ABSTRACT

We report the first extragalactic detection of chloronium (H\textsubscript{2}Cl\textsuperscript{+}) in the $z = 0.89$ absorber in front of the lensed blazar PKS 1830–211. The ion is detected through its $1_{11}-0_{00}$ line along two independent lines of sight toward the North-East and South-West images of the blazar. The relative abundance of H\textsubscript{2}Cl\textsuperscript{+} is significantly higher (by a factor $\sim 7$) in the NE line of sight, which has a lower H\textsubscript{2}/H\textsubscript{\alpha} fraction, indicating that H\textsubscript{2}Cl\textsuperscript{+} preferably traces the diffuse gas component. From the ratio of the H\textsubscript{35}\text{Cl}/H\textsubscript{37}\text{Cl} absorptions toward the SW image, we measure a $^{35}\text{Cl}/^{37}\text{Cl}$ isotopic ratio of 3.1$^{+0.3}_{-0.2}$ at $z = 0.89$, similar to that observed in the Galaxy and the solar system.

Key words. quasars: absorption lines – galaxies: ISM – galaxies: abundances – ISM: molecules – radio lines: galaxies – quasars: individual: PKS 1830–211

1. Introduction

A plethora of new interstellar molecules, notably simple hydrides, has been discovered as a result of the recent opening of the submillimeter window, from space with the Herschel Space Observatory, or from the ground, for example with the Atacama Pathfinder EXperiment (APEX) and Caltech Submillimeter Observatory (CSO) telescopes. Hydrides (that is, molecular species composed of a single heavy element with one or more hydrogen atoms) are formed by the first chemical reactions in the atomic gas component, and are therefore at the basis of interstellar chemistry. They are powerful probes of the interstellar environment and offer a variety of astrophysical diagnostics (e.g., Qin et al. 2010; Gerin et al. 2010; Godard et al. 2012; Flagey et al. 2013; Schilke et al. 2014).

One such hydride is chloronium, H\textsubscript{2}Cl\textsuperscript{+}, which was first detected by Lis et al. (2010) in foreground absorption toward the sources NGC 6334I and Sgr B2(S) with the Herschel Space Observatory. Neufeld et al. (2012) extended observations of H\textsubscript{2}Cl\textsuperscript{+} to six Galactic sources, four in absorption and two in emission (toward OMC 1: Orion Bar and Orion South). These constitute the only observations of chloronium in the literature to date. The other chlorine-bearing molecules detected in the interstellar medium are hydrogen chloride, HCl (Blake et al. 1985) and the chloroniumyl ion, HCl\textsuperscript{+} (de Luca et al. 2012), while metal halides such as NaCl, AlCl, and KCl were detected in the circumstellar envelope IRC+10216 (Cernicharo & Guélin 1987) and in the atmosphere of Io (Lellouch et al. 2003; Mouillet et al. 2010, 2013).

Here, we report the first extragalactic detection of chloronium, in the $z = 0.89$ absorber toward the $z = 2.5$ blazar PKS 1830–211, and a measurement of the $^{35}\text{Cl}/^{37}\text{Cl}$ isotopic ratio at a look-back time of more than half the present age of the Universe.

2. Data

The $1_{11}-0_{00}$ line of the para spin-species of both the H\textsubscript{35}\text{Cl}/H\textsubscript{37}\text{Cl} isotopologues, with rest frequencies of $\sim 485.4$ GHz and $\sim 484.2$ GHz, respectively, was detected in absorption at $z_{\text{abs}} = 0.89$ (i.e., redshifted to $\sim 257$ GHz) toward the blazar PKS 1830–211 with the Atacama Large Millimeter/submillimeter Array (ALMA). The observations and details of the data reduction are described by Muller et al. (2014, hereafter Paper I). We used ALMA Band 6 data from four observing runs performed between April and June 2012. The total resulting on-source integration time was approximately 30 min. The two lensed images of the background blazar, separated by 1", were resolved by the ALMA array, but each remained a point-like source. One absorption spectrum was extracted toward
3. Discussion

