial. An enhancement of molecular gas content with respect to isolated galaxies has been reported for strongly interacting systems (Casasola et al., 2004, and references therein), defined in that work as galaxies appearing to be clearly interacting with nearby objects, presenting tidal tails or bridges, and merging systems and galaxies with disturbed structures. With respect to galaxies in clusters, no deficiency in the molecular gas content has been found in any global studies of the Virgo cluster (Kenney & Young 1986; Boselli et al. 2002) and the Coma Supercluster (Casoli et al. 1991; Boselli et al. 1997) in spite of the large HI deficiencies that some galaxies presented. The spatially resolved study of Fumagalli et al. (2009) found, however, that a significant number (~40%) of HI-deficient spiral galaxies were also depleted in molecular gas, if the HI was removed from within the optical disk. Scott et al. (in prep.) find a trend for spirals in Abell 1367 in more evolved evolutionary states to be more depleted in HI than those in less evolved evolutionary states. Thus, there are indications that the cluster environment does affect the molecular gas content.

Observations of the molecular gas in galaxies in HCGs have given until now contradictory results. Leon et al. (1998) found the $M_{HI}/L_B$ ratio of galaxies in HCGs to be enhanced with respect to a sample of field and interacting galaxies. In contrast, Verdes-Montenegro et al. (1998) found no evidence for an enhancement of the molecular gas mass ($M_{HI}$) in HCG galaxies relative to a sample of isolated galaxies. Studying the relation between atomic and molecular gas for a sample of 32 spiral galaxies, Verdes-Montenegro et al. (2001) have found tentative evidence of a depressed molecular gas content in HI deficient galaxies in HCGs.

The level of star formation (SF) in HCGs has also been subject to considerable debate with original claims of a far-infrared (FIR) excess (Hickson et al., 1989), which was subsequently challenged (Sulentic & de Mello Rabaca 1993). From the enhanced SF observed in galaxy pairs (Xu & Sulentic 1991), an increase in SF in HCGs might be expected as a consequence of the continuous encounters and tidal interactions that take place within such groups. Nevertheless, the star formation rate (SFR) in HCGs, obtained from FIR (Verdes-Montenegro et al. 1998), mid-infrared (Bitsakis et al. 2010), a combination of mid-infrared and ultraviolet (Tzanavaris et al. 2010), and Hr luminosities (Iglesias-Páramo & Vilchez 1999) has been found to be similar to those of the control samples.

There have been a few attempts to study the relation of $M_{HI}$ and $L_{FIR}$ with the HI properties of the HCG galaxies. Based on CO, FIR, and HI single-dish data, together with VLA maps for eight groups, Verdes-Montenegro et al. (2007) found that the $M_{HI}$ and $L_{FIR}$ are lower than expected for HI deficient galaxies, when compared to a well-defined sample of isolated galaxies (AMIga project, Analysis of the interstellar Medium of Isolated Galaxies, http://amiga.iaa.es; Verdes-Montenegro et al. 2005). A possible explanation for this trend is that, since HI is needed to replenish the molecular clouds and molecular gas is necessary to fuel SF, an HI deficiency can ultimately lead to a decrease in the SFR. However, the result of Verdes-Montenegro et al. (2007) was based on a small sample of galaxies that does not cover the wide range of properties of HCGs and was therefore not statistically significant. On the other hand, while previous works studying $M_{HI}$ and SFR of galaxies in HCGs (Verdes-Montenegro et al. 1998; Leon et al. 1998) were based on larger samples, those did not have the HI mass of the individual galaxies to compare with $M_{HI}$ and $L_{FIR}$. Thus, to date, no study of the relation between $M_{HI}$, $M_{H2}$ and the SFR for a statistically significant sample has been carried out.

To shed light on the relations between $M_{HI}$ and SFR with $M_{H2}$ properties of the HCGs, we present here a systematic study of galaxies in a sample of 20 HCGs for which we have HI measurements for the entire groups, as well as for a large fraction of the individual galaxies. This enables us to consider $M_{HI}$ of the galaxies as an additional parameter, as well as the evolutionary phase of the group according to Verdes-Montenegro et al. (2001) (see Sect. 2). We compare the properties of galaxies in HCGs with those of isolated galaxies in the AMIGA sample (Verdes-Montenegro et al. 2005). Our goal is to determine whether deviations in the HI content with respect to isolated galaxies translate into anomalies in the $M_{HI}$ and the SFR.

The outline of this paper is as follows. We present the sample in Sect. 2. CO(1−0) and CO(2−1) data coming either from our observations or from the literature, together with reprocessed IRAS FIR data, are presented in Sect. 3. In Sect. 4 we compare the $M_{HI}$, $L_{FIR}$ (as a tracer of the SFR), and $M_{H2}$ of the galaxies, studying their deficiencies and their relation with the HI content and evolutionary phase of the group. A discussion of a possible evolutionary sequence for the molecular gas content in the HCGs is presented in Sect. 5. Finally, the conclusions of our work are summarized in Sect. 6.

2. The samples

2.1. Galaxies in HCGs

Our sample was selected from the revision of the original Hickson (1982) catalog performed by Hickson et al. (1992). From the groups included in that work, we studied 86 galaxies belonging to 20 different HCGs: 7, 10, 15, 16, 23, 25, 30, 31, 37, 40, 44, 45, 58, 67, 68, 79, 88, 92, 93, 97, and 100. The groups, which cover all evolutionary stages and a wide range of HI deficiencies, satisfy the following criteria:

- have at least four members, so triplets are excluded, according to the original Hickson (1982) criterion. We also exclude false groups, where a single knotty irregular galaxy has been confused with separated galaxies (Verdes-Montenegro et al. 2001);
- contain at least one spiral galaxy, since we are mainly interested in studying the relation between the SF process and $M_{HI}$, which are most clearly linked for spiral galaxies;
- are at a distance $D \leq 100$ Mpc (assuming $H_0 = 75 \text{ km s}^{-1} \text{ Mpc}^{-1}$), in order to guarantee a good sensitivity and to minimize possible source confusion within the telescope beam. At 100 Mpc, the 30 m beam would have a size of 10.7 kpc and the VLA beam (considering a size of $50\arcsec \times 50\arcsec$) 24.2 kpc.
Verdes-Montenegro et al. (2001) propose an evolutionary sequence model where the HI is continuously stripped from the galaxies. According to this model, HCGs can be classified into three phases as follows. In Phase 1 the HI is mainly found in the disks of galaxies. In Phase 2, 30% to 60% of the HI has been removed from the disks by tidal interaction. Finally, in Phase 3, almost all the HI is found outside of the galactic disks, either forming tidal tails of stripped gas (Phase 3a) or, in a few cases, in a large HI cloud with a single velocity gradient in which the galaxies are embedded (Phase 3b).

