Abstract. We make use of two empirical relations between the black hole mass and the global properties (bulge luminosity and stellar velocity dispersion) of nearby elliptical galaxies, to infer the mass of the central black hole (M_{BH}) in low redshift radiogalaxies. Using the most recent determinations of black hole masses for inactive early type galaxies we show that the bulge luminosity and the central velocity dispersion are almost equally correlated (similar scatter) with the central black-hole mass. Applying these relations to two large and homogeneous datasets of radiogalaxies we find that they host black-holes whose mass ranges from $\sim 5 \times 10^7$ to $\sim 6 \times 10^9 M_{\odot}$ (average $\langle \text{Log} M_{\text{BH}} \rangle \sim 8.9$). M_{BH} is found to be proportional to the mass of the bulge (M_{bulge}). The distribution of the ratio $M_{\text{BH}}/M_{\text{bulge}}$ has a mean value of 8×10^{-4} and shows a scatter that is consistent with that expected from the associated errors. At variance with previous claims no significant correlation is instead found between M_{BH} (or M_{bulge}) and the radio power at 5 GHz.

Key words. black hole physics – galaxies: active – galaxies: nuclei – radio continuum: galaxies

1. Introduction

There is consensus about the existence of super massive black holes (SBHs) at the center of nearby inactive galaxies as well as in the nuclei of active galaxies and quasars (see e.g. for a recent review Ferrarese 2002). A large body of data, in particular based on high resolution HST observations, is now available (see e.g. Kormendy & Gebhardt 2001) to support the presence of such massive black holes (BH) using different techniques.

It is believed that SBHs play an important role in the formation and evolution of massive galaxies and also are a key component in the development of the nuclear activity. However in spite of this apparently ubiquitous presence of SBHs in galaxies, our understanding of how the galaxies and their central BHs are linked in the process of formation of the observed structures is still poor (see Silk & Rees 1998; Haehlnet & Kauffmann 2000; Adams et al. 2001).

The most important result obtained from the measured BH masses in nearby galaxies is the significant correlation between the black hole mass (M_{BH}) and the mass of the bulge component (M_{bulge}) of the host galaxy (M_{bulge}). From the observational point of view this correlation is translated into relationships between M_{BH} and bulge luminosity L_{bulge} (Magorrian et al. 1998; Kormendy & Gebhardt 2001) and between M_{BH} and the stellar velocity dispersion σ (Ferrarese & Merritt 2000; Gebhardt et al. 2000).

Although based on a small number (~ 30) of nearby galaxies for which direct dynamical measurements of M_{BH} have

been secured, and in spite of their scatter [~ 0.4 in $\text{Log}(M_{\text{BH}})$], these empirical relationships offer a new tool for evaluating M_{BH} in various types of AGN, provided that bulge luminosities and/or velocity dispersions are available (see also McLure & Dunlop 2002; Falomo et al. 2002).

In this paper we make use of such relationships to investigate the BH mass distribution of two large and homogeneous datasets of low redshift radiogalaxies (RG) for which we have previously studied the morphological, structural, photometrical and kinematical properties (Fasano et al. 1996; Govoni et al. 2000a, b; Bettoni et al. 2001). The derived BH masses of radiogalaxies are then used to investigate the connections between M_{BH} , the mass of the galaxy and the radio power.

To this aim we first describe our samples (Sect. 2) and revisit the relations $M_{\text{BH}}-L_{\text{bulge}}$ and $M_{\text{BH}}-\sigma$ for nearby early-type galaxies (Sect. 3). Then we use these relationships to evaluate M_{BH} of radio galaxies (Sect. 4) and to study the connections between M_{BH} and the mass of the bulge component of the host galaxy and between M_{BH} and the radio luminosity. A summary of the main conclusions of this study is reported in Sect. 5. In our analysis we assume $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$ and $\Omega_0 = 0$.

2. The samples

2.1. The sample of inactive nearby ellipticals

In order to investigate the relations $M_{\text{BH}}-L_{\text{bulge}}$ and $M_{\text{BH}}-\sigma$ of E-type galaxies we have considered a sample of 20 objects

of E-type morphology (excluding lenticulars) in the Kormendy & Gebhardt (2001) galaxy list with measured BH masses. The Milky Way was therefore not considered. In Table 1 we report the relevant data for this sample: Cols. 1 and 2 give the name and the morphological type from RC3; Col. 3 the distance, derived from Surface Brightness Fluctuations (SBF, Tonry et al. 2001); Cols. 4–7 report the adopted apparent total B magnitude corrected for extinction, the $B - R$ color, the galactic extinction, derived from the Bell Laboratories Survey of neutral hydrogen (Stark et al. 1992) and the absolute B magnitude respectively. The B -band bulge magnitudes were taken from Faber et al. (1997) for all the 20 objects but for NGC 5128, NGC 6251 and NGC 7052 we adopted the magnitudes given in RC3 (de Vaucouleurs et al. 1991). Note that for this sample the bulge magnitude is coincident with the total magnitude of the galaxy since the galaxy luminosity profile is always well represented by an $r^{1/4}$ law. The adopted values for the velocity dispersion (from Ferrarese & Merritt 2000), effective radius R_e (from Faber et al. 1989 and using the distance in Col. 3) and M_{BH} are reported in Cols. 8–10. The latter values are taken from Tremaine et al. (2002) that give the most recent revision of M_{BH} for this data set.