3.1. Column densities and abundances

Chloronium is a widespread species in the Galactic diffuse medium (Neufeld et al. 2012), and it is not surprising to detect it in the SW absorption toward PKS 1830–211. Indeed, the SW line of sight is particularly rich in molecules, with more than 40 species detected to date (Muller et al. 2011 and Paper I). What is surprising at first glance, however, is to detect chloronium absorption toward the NE image, with a SW/NE absorption depth ratio of only 3–4, while all other molecular species observed so far have a much deeper absorption toward the SW image, with SW/NE abundance ratios of a few tens (e.g., Muller et al. 2011). This is well illustrated in Fig. 1 by the comparison of the chloronium absorption toward both images with the absorption from species such as H$_2$O, CH, NH$_3$, and H$^{13}$CO$^+$. All spectra were observed by ALMA between April and June 2012 and are not affected by time variations (see Muller & Guélin 2008 and the discussion in Paper I). Note that the H$_2$O absorption is heavily saturated toward the SW image. Only the H I line (e.g., Koopmans & de Bruyn 2005) shows an absorption deeper (by a factor ~2) toward the NE image than toward the SW image.

The line profile of the H$_{35}^{32}$Cl$^+$ absorption toward the SW image is wider (FWHM = 32 ± 1 km s$^{-1}$) than that of the optically thin H$_{35}^{32}$CO$^+–1$ line (FWHM = 17.1 ± 0.3 km s$^{-1}$). In particular, the H$_{35}^{32}$Cl$^+$ absorption shows an additional weak feature at a velocity of ~30 km s$^{-1}$, where the H$_2$O and CH profiles have a prominent line wing, which most likely represents a diffuse gas component (see the discussion in Paper I).

We estimate an integrated opacity of ~1.5 km s$^{-1}$ along the SW line of sight for the H$_{35}^{32}$Cl$^+$$\rightarrow$1 para line. Assuming a rotation temperature locked to the temperature of the cosmic microwave background, $T_{CMB} = 5.14$ K at $z = 0.89$ (see Muller et al. 2013), a source-covering factor $f_c$ of unity, and an ortho/para ratio of 3 (Gerin et al. 2013), we derive a column density of ~1.4 $\times$ 10$^{13}$ cm$^{-2}$. In fact, the covering factor of the SW image is not unity, but ~95%, as shown by the saturation level of the 557 GHz water line (see Paper I). However, this does not introduce a noticeable difference in the apparent opacity of H$_2$Cl$^+$ since the line is optically thin and $f_c < 1$. With the same assumptions along the NE line of sight, we estimate an integrated opacity of ~0.4 km s$^{-1}$, corresponding to a H$_{35}^{32}$Cl$^+$ column density of 4 $\times$ 10$^{12}$ cm$^{-2}$. With total H$_2$ column densities of 2 $\times$ 10$^{22}$ and 1 $\times$ 10$^{21}$ cm$^{-2}$ along the SW and NE lines of sight, respectively (Muller et al. 2011 and Paper I), we finally derive fractional abundances of [H$_{35}^{32}$Cl$^+$]/[H$_2$] $\sim$ 6 $\times$ 10$^{-10}$ (SW) and $\sim$ 4 $\times$ 10$^{-9}$ (NE), that is, a H$_2$Cl$^+$ abundance relative to H$_2$ $\sim$ 7 higher along the NE line of sight. Note that the covering factor is not well known toward the NE image, but the ALMA data suggest $0.3 < f_c < 1.0$. Assuming $f_c < 1$ would increase the true opacity, column density, and relative abundance of H$_2$Cl$^+$, and give an even higher relative abundance ratio than for the SW line of sight.

The chemistry of interstellar chlorine is thought to be simple and well understood (see Neufeld & Wolfe 2009); but the observed abundances of the ions HCI$^+$ and H$_2$Cl$^+$ in the Galactic interstellar medium are rather higher than predicted in current models (Neufeld et al. 2012). In diffuse clouds, the chemistry starts from ionized chlorine (the first ionization potential of chlorine, 12.97 eV, is slightly lower than that of hydrogen), forming HCI$^+$ by reaction with H$_2$. A further reaction of HCl$^+$ with H$_2$ leads to H$_2$Cl$^+$. The molecule can in turn react with free electrons (dissociative recombination) to form HCI or Cl. In dense...

clouds, the chemistry is driven by cosmic-ray ionization and not by UV-photoionization, and neutral chlorine can react with the H$^+$ ion to form HCl$^+$, which again can react with H$_2$ to produce H$_2$Cl$^+$. The chemical rates and balance of the above reactions are not precisely known, but the relative abundance of H$_2$Cl$^+$ clearly depends on the ionization level of chlorine, that is, on the UV irradiation field and atomic hydrogen density (Neufeld & Wolfire 2009).