According to the evolutionary phases defined in Verdes-Montenegro et al. (2001), the HCGs in our sample were classified by Borthakur et al. (2010) as

- HCGs with a normal HI content (at least 2/3 of its expected value): HCG 23, 25, 68, and 79;
- HCGs with a slight HI deficiency (between 2/3 and 1/3 of the expected value): HCG 7, 10, 15, 16, 31, 37, 40, 58, 88, 92, 97, and 100;
- HCGs with a large HI deficiency (under 1/3 of the expected value): HCG 30, 44, 67, and 93.

Verdes-Montenegro et al. (2001) has been added: HCG100d, which had no velocity measurements taken from the LEDA database. We revised the velocities of the individual galaxies in the HCGs of our sample. Two galaxies not considered in Hickson et al. (1992) have been added: HCG100d, which had no velocity data in that work, and HCG31g, added to the catalog of HCGs by Rubin et al. (1990).

The basic properties of the galaxies in our sample are detailed in Table 1. The columns are

1. Galaxy: galaxy designation, following the notation of Hickson (1982).
2. V: heliocentric radial velocity in km s$^{-1}$ (weighted average of optical measurements taken from the LEDA database) converted from the optical to the radio definition for comparison with the CO spectra.
3. $\sigma_V$: velocity dispersion of the galaxies in the group.
4. D: distance to the corresponding HCG in Mpc, derived from the mean heliocentric velocity of the group as $D = V/H_0$, assuming a value of $H_0 = 75$ km s$^{-1}$ Mpc$^{-1}$. The mean velocity of the group is calculated averaging the velocity of the individual galaxies (Col. 2).
5. $T$: morphological type taken from LEDA, following the RC3 classification (de Vaucouleurs et al. 1991).
6. $D_{25}$: optical major diameter in arcmin at the 25 mag arcsec$^{-2}$ isophot taken from LEDA.
7. $B_L^1$: apparent blue magnitude taken from LEDA, corrected for Galactic dust extinction, internal extinction, and K-correction.
8. $\log(L_B)$: decimal logarithm of the blue luminosity, derived from $B_L^1$ as

$$\log\left(\frac{L_B}{L_\odot}\right) = 2\log D - 0.4B_L^1 + 11.95. \quad (1)$$

This definition provides an estimate of the blue luminosity ($L_B$) at 4400 Å.
9. $\log(L_K)$: decimal logarithm of the luminosity in the $K$-band in units of the solar luminosity in the $K_S$-band ($L_{K,S} = 5.0735 \times 10^{32}$ erg s$^{-1}$), calculated from the extrapolated magnitude in the $K_S$ (2.17 μm) band from the 2MASS Extended Source Catalog (Jarrett et al. 2000). We calculated the $K_S$ luminosity, $L_K$, from the total (extrapolated) $K_S$ flux, $f_K$, as

$$L_K = \nu f_K(\nu) \text{ where } \nu \text{ is the frequency of the } K\text{-band, } 1.38 \times 10^{14} \text{ Hz}.$$  

10. $\log(M_{HI})$: logarithm of the mass of the atomic hydrogen, in solar masses, for 66 of the galaxies in our sample observed with the VLA, using different combinations of the C and D configurations with beam sizes ranging from $16'' \times 14''$ to $72'' \times 59''$ (Verdes-Montenegro et al. 2001; and Verdes-Montenegro, priv. comm.).
2.2. Reference sample: isolated galaxies

We chose the AMIGA sample of isolated galaxies (Verdes-Montenegro et al. 2005), which is based on the CIG catalog (Karachentseva 1973), as a reference for the FIR and molecular gas properties. The FIR properties of an optically complete subsample of this catalog have been studied in Lisenfeld et al. (2007). The data that we are using for this subsample are slightly different from Lisenfeld et al. (2007) because we have taken a recent update of some basic properties into account that affects the blue magnitude, distance, morphological type, and isolation degree (detailed information provided in Fernández-Lorenzo 2012). We also used the CO data of a velocity restricted subsample (1500 < V < 5000 km s\(^{-1}\)) of 173 AMIGA galaxies (Lisenfeld et al. 2011) to compare to our galaxies. The data for L\(_k\) is also taken from Lisenfeld et al. (2011). When we quote mean values of the AMIGA galaxies we derived them for the subsample of galaxies with \(M_{HI}\) data. For the analysis of the HI properties we used the work of Haynes & Giovanelli (1984), which presents the observations and analysis of CIG galaxies, as a reference.

There are two intrinsic differences between the AMIGA and the HCG samples that must be taken into account when performing a comparison: (i) the HCG sample has a higher rate of early-type galaxies (~45%), whereas 87% of the AMIGA galaxies are spirals (Fig. 1); and (ii) the sample of AMIGA galaxies with \(M_{HI}\) data is restricted to a velocity range of 1500 < V < 5000 km s\(^{-1}\), while the range of the HCGs extends to higher velocities. Thus, the isolated galaxies are, on average, at a shorter distance (47 Mpc average distance versus 68 Mpc for the HCG sample), which can explain their lower average luminosities (see Table 6). However, the values of the deficiencies, ratios or correlations, that we are going to discuss in the following are not expected to be affected by the difference in distance.

3. The data

3.1. CO data

We obtained CO data either by our observations or from the literature, for 86 galaxies in the selected 20 HCGs. CO data are missing for only two galaxies in these 20 groups, HCG 67d and HCG 92f. The CO(1−0) line was detected for 45 galaxies.

3.1.1. IRAM CO(1−0) and CO(2−1) observations and data reduction

We observed 47 galaxies belonging to 14 different HCGs. The observations of the CO rotational transition lines \(J = 1 \rightarrow 0\) and \(J = 2 \rightarrow 1\) (at 115.271 and 230.538 GHz, respectively) were carried out with the IRAM 30 m radio telescope at Pico Veleta\(^4\) during June, October, and December 2006. We performed single-pointing observations using the wobbler switch mode, with a switch frequency of 0.5 Hz and a throw of 200″. We checked for all the objects that the off-position did not coincide with a neighboring galaxy.

The dual polarization receivers A100 and B100 were used to observe the CO(1−0) and CO(2−1) lines in parallel. The median system temperature was 231 K for the CO(1−0) observations, with ~80% of the galaxies observed with system temperatures between 150 and 350 K. In the case of CO(2−1), the median system temperature was 400 K, with a temperature range between 230 and 800 K for 85% of the galaxies. For CO(1−0) the 1 MHz filterbank was used, and for CO(2−1) the 4 MHz filterbank. The corresponding velocity resolutions were 2.6 km s\(^{-1}\) for CO(1−0) and 5.3 km s\(^{-1}\) CO(2−1), respectively. The total bandwidth was 1 GHz. The half power beam width (HPBW) is 22″ and 11″ for 115 and 230 GHz, respectively. All CO spectra and intensities are presented on the main beam temperature scale (T\(_{mb}\)) which is defined as

\[
T_{mb} = \frac{F_{eff}}{B_{eff}} \times T_A^* \text{,}
\]

where \(T_A^*\) is the main beam temperature and \(B_{eff}\) is the effective beam, which is given by

\[
B_{eff} = \frac{\pi \Omega^2}{12} \text{,}
\]

\(\Omega\) being the area of the main beam and \(\Omega^2\) being the area of the main beam as seen in the reference direction.\(^5\) The IRAM forward efficiency, \(F_{eff}\), was 0.95 at 155 GHz and 0.91 at 230 GHz and the beam efficiency, \(B_{eff}\), was 0.75 and 0.54, respectively.

The data reduction and analysis was performed using CLASS, while further analysis used GREG, both part of the GILDAS\(^6\) package developed by IRAM. First we visually inspected the spectra and discarded bad scans. Then, spikes were removed and a constant or linear baseline was subtracted from each spectrum. The scans were then averaged to achieve a single spectrum for each galaxy and transition. These spectra were smoothed to a velocity resolution of 21 to 27 km s\(^{-1}\), depending on the rms. A total of 24 galaxies were detected in CO(1−0) (2 of them marginal), 22 in CO(2−1) (4 of them marginal) and 18 in both transitions. The spectra are shown in Appendix A, where Fig. A.1 displays the spectra detected in CO(1−0) and Fig. A.2 those detected in CO(2−1).

For each spectrum, we integrated the intensity along the velocity interval where emission was detected. For nondetections we set an upper limit as

\[
I_{CO} < 3 \times \text{rms} \times \frac{\delta V}{\Delta V},
\]

where \(\delta V\) is the channel width and \(\Delta V\) the total line width. We used a value of \(\Delta V = 300\) km s\(^{-1}\) for nondetections in both CO(1−0) and CO(2−1). When the source was detected in only one transition, this line width was used to calculate the upper limit in the other transition.

The results of our CO(1−0) and CO(2−1) observations are displayed in Table 2. The columns are

1. Galaxy: galaxy designation;
2. \(I_{CO(1−0)}\): velocity integrated intensity of the CO(1−0) emission in K km s\(^{-1}\).

3. rms: root-mean-square noise of the CO(1–0) spectrum (if available) in mK;
4. Ref.: reference of the CO(1–0) data, detailing whether data come from our observations or from the literature (see Sect. 3.1.2);
5. Beam: HPBW of the telescope in arcsecond;
6. $\Delta V_{\text{CO}(1-0)}$: line width of the CO(1–0) emission (if detected) in km s$^{-1}$;
7. $I_{\text{CO}(2-1)}$: velocity integrated intensity of the CO(2–1) emission (if observed) in K km s$^{-1}$;
8. rms: rms of the CO(2–1) spectrum (if observed) in mK;
9. $\Delta V_{\text{CO}(2-1)}$: line width of the CO(2–1) emission (if detected) in km s$^{-1}$;
10. log($M_{\text{H}_2}$,obs): logarithm of the H$_2$ mass (in solar masses) calculated from the observed central $I_{\text{CO}}$ (see Sect. 3.1.3);
11. log($M_{\text{H}_2}$): logarithm of the H$_2$ mass (in solar masses) extrapolated to the emission from the total disk (see Sect. 3.1.3).

3.1.2. CO(1–0) data from the literature

We have searched in the literature for available CO(1–0) data for the 20 HCGs of our sample and have compiled data for the velocity-integrated CO(1–0) intensities and line widths (also listed in Table 2) from the following sources:

- Verdes-Montenegro et al. (1998): 24 galaxies from nine different HCGs. Twenty of them were observed with the NRAO 12 m telescope at Kitt Peak with a beam size of 55$''$. The data from the four other galaxies are from Boselli et al. (1996), observed with the SEST 15 m telescope, with a 43$''$ beam. Two of these galaxies (68d and 88c) were also observed by us, but we chose the Verdes-Montenegro et al. (1998) data because of their better quality.
- Leon et al. (1998): 17 galaxies corresponding to ten different HCGs, observed with the IRAM 30 m telescope with a similar setting as in our observations (see Sect. 3.1.1).

There are 16 galaxies that were observed both by us and by Verdes-Montenegro et al. (1998) or Leon et al. (1998). Furthermore, 14 were observed by both Verdes-Montenegro et al. (1998) and Leon et al. (1998). To choose between the different existing spectra (either from our observations or from the literature), we first checked that they were consistent and then applied the following criteria: if available, we chose the spectrum with detected emission. If more than one detected spectrum existed, we chose the one with the lower rms or – in case of comparable rms- the spectrum observed with a larger beam, in order to probe a larger fraction of the disk. Except for the two galaxies mentioned above, we always selected our data due to their better quality in case of duplication. In total, we have CO(1–0) spectra for 86 galaxies (45 from our own observations and 41 from the literature) for our statistical analysis.

3.1.3. Molecular gas mass

We calculate the molecular gas mass, $M_{\text{H}_2}$ using the following equation:

$$M_{\text{H}_2} = 75 \times D^2 I_{\text{CO}(1-0)} \Omega$$  \hspace{1cm} (3)

where $\Omega$ is the area covered by the observations in arcsec$^2$ (i.e. $\Omega = 1.13 \theta^2$ for a single pointing with a Gaussian beam where $\theta$ is the HPBW). This equation assumes a CO-to-H$_2$ conversion factor $X = N_{\text{H}_2}/I_{\text{CO}} = 2 \times 10^{20}$ cm$^{-2}$ (K km s$^{-1}$)$^{-1}$ (e.g. Dickman et al. 1986). No correction factor for the fraction of helium and other heavy metals is included. The molecular gas masses of the AMIGA galaxies are calculated in the same way.

In both the observations that we carried out and the data from the literature, a single position at the center of the galaxy was observed. Because of this and the different beams used by us and others we need to correct for possible emission outside the beam. To extrapolate the observed CO intensities to the total value within the disk we need to know the distribution and extension of the CO emission. Different authors (Nishiyama et al. 2001; Regan et al. 2001; Leroy et al. 2008) have found that the velocity-integrated CO intensity in spiral galaxies follows an exponential distribution as a function of radius with a scale length $r_e$:

$$I_{\text{CO}}(r) = I_0 \exp(r/r_e).$$  \hspace{1cm} (4)

We adopt a scale length of $r_e = 0.2 \times r_{25}$, where $r_{25}$ is the major optical 25 mag arcsec$^{-2}$ isophotal radius, following Liskenfeld et al. (2011), who derive this scale length from studies of the mentioned authors and from their own CO data. We used this distribution to calculate the expected CO emission from the entire disk, taking the galaxy inclination into account (see Liskenfeld et al. 2011, for more details). This approach assumes that the distribution of the molecular gas in galaxies in HCGs is the same as in field spiral galaxies. The implications of this approach are discussed below.