The significantly higher relative abundance of H$_2$Cl$^+$ in the NE line of sight, where the absorbing gas has a lower molecular fraction (H$_2$) than in the SW, confirms that the chloronium abundance is enhanced in the diffuse, more atomic, interstellar component (Neufeld et al. 2012).

3.2. $^{35}\text{Cl}/^{37}\text{Cl}$ isotopic ratio at $z = 0.89$

The clear detection of both H$_2^{35}$Cl$^+$ and H$_2^{37}$Cl$^+$ isotopologues toward the SW image allows us to measure their abundance ratio. The simple, well-known chlorine chemistry and the most likely weak fractionation between both isotopologues ensure that this ratio reflects the $^{35}\text{Cl}/^{37}\text{Cl}$ isotopic ratio. Note that both isotopologues were observed simultaneously and within the same 1.875 GHz-wide spectral window, which minimizes instrumental uncertainties. From a simultaneous fit of the SW spectrum with a single Gaussian component (centroid and width constrained to the same values for both isotopologues), we derive an isotopic ratio $^{35}\text{Cl}/^{37}\text{Cl}$ of 3.1$^{+0.3}_{-0.2}$, where uncertainties correspond to a 68% confidence level from a Monte Carlo analysis. If the ratio is the same toward the NE image, H$_2^{35}$Cl$^+$ should be just at the limit of detection. We estimate a lower limit of $^{35}\text{Cl}/^{37}\text{Cl}$ > 1.9 at a 99.7% confidence level. Slightly deeper observations should thus allow us to measure the $^{35}\text{Cl}/^{37}\text{Cl}$ ratio toward this component, which intercepts the absorber at a larger galactocentric radius (~4 kpc vs. ~2 kpc for the SW image).

The measurement of $^{35}\text{Cl}/^{37}\text{Cl}$ at $z = 0.89$ (SW) is within the range of values found in Galactic sources (see Table 1), and is, in particular, identical to the terrestrial ratio within the uncertainty. In contrast to $^{35}\text{Cl}/^{37}\text{Cl}$, the isotopic ratios of $^{18}\text{O}/^{16}\text{O}$, $^{30}\text{Si}/^{28}\text{Si}$, and $^{32}\text{S}/^{34}\text{S}$ in the same $z = 0.89$ absorber (SW line of sight) were found to deviate significantly by factors of 2–3 from their local Galactic values (see Muller et al. 2006, 2011, 2013). While little is known about the conditions of the $z = 0.89$ absorber (metallicity, elemental abundances, star formation activity), its look-back time is more than half the present age of the Universe. Consequently, we expect that the interstellar enrichment is more dominated by nucleosynthesis products from massive stars, especially concerning heavy elements such as silicon, sulfur, and chlorine, than a region with a similar galactocentric radius in the Milky Way.

The two stable isotopes of chlorine can be produced during hydrostatic oxygen burning from the α-elements $^{32}\text{S}$ and $^{36}\text{Ar}$ via $^{32}\text{S}(\alpha, p)^{35}\text{Cl}$ and $^{36}\text{Ar}(n, p)^{35}\text{Ar}(p)^{35}\text{Cl}$, respectively (e.g., Thielemann & Arnett 1985). $^{36}\text{Cl}$ can also be produced from $^{35}\text{Cl}$ by s-process. $^{36}\text{Cl}$ is unstable, but its half-lifetime is of about 3 × 10$^9$ yr, long enough to catch a second neutron to reach $^{37}\text{Cl}$ before decay. In the interstellar gas, spallation reactions from cosmic rays on argon can also lead to chlorine isotopes.