The resulting aperture correction factor for $M_{\text{H}_2}$ (defined as the ratio between $M_{\text{H}_2}$ observed in the central pointing and $M_{\text{H}_2}$ extrapolated to the entire disk) is shown in Fig. 2. The ratio between the extrapolated and central intensities is below two for most galaxies (66 out of 86, or 77%), with an average value of 1.78. To check the consistency of the extrapolation, we also performed the analysis presented in this paper for a sample restricted to galaxies with a small (less than a factor 1.6) aperture correction ($n = 45$), finding no significant differences with...
The values for the molecular gas mass in the central pointing and the extrapolated molecular gas mass are listed in Table 2. Here, and in the following, we always use the extrapolated molecular gas mass and denote it as $M_{\text{H}_2}$ for simplicity. The $M_{\text{H}_2}$ distribution is shown in Fig. 3. The average value for spiral galaxies ($T \geq 1$) is listed in Table 6. The distribution and average values of $M_{\text{H}_2}$, as well as the statistical distributions and average values throughout this work, have been calculated using the Kaplan-Meier estimator implemented in ASURV$^5$, to take the upper limits in the data into account.

### 3.2. Far-infrared data

FIR fluxes were obtained from ADDSCAN/SCANPI, a utility provided by the Infrared Processing and Analysis Center (IPAC)$^6$. This is a one-dimensional tool that coadds calibrated survey data of the Infrared Astronomical Satellite (IRAS). It makes use of all scans that passed over a specific position and produces a scan profile along the average scan direction. It is three to five times more sensitive than the IRAS Point Source Catalog (PSC) since it combines all survey data, so it is more suitable for detection of the total flux from slightly extended objects.

We have compiled the FIR data (also derived using ADDSCAN/SCANPI) for 63 galaxies in our sample from Verdes-Montenegro et al. (1998). In the case of the remaining 23 galaxies, we derived FIR fluxes directly using ADDSCAN/SCANPI. To choose the best flux estimator we have followed the guidelines given in the IPAC website$^7$, which are explained in Lisenfeld et al. (2007). As a consistency check, we also applied this procedure to 14 galaxies in the list of Verdes-Montenegro et al. (1998). We found no significant differences, with an average difference of 15% between our reprocessed fluxes and those in Verdes-Montenegro et al. (1998).

$^7$ http://irsa.ipac.caltech.edu/IRASdocs/scanpi_interp.html
In this section, we aim to study the relation between the SFR and other parameters in HCG galaxies and compare them to isolated galaxies. Furthermore, we search for relations with the atomic gas deficiency of the galaxies and the groups and with the evolutionary phase of the groups. We furthermore investigate the ratio between the two CO transitions, CO(1–0) and CO(2–1).

To search for differences to isolated galaxies, we used two methods: (i) we normalized $M_{\text{H}}$ and $L_{\text{FIR}}$ to the blue luminosity, $L_b$, or the luminosity in the K-band, $L_K$, and compared the ratios to those of isolated galaxies, and (ii) we calculated the deficiency parameters of $M_{\text{H}}$, $L_{\text{FIR}}$ and $M_{\text{HI}}$ of the galaxies (see Sect. 4.2). In general, we obtained very consistent results for $L_b$ and $L_K$.

We carry out this analysis separately for early-type galaxies and spirals for the following reasons. (i) The morphological distribution is very different for both samples with a much higher fraction of early-type galaxies among HCG galaxies. (ii) The number of early-type galaxies in the AMIGA reference sample is very small so that no statistically significant comparison sample is available. In particular, no deficiency parameter can be derived. (iii) Early-type galaxies tend to have a significantly lower molecular gas content than late-type galaxies, and their FIR emission is not as clearly related to their SFR as it is in late-type galaxies, as a result of the lack of strong SF. Therefore, the use of $L_{\text{FIR}}$ as an SF tracer is more questionable.

4.1. Relation between $M_{\text{H}}$, $L_{\text{FIR}}$, $M_{\text{HI}}$, and $L_b$

Figure 4 shows $M_{\text{H}}$ (top) and $L_{\text{FIR}}$ (bottom) versus $L_b$ for spirals galaxies (left) and early-type galaxies (right). For spiral galaxies, good correlations exist between both $M_{\text{H}}$, $L_{\text{FIR}}$, and $L_b$. A linear fit to the total sample of HGCs is plotted, along with the corresponding fit to the AMIGA sample. The coefficients are listed in Table 4. The fits on $L_{\text{FIR}}$ vs. $L_b$ for the AMIGA sample are slightly different from the values in Lisenfeld et al. (2007) because we have considered a recent update of the basic properties of the galaxies (e.g. distance and morphological type; see Fernández-Lorenzo 2012, for more details). A slight shift towards higher values in $M_{\text{H}}$ seems to be present in comparison to the best-fit line of isolated galaxies. The linear regressions between $L_{\text{FIR}}$ and $L_b$, $M_{\text{H}}$, and $L_{\text{FIR}}$ (Table 4) show no significant differences between HCGs and isolated galaxies. No clear correlation is visible for early-type galaxies and for $\log(L_b) \gtrsim 10$, the values of both $M_{\text{H}}$ and $L_{\text{FIR}}$ are below those of spiral galaxies.

We note that, in contrast to $M_{\text{H}}$, $L_{\text{FIR}}$, and $L_b$, $M_{\text{HI}}$ shows no correlation with $L_b$ (Fig. 5), reflecting that HI is very strongly

Notes. The full table is available in electronic form at the CDS and from http://amiga.iaa.es. $^a$Reference code (see Sect. 3.2): 1: our data analysis. 2: Verdes-Montenegro et al. (1998). $^b$The value of the SFE is not displayed for the galaxies with upper limits in both $L_{\text{FIR}}$ and $M_{\text{HI}}$.
affected by the interactions and in many galaxies of our evolved groups largely removed from the galaxies.

Previous surveys (see e.g. Young & Scoville 1991) have found a linear correlation between \( M_{\text{H}_2} \) and \( L_{\text{FIR}} \). A linear correlation can also be seen in our sample (Fig. 6). We include in this figure the lines for constant \( L_{\text{FIR}}/M_{\text{H}_2} \) values equal to 1, 10, and 100 \( L_{\odot}/M_{\odot} \). Practically all of our galaxies lie in the range of \( L_{\text{FIR}}/M_{\text{H}_2} = 1-10 \ L_{\odot}/M_{\odot} \), which is typical of normal, quiescent galaxies (Young & Scoville 1991).

Finally, we have directly compared E and S0 galaxies in HCGs to galaxies of the same types in the AMIGA sample. In the case of lenticular galaxies we limited the sample of galaxies in HCGs to galaxies of the same types in the AMIGA sample. In Fig. 7 (top) we show the relation between \( M_{\text{H}_2} \) and \( L_B \) for the S0s in HCGs and from the AMIGA sample. Even though the number of data points is low, a trend seems to be present for S0s in isolated galaxies to have a higher \( M_{\text{H}_2} \) for the same \( L_B \). A similar result is found for \( L_{\text{FIR}} \) (not shown here), where most lenticular isolated galaxies present higher values than expected for their optical luminosity, while most of the objects in HCGs show upper limits excluding any excess. If S0 galaxies in these dense environments originate from stripping of spirals, this might indicate that molecular gas has also been removed in the process. Although this interpretation is speculative owing to the low-quality statistics, it provides hints for further research in future works.

Concerning the elliptical galaxies, none of the isolated galaxies is detected in CO, while among the four detections in HCGs two have a mass similar to the expected for spiral isolated galaxies (HCG 15d and HCG 79b), and the other two show significantly lower masses (HCG 37a and HCG 93a), pointing to an external origin (Fig. 7, bottom). The FIR luminosity of the Es in HCGs (not shown here) is similar to what is expected for spiral galaxies. It is also noticeable that, while the range of \( L_B \) values for the S0s in HCGs covers about the same range as for isolated galaxies, Es in HCGs are up to half an order of magnitude more luminous than isolated Es.

### Table 4. Correlation analysis of \( M_{\text{H}_2} \) vs. \( L_B \), \( L_{\text{FIR}} \) vs. \( L_B \), and \( M_{\text{H}_2} \) vs. \( L_{\text{FIR}} \).

**Notes.** The slope and intercept are defined as \( \log (M_{\text{H}_2}) = \log (L_B) \times \text{slope} + \text{intercept} \), \( \log (L_{\text{FIR}}) = \log (L_B) \times \text{slope} + \text{intercept} \) and \( \log (M_{\text{H}_2}) = \log (L_{\text{FIR}}) \times \text{slope} + \text{intercept} \). The AMIGA fits involving \( M_{\text{H}_2} \) are taken from Lisenfeld et al. (2011).
4.2. Deficiencies

We have calculated the $M_{H_2}$, $L_{FIR}$, and $M_{HI}$ deficiencies following the definition of Haynes & Giovanelli (1984) as

$$\text{Def}(X) = \log(X_{\text{predicted}}) - \log(X_{\text{observed}})$$

where we calculated the predicted value of the variable $X$ from $L_B$. Following this definition, a negative deficiency implies an excess with respect to the predicted value.

The expected $M_{HI}$ for each galaxy is calculated from its $L_B$ using the fit to the AMIGA sample in Lisenfeld et al. (2011). The fit, which is given in Table 4, was calculated without distinguishing morphological types. The dominance of spiral galaxies in the AMIGA sample means that the fit is only adequate for spiral galaxies. Because of the low number of early-type galaxies in the AMIGA sample, it is not possible to derive a meaningful deficiency parameter for them. In addition, we calculated the deficiency derived from the relation between $M_{HI}$ and $L_K$ of the AMIGA sample (Lisenfeld et al. 2011), log ($M_{HI}$) = -2.27 + 1.05 x log ($L_K$). In a similar way, the expected $L_{FIR}$ is calculated from the fit between $L_{FIR}$ and $L_B$ obtained for the AMIGA isolated galaxies (Table 4) for the sample presented in Lisenfeld et al. (2007).

The correlations between $M_{HI}$ ($L_{FIR}$) and $L_B$, or $L_K$, have a considerable scatter with standard deviations of 0.35 dex for $M_{HI}$, and 0.4 dex for $L_{FIR}$. These standard deviations are much higher than the observational measurement errors. In this case, the error of the mean values are completely dominated by the statistical errors, so we neglect the observational errors in our calculations. The high standard deviation means that individual galaxies with deficiencies up to about these values represent normal deviations from the mean. However, the much smaller error of the mean deficiency allows samples of galaxies (here: galaxies in HCGs and isolated galaxies) to be compared with a much higher precision.

The HI deficiency of the galaxies is calculated following the morphology-dependent fit between $M_{HI}$ and $L_B$ in Haynes & Giovanelli (1984). We have considered $h = H_0/100 = 0.75$. We adapted their results, which were based on $mag_{B_{58}}$ to our use of $B^I$ with the relation found by Verdes-Montenegro et al. (2005) ($mag_{B_{58}} = B^I +0.136$). Furthermore, considering that we express $L_B$ as a function of the solar bolometric luminosity (mag = 4.75), we introduce the correction

$$\log L_B^\text{Haynes} = \log L_B^\text{suns} + 0.14$$

(8) to express $L_B$ in the terms we assume (Sect. 2) to calculate the expected content of HI. The deficiencies in $M_{HI}$, $L_{FIR}$, and $M_{HI}$ derived from $L_B$ are listed in Table 5.

4.2.1. $M_{HI}$ and $L_{FIR}$ deficiencies

The mean $M_{HI}$ and $L_{FIR}$ deficiencies for spiral galaxies in HCGs are similar, as can be seen in Table 6. Galaxies showing an excess in $M_{HI}$, or $L_{FIR}$ have values spanning the full range of $L_B$, as can be seen in Fig. 4. Thus, the excess in $M_{HI}$, or $L_{FIR}$ is not associated with the brightest objects per se. We checked in detail the properties of the nine galaxies showing the largest $M_{HI}$ excess (HCG 10c, HCG 16a, HCG 16c, HCG 16d, HCG 23b, HCG 23d, HCG 40c, HCG 58a, HCG 88c), and we find that half of them present strong signs of distortion (tidal tails in the optical and/or HI, kinematical perturbations, etc.).

Figure 8 (left) shows Def($M_{HI}$) (from $L_B$) vs. Def($L_{FIR}$) for each galaxy. Both are strongly correlated, which can be understood coming from the causal relation between the molecular gas and SFR, leading to a lower SFR if the molecular gas as the fuel for SF decreases. For comparison, Fig. 8 (right) displays Def($M_{HI}$) of the isolated galaxies versus their Def($L_{FIR}$). The behavior of the isolated galaxies does not show a significant difference compared to galaxies in HCGs with a very similar range covered by both samples. However, for the isolated galaxies, Def($M_{HI}$) extends to slightly lower values for a given Def($L_{FIR}$). This is also reflected in the mean values of Def($M_{HI}$) and Def($L_{FIR}$) of AMIGA and HCG galaxies (Table 6): (i) values of Def($L_{FIR}$) for spiral galaxies are almost the same for both samples; and (ii) Def($M_{HI}$) in spirals is higher by 0.15–0.20 for HCG

Notes. ($^1$) For each subsample, n is the number of galaxies and $n_{UL}$ is the number of upper limits.

Fig. 8. $M_{H_2}$ deficiency vs. $L_{FIR}$ deficiency for late-type ($T \geq 1$) galaxies in HCGs (left) and from the AMIGA sample (right). Red symbols represent upper limits in either $M_{H_2}$ or $L_{FIR}$, and black symbols detections. The $g = x$ line is plotted as reference and does not represent a fit to the data.

than for AMIGA galaxies (corresponding to a 40–60% higher $M_{H_2}$ than expected for isolated galaxies).