In Fig. 2, we compare the isotopic ratios measured at $z = 0.89$ toward PKS 1830–211(SW) with theoretical predictions of time/metallicity evolution models by Kobayashi et al. (2011) in the Milky Way. For the solar neighbourhood, three epochs/metallicities are considered by Kobayashi et al. (2011): at [Fe/H] = −2.6 (metal-poor type-II supernovae, SNe II), [Fe/H] = −1.1 (SNe II + AGB stars), and [Fe/H] = −0.5 (SNe II + AGB + SNe Ia). Predictions at [Fe/H] = −0.5 for the halo and bulge components are also reported in the figure. The interstellar $^{13}\text{C}/^{12}\text{C}$, $^{14}\text{N}/^{15}\text{N}$, and $^{16}\text{O}/^{18}\text{O}$ ratios are difficult to measure in general, mainly because of their relatively high values that result in either high opacity for lines of the most abundant isotopologues or sensitivity problems for lines of the rarest isotopologues. To alleviate these problems, we normalized the $^{14}\text{N}/^{15}\text{N}$ and $^{16}\text{O}/^{18}\text{O}$ ratios by $^{12}\text{C}^{16}\text{O}/^{14}\text{N}$, considering the double-ratio obtained from, for example H$^{13}$CN/H$^{15}$N or H$^{13}$CO$^{+}$/H$^{18}$O$^{+}$ (see Muller et al. 2011). Hence, all the ratios for the $z = 0.89$ absorber in Fig. 2 are measured through optical thin lines and are therefore reliable.

All the ratios measured at $z = 0.89$ (SW), including $^{35}\text{Cl}/^{37}\text{Cl}$, agree very well with the predictions by Kobayashi et al. (2011) for the solar neighbourhood at [Fe/H] = −2.6, except those of silicon and sulfur. This discrepancy should be viewed as an interesting constraint for chemical evolution models.

4. Summary and conclusions

The chloronium ion, H$_2$Cl$^+$, was detected in the $z = 0.89$ absorber toward the lensed blazar PKS 1830–211. The H$_2$Cl$^+$ relative abundance along the NE line of sight was found to be enhanced by a factor ~7 with respect to the SW line of sight. Since the NE line of sight is thought to be more diffuse, with a lower molecular gas fraction (H$_2$/H$_3$), this suggests that H$_2$Cl$^+$ is a good tracer of the diffuse gas component. Toward the SW image, at a look-back time of more than half the present age of the Universe, we measured a $^{35}\text{Cl}/^{37}\text{Cl}$ isotopic ratio of 3.1$^{+0.2}_{-0.3}$ identical to its value in the solar system within the uncertainty, and within the range of values found in Galactic sources. Slightly deeper observations are expected to allow us to measure the $^{35}\text{Cl}/^{37}\text{Cl}$ ratio in the NE line of sight, that is, at a larger galactocentric radius in the...
Fig. 2. Comparison of the isotopic ratios of C, N, O, S, Si, and Cl measured at $z = 0.89$ toward PKS 1830−211 (SW) (Muller et al. 2006, 2011, 2013 and this work) and in the solar system (solar symbols in green, Lodders 2003), and predictions from evolution models from Kobayashi et al. (2011) (black squares) for the solar neighbourhood (solar, at $[\text{Fe}/\text{H}] = -2.6$, −1.1, and −0.5), and halo and bulge at $[\text{Fe}/\text{H}] = -0.5$. The $^{14}\text{N}/^{15}\text{N}$ and $^{16}\text{O}/^{18}\text{O}$ ratios are normalized by the $^{12}\text{C}/^{13}\text{C}$ ratio, because of the difficulties of measuring all three separately in the $z = 0.89$ absorber toward PKS 1830−211.

The detection of $\text{H}_2\text{Cl}^+$ toward PKS 1830−211 suggests that other chlorine-bearing species might be easily detectable (e.g., with ALMA), in particular hydrogen chloride, HCl. Future observations of other hydrides, such as $\text{CH}^+$, $\text{OH}^+$, $\text{H}_2\text{O}^+$, H, or ArH$^+$, will provide more information on the conditions in this (so far unique) extragalactic molecular absorber.