The histograms shown in Fig. 9 underline these findings: whereas the distribution of Def($M_{H_2}$) for spiral galaxies in HCGs is shifted to negative deficiencies (i.e., an excess) compared to AMIGA galaxies, the distribution of Def($L_{FIR}$) is very similar for spiral galaxies in HCGs and in the AMIGA sample. Two sample tests (Gehan’s Generalized Wilcoxon Test and Logrank Test) confirm that the distributions of Def($M_{H_2}$) are different with a probability of >96%, whereas the distributions Def($L_{FIR}$) are identical with a non-negligible probability.

As an additional test, we compared the ratios $M_{H_2}/L_B$ and $M_{H_2}/L_K$ of HCG galaxies to those of isolated galaxies (listed in Table 6). In the case of $M_{H_2}/L_B$ we derived the ratios both for the entire luminosity range and for low ($L_B \leq 10^{10}$ $L_\odot$) and high ($L_B > 10^{10}$ $L_\odot$) luminosity galaxies in order not to be affected by the non-linearity of the $M_{H_2}/L_B$ relation. In all cases we found a lower ratio (by ∼0.2–0.3 dex) for the isolated galaxies, confirming our findings from the deficiency parameter.

The higher $M_{H_2}$ for a given $L_B$ found for spiral galaxies in HCGs could be explained in three ways: a) a real excess of the total molecular gas mass (and will be further discussed as such in the following section); b) a higher concentration towards the center than for AMIGA galaxies (corresponding to a 40–60% higher $M_{H_2}$ than expected for isolated galaxies).

The histograms shown in Fig. 9 underline these findings: whereas the distribution of Def($M_{H_2}$) for spiral galaxies in HCGs is shifted to negative deficiencies (i.e., an excess) compared to AMIGA galaxies, the distribution of Def($L_{FIR}$) is very similar for spiral galaxies in HCGs and in the AMIGA sample. Two sample tests (Gehan’s Generalized Wilcoxon Test and Logrank Test) confirm that the distributions of Def($M_{H_2}$) are different with a probability of >96%, whereas the distributions Def($L_{FIR}$) are identical with a non-negligible probability.

In the case of $M_{H_2}/L_B$ we derived the ratios both for the entire luminosity range and for low ($L_B \leq 10^{10}$ $L_\odot$) and high ($L_B > 10^{10}$ $L_\odot$) luminosity galaxies in order not to be affected by the non-linearity of the $M_{H_2}/L_B$ relation. In all cases we found a lower ratio (by ∼0.2–0.3 dex) for the isolated galaxies, confirming our findings from the deficiency parameter.
Def(\text{phological types}, which is one order of magnitude more than density, and velocity dispersion (e.g. Maloney & Black 1988; both samples because of the similar ranges in Narayanan et al. 2011). These properties are likely similar in the present paper and in Verdes-Montenegro et al. (2001).

4.2.2. Comparison to the MHI deficiency

The center of the molecular gas in HCG galaxies compared to isolated galaxies, so that the extrapolation of the flux based on a similar extent (see Sect. 3.1.3) would lead to an overestimate of \(M_{\text{HI}}\), or c) a systematic difference in the CO-to-H\(_2\) conversion factor between the AMIGA and HCG sample. Although we cannot exclude this possibility, we do not consider it very likely. The CO-to-H\(_2\) conversion factor is known to depend on a number of galactic properties such as the metallicity, gas temperature, gas density, and velocity dispersion (e.g. Maloney & Black 1988; Narayanan et al. 2011). These properties are likely similar in both samples because of the similar ranges in \(L_{\text{B}}\) and \(L_{\text{FIR}}\) (tracing SFR) that they cover. The first two effects (a and b) could both be at work at the same time. In fact, as indicated in e.g. Leon et al. (2008), galaxies in the AMIGA sample are dominated by disk SF while surveys of compact groups (Menon 1995) show that most radio detections involve compact nuclear emission. This can be explained since nuclear emission is thought to be enhanced by interactions that produce a loss of angular momentum of the molecular gas, which subsequently falls towards the center of the galaxy. These dissipative effects are likely near minimum in isolated galaxies. This result was also proposed by Verdes-Montenegro et al. (1998), where the enhanced \(I_{25}/I_{100}\) ratio in HCGs is said to be caused by local starbursts, presumably in the nuclear region. This result is still compatible with the conclusion of a normal level of FIR emission among the HCG galaxies that we find here, if the activity responsible for enhanced 24 \(\mu\)m emission and enhanced/more concentrated molecular gas is localized compared to the overall distribution of gas and dust in the galaxies.

4.3. Comparison to the HI content and evolutionary stage of the group

To study the influence of the global HI content of the group on \(M_{\text{HI}}\), and SFR of the individual galaxies we have classified the groups as a function of their Def(\(M_{\text{HI}}\)) as listed in Sect. 2. The average Def(\(M_{\text{HI}}\)) and Def(\(L_{\text{FIR}}\)) of the galaxies belonging to these groups are given in Table 7. We find no relation between the Def(\(M_{\text{HI}}\)) of the galaxies and the global Def(\(M_{\text{HI}}\)) of the groups, and neither between the Def(\(L_{\text{FIR}}\)) and the Def(\(M_{\text{HI}}\)) of the groups.

In a similar way, we calculated the average Def(\(M_{\text{HI}}\)) and Def(\(L_{\text{FIR}}\)) of the galaxies belonging to HCGs in different evolutionary states, as defined by (Borthakur et al. 2010, see Sect. 2), which are also given in Table 7. The Def(\(M_{\text{HI}}\)) of the galaxies increases slightly as the group evolves along the evolutionary sequence. This trend is also visible in the ratios \(M_{\text{HI}}/L_{\text{B}}\) and \(M_{\text{HI}}/L_K\). For Def(\(L_{\text{FIR}}\)), there is no clear relation for spiral galaxies with the evolutionary state, and we only find a trend when considering the total sample, most likely due to a changing fraction of ellipticals.

A very pronounced variation with evolutionary phase is shown by the morphological types (Fig. 11). The ratio of elliptical and S0 galaxies increase strongly in groups in phase 3. It has been proposed (e.g. Verdes-Montenegro et al. 2001; Bekki & Couch 2011) that S0 galaxies in HCGs might be stripped spirals.

4.4. Star formation rate, star formation efficiency and specific SFR

We calculate the SFR from \(L_{\text{FIR}}\) following the prescription of Kennicutt (1998):

\[
SFR(M_\odot/\text{yr}) = 4.5 \times 10^{-44} L_{\text{IR}}(\text{erg s}^{-1})
\]

where \(L_{\text{IR}}\) refers to the IR luminosity integrated over the entire mid- and far-IR spectrum (10–1000 \(\mu\)m). This expression is based on a Salpeter initial mass function (IMF). We convert it to the Kroupa (2001) IMF by dividing by a factor 1.59 (Leroy et al. 2008). In our analysis we use \(L_{\text{FIR}}\) (Eq. (6)), which estimates the FIR emission in the wavelength range of 42.5–122.5 \(\mu\)m. We estimate \(L_{\text{IR}}\) from \(L_{\text{FIR}}\) using the result of Bell (2003) that on average \(L_{\text{IR}} \sim 2 \times L_{\text{FIR}}\). Taking this into account, we can calculate the SFR from \(L_{\text{FIR}}\) as

\[
SFR(M_\odot/\text{yr}) = 4.5 \times 2 \times \frac{1}{1.59} \times 10^{-44} L_{\text{FIR}}(\text{erg s}^{-1}) = 2.2 \times 10^{-10} L_{\text{FIR}}(L_\odot).
\]

Notes. ($^1$) Galaxies detected in both CO and FIR and galaxies detected in FIR but not in CO. ($^2$) Galaxies detected in both CO and FIR and galaxies detected in CO but not in FIR. ($^3$) From Bigiel et al. (2011). The 1σ standard deviation is 0.24 dex.

The values of the SFR of the galaxies in our sample are listed in Table 3. We define the SFE as the ratio between the SFR and the molecular gas mass, SFE = $SFR/M_{HI}$. The SFE of the individual galaxies in our sample are listed in Table 3. Figure 6 shows a good, roughly linear correlation between $L_{FIR}$ and $M_{HI}$, and indicates that the SFE in our sample is expected to show a fairly narrow range. To calculate the average SFE of our sample, we must consider that ASURV can only handle data showing upper or lower limits, but not both. Thus, we first calculated the average SFE considering only galaxies detected in CO with an upper limit in FIR, together with the ones detected in both bands. Separately, we considered only those detected in FIR but not detected in CO and the ones detected in both bands. The average values are listed in Table 8.

We calculated the average SFE for the AMIGA sample of isolated galaxies, taking $M_{HI}$ from Lisenfeld et al. (2011) and $L_{FIR}$ from Lisenfeld et al. (2007), for comparison with the SFE in HCG galaxies. The values are listed in Table 8. We furthermore list the SFE derived from a spatially resolved analysis for 30 nearby galaxies from the HERACLES survey (Bigiel et al. 2011). All values are adjusted to our CO-to-H$_2$ conversion factor, Kroupa IMF, and no consideration of helium in the molecular gas mass. Table 8 shows a slightly lower SFE in HCGs than in AMIGA galaxies, in line with the previous results of an excess in $M_{HI}$ but a normal value of $L_{FIR}$. In comparison to the galaxies from the HERACLES survey there is no noticeable difference. Thus, overall there are no strong indications that the process of SF occurs in a different manner in the different environments of HCGs.

The specific SFR, sSFR, is defined as the ratio between the SFR and the stellar mass of a galaxy. We calculated the stellar mass from the $K$ band luminosity since the light in this band is dominated by the emission of low-mass stars, which are responsible for the bulk of stellar mass in galaxies. From $L_K$ we derived the stellar mass, $M_*$, by adopting a mass-to-luminosity ratio of $M_*/L_K = 1.32$ (Cole et al. 2001) for the Salpeter IMF, and applying a correction factor of 0.5 (from Bell et al. 2003) to change to the Kroupa (2001) IMF used in this paper. The values for the individual galaxies are listed in Table 3. The average sSFR for spiral galaxies in our sample is log (sSFR) = −10.61 ± 0.07 yr$^{-1}$.

4.4.1. SFE and sSFR functions of the deficiencies of the galaxies

In Fig. 12 we display the SFE and the sSFR of the spiral galaxies in our sample as a function of their Def($M_{HI}$) and Def($M_{HI}$). There is no clear trend of the SFE with the gas deficiency of the galaxies, whether atomic or molecular. This is confirmed by the mean values listed in Table 9. This result indicates that SF proceeds with the same efficiency, regardless of whether it occurs in a galaxy with a low or high $M_{HI}$ deficiency.

On the other hand, galaxies with lower Def($M_{HI}$) or Def($M_{HI}$) tend to have a higher sSFR (see Fig. 12, as well as Table 9 for the quantitative trends). In particular, the trend with Def($M_{HI}$) is interesting because it suggests that, although the Def($M_{HI}$) of a galaxy has no influence on the absolute SFR or SFE, it has a noticeable effect on the SFR per stellar mass.

4.5. Line ratio

Figure 13 shows the CO(1–0) versus the CO(2–1) intensity for the galaxies we observed (Sect. 3.1.1). The plotted intensities
are not aperture corrected. The mean ratio between both intensities is $I_{\text{CO}(2-1)}/I_{\text{CO}(1-0)} = 1.13 \pm 0.11$ for the full sample and $1.13 \pm 0.12$ for spiral galaxies alone. To calculate this mean ratio with ASURV, we have taken galaxies into account with detections in both CO transitions, as well as those detected only in CO(1–0). These values are slightly higher than those found by Leroy et al. (2009) from CO(2–1) and CO(1–0) maps for nearby galaxies from the SINGS sample ($I_{\text{CO}(2-1)}/I_{\text{CO}(1-0)} \sim 0.8$) and than those from Braine et al. (1993) who obtained a mean line ratio of $I_{\text{CO}(2-1)}/I_{\text{CO}(1-0)} = 0.89 \pm 0.06$ for a sample of nearby spiral galaxies. Both values are, in contrast to ours, corrected for beam-size effects.

![Fig. 11. Morphological type distribution for different evolutionary phases. From top to bottom, the morphological type distribution of galaxies in HCGs in evolutionary phases 1, 2, and 3 are plotted. The filled red bins correspond to the distribution for the groups in each evolutionary state, while the black line bins correspond, for comparison, to galaxies of all phases.](image)

To interpret the ratio of $I_{\text{CO}(2-1)}/I_{\text{CO}(1-0)}$ one has to consider two main parameters: the source distribution and the opacity. For optically thick, thermalized emission with a point-like distribution we expect a ratio $I_{\text{CO}(2-1)}/I_{\text{CO}(1-0)} = (\theta_{\text{CO}(1-0)}/\theta_{\text{CO}(2-1)})^2 \approx 4$ (with $I_{\text{CO}}$ in $T_{\text{mb}}$ and $\theta$ being the FWHM of the beams). On the other hand, for a uniform source brightness distribution we expect ratios over 1 for optically thin gas, and ratios between about 0.6 and 1 for optically thick gas (with excitation temperatures above 5 K).

Owing to the different beam sizes of CO(1–0) and CO(2–1) in our observations we cannot distinguish these two cases. However, we can conclude that our values are consistent with optically thick, thermalized gas with an extended distribution. Our mean value is slightly higher than the (beam-corrected) values of Leroy et al. (2009) and Braine et al. (1993) which might indicate that the molecular gas is not completely uniform over the CO(1–0) beam, but slightly concentrated towards the center.

5. A possible evolutionary sequence of the molecular gas content and SFR in HCGs

In contrast to the HI content, which can be highly deficient, the mean deficiencies for both $M_{\text{HI}}$ and $L_{\text{FIR}}$ are low and close to the
values found for isolated galaxies. In the case of $M_{\text{HI}}$, we even find indications for a 40–60% excess compared to isolated galaxies. The difference in deficiency between the atomic and molecular gas is most likely due to the larger extent of the HI gas, which can thus be removed more efficiently from the galaxies, while the molecular gas, which is typically more concentrated in the inner regions, is presumably less affected by the environment. Subsequently, the lower HI mass might cause lower $M_{\text{HI}}$, which in turn leads to lower SFR. It is, however, remarkable that galaxies with a high HI deficiency can still contain a considerable amount of molecular gas and continue to form stars with a normal SFE. This SF is not expected to last very long because once the molecular gas is used up, no HI is available to provide fuel for future SF.

Within this general picture of the relative normality of $M_{\text{HI}}$ and $L_{\text{FIR}}$, we have found a relation between Def($M_{\text{HI}}$) and the sSFR, and a tentative trend with Def($M_{\text{HI}}$) and Def($L_{\text{FIR}}$). Furthermore, there is a trend of Def($M_{\text{HI}}$) with the evolutionary phase (Table 7), in the sense that galaxies in HCGs belonging to phase 1 have the highest excess in $M_{\text{HI}}$. These trends might suggest that two mechanisms are in play. First, an increasing $M_{\text{HI}}$ deficiency can be interpreted within a scenario in which galaxies in HCGs lose part of their HI as a result of mostly tidal stripping during the initial evolutionary phase, as suggested in the evolutionary model of Verdes-Montenegro et al. (2001). On the other hand, in an early evolutionary phase the HI-to-$H_2$ conversion rate might be enhanced as a result of the continuous interactions between galaxies, leading to the enhancement in $M_{\text{HI}}$ that we observe in evolutionary phase 1. This enhancement of $M_{\text{HI}}$ cannot explain the high HI deficiencies observed in most galaxies, in agreement with the conclusions of Rasmussen et al. (2008), but it could partly explain the lack of HI, especially in the galaxies with the lowest HI deficiencies.

Based on our results, we thus suggest the following scenario, which is speculative but compatible with our observations. Galaxies in an HCG start with a normal content in $M_{\text{HI}}$ and $M_{\text{HI}}$; i.e., they have Def($M_{\text{HI}}$) = 0 and Def($M_{\text{HI}}$) = 0. Then, during the early evolutionary phase, tidal interactions enhance the conversion from atomic to molecular gas at the same time as they strip the HI from the galaxies, which leads to Def($M_{\text{HI}}$) > 0 and Def($M_{\text{HI}}$) < 0. Finally, the multiple interactions within the group strip the main part of the HI in the disks, resulting in Def($M_{\text{HI}}$) >> 0 and, as a consequence also increase in Def($M_{\text{HI}}$). This last effect could have contributed to an increase in the fraction of lenticular galaxies along the evolutionary sequence due to HI and $H_2$ stripping of spirals.

6. Summary and conclusions

We analyzed data for $M_{\text{HI}}$, which was obtained from observations with the IRAM 30 m telescope and from the literature, $L_{\text{FIR}}$ from IRAS, and $M_{\text{HI}}$ for 86 galaxies in 20 HCGs in order to study the relation between atomic gas, molecular gas, and SFR, traced by $L_{\text{FIR}}$ in these galaxies. We compared these properties to those of isolated galaxies from the AMIGA project (Verdes-Montenegro et al. 2005). We adopted the same CO-to-$H_2$ conversion factor for both samples. The main conclusions of our study can be summarized as follows:

- The relation between $M_{\text{HI}}$, $L_{\text{FIR}}$, and $L_\text{B}$ in the galaxies in HCGs is not significantly different from the one found in isolated galaxies. The values of $L_{\text{FIR}}$ for spirals galaxies in HCGs are similar to those of the AMIGA galaxies for the same $L_\text{B}$. For $M_{\text{HI}}$, we find, however, a slight, but statistically significant, excess (~50%) of HCGs spiral galaxies relative to AMIGA galaxies. This could alternatively be explained by a higher radial concentration of the molecular gas in HCG galaxies to the center when compared with isolated galaxies, so that the extrapolation of the flux based on a similar extent (see Sect. 3.1.3) would lead to overestimating $M_{\text{HI}}$ for the group galaxies. Another possible explanation could be a systematically lower CO-to-$H_2$ conversion factor for spirals in HCGs.
- For elliptical and S0 galaxies, the large number of upper limits do not allow strong conclusions about their $M_{\text{HI}}$, or $L_{\text{FIR}}$. We note, however that, while the $L_\text{B}$ range for S0s is comparable to isolated S0 galaxies, Es in HCGs are up to half an order magnitude more luminous in $L_\text{B}$ than isolated Es are.
- Practically all of our galaxies lie in the range of $L_{\text{FIR}}/M_{\text{HI}} = 10 L_\odot/M_\odot$, which is typical of normal, quiescent galaxies. The deficiencies in $M_{\text{HI}}$, and $L_{\text{FIR}}$ are tightly correlated and cover about the same range as in isolated galaxies.
- The $M_{\text{HI}}$ deficiency, calculated from the VLA data for individual galaxies, is much greater than the other deficiencies with a mean value of $0.93 \pm 0.13$ (12% of the expected value) for spiral galaxies and $1.31 \pm 0.11$ (5% the expected value) for all morphological types, and it represents the largest difference with respect to isolated galaxies. These values are significantly higher than those obtained in Verdes-Montenegro et al. (2001) since the sample in that study was biased towards HI bright galaxies, while here we present a redshift-selected sample.
- The SFE of the spiral galaxies in the HCGs is slightly lower than in isolated galaxies, but in the range of values found for nearby spiral galaxies (Bigiel et al. 2011). We have found no relation of the SFE with either Def($M_{\text{HI}}$) or Def($M_{\text{HI}}$).
- There is a trend for the sSFR to increase with decreasing Def($M_{\text{HI}}$) and Def($M_{\text{HI}}$). This suggests that, although the Def($M_{\text{HI}}$) of a galaxy only has a weak influence on the absolute SFR, it has a stronger influence on the SFR per stellar mass.
There is a trend toward decreasing molecular gas deficiency with evolutionary phase, with galaxies in groups in an early phase showing an excess in $M_{H_2}$. This excess goes to 0 in later phases. A similar trend might exist with Def($M_{HI}$), but is statistically only marginally significant in our sample. This is interpreted as an initial enhancement of the conversion from atomic to molecular gas due to ongoing tidal interactions, later followed by stripping of most of their HI. In these later phases, evolution of spiral to lenticular galaxies would explain both the overabundance of those morphological types and the $M_{HI}$ deficiency and decrease in $M_{H_2}$ content of the galaxies.

No trend in the global HI deficiency of the groups is found, which suggests that the molecular gas content and SF are more driven by one-to-one interaction than directly by the local environment.