2.2. The radio-galaxies sample

We have considered the following two samples of radio galaxies:

- *Sample A*: this consists of 72 radio-galaxies at $z < 0.2$ with available values of the absolute magnitude M_R , the

effective radius R_e and the velocity dispersion σ . We used these data in a previous work (Bettoni et al. 2001) to study the Fundamental Plane of RGs. In this sample 22 objects were observed by us, 22 galaxies were taken from Smith et al. (1990, SHI90), 16 from Ledlow & Owen (1995), 7 from Gonzalez-Serrano & Carballo (2000) and 5 from Faber et al. (1989, FA89). In Table 2 we report the relevant data for the radio-galaxies in this sample: in Cols. 1, 2 we give the name and the redshift; in Col. 3 we list the absolute R (Cousins) magnitude to which we have also applied a correction to set the host galaxy luminosity to the present epoch assuming a passive stellar evolution for massive ellipticals (Bressan et al. 1994). Columns 4–7 report the Log(σ), the total and core radio luminosity at 4800 MHz and the reference for these radio data. The velocity dispersion is normalized to a circular aperture of metric radius $1.19h^{-1}$ kpc (Jørgensen et al. 1996). This normalization is practically equivalent to that adopted by Ferrarese & Merritt (2000), who consider σ within an aperture radius of $r_e/8$. The average difference between the two normalizations for our objects is ≤ 5 km s⁻¹.

- *Sample B*: this consists of 79 radiogalaxies at $z < 0.1$ for which we secured homogeneous photometric and structural parameters (Fasano et al. 1996; Govoni et al. 2000a, b). These radio galaxies are extracted from two complete surveys of radio sources (Wall & Peacock 1985: WP, Ekers et al. 1989: EK) according to the specifications given in Fasano et al. (1996), sample B has 22 objects in common

Fig. 1. **a)** The M_{BH} vs. M_{bulge} relation for the 20 nearby inactive ellipticals (see Table 1). **b)** Same as **a)** but for the M_{BH} vs. $\text{Log}(\sigma)$ relation. The solid lines refer to our linear best fits. The dashed lines represent the relation of McLure & Dunlop (2002) scaled to our cosmology (panel **a**) and that of Ferrarese & Merritt (2000) (panel **b**).

with sample A. In Table 3 we report the relevant data for this sample. In Cols. 1, 2 we give the name and the redshift; in Cols. 3–6 we list the absolute R magnitude, the total and core radio luminosity at 4800 MHz and the reference for the radio data.

3. The $M_{\text{BH}}-M_{\text{R}}(\text{host})$ and $M_{\text{BH}}-\text{Log}(\sigma)$ relations for normal, nearby ellipticals

Using the dataset of nearby inactive ellipticals described in Sect. 2.1 we have derived the best fit of the relations $\text{Log}(M_{\text{BH}})-M_{\text{R}}(\text{host})$ and $\text{Log}(M_{\text{BH}})-\text{Log}(\sigma)$. In order to obtain a relationship between M_{BH} and M_{R} usable for $H_0 = 50$ we need to apply a color correction (to convert the B magnitude into the R band) and a term that takes into account the consistency between the adopted distances of nearby galaxies (see Table 1) and the chosen value of H_0 . The latter term can be written as $5\text{Log}(H'_0/H_0)$, where $H'_0 = 74 \text{ km s}^{-1} \text{ Mpc}^{-1}$ (Tonry et al. 2001). The color correction was derived from LEDA (Prugniel & Maubon 2000) with the exception of NGC 4291 and of the three galaxies for which the B magnitude has been obtained from RC3. For these objects a standard color ($B - R = 1.60$) was assumed (Fukugita et al. 1995).

The data used to fit the two relations $M_{\text{BH}}-M_{\text{R}}(\text{host})$ and $M_{\text{BH}} - \text{Log}(\sigma)$ are shown in Fig. 1. The best fit to the data was derived following the procedure outlined in Fasano & Vio (1988), which takes into account the individual measurement errors in both coordinates and allows us to estimate the residual scatter s_r .

The two fitted relations are:

$$\text{Log}(M_{\text{BH}}/M_{\odot}) = -0.50(\pm 0.06) \times M_{\text{R}} - 3.00(\pm 1.35) \quad (1)$$

rms = 0.39

$$\text{Log}(M_{\text{BH}}/M_{\odot}) = 4.55(\pm 0.49) \times \text{Log}(\sigma) - 2.27(\pm 1.13) \quad (2)$$

rms = 0.41

where $M_{\text{R}} = M_B - (B - R) - 5\text{Log}(H'_0/H_0)$. The residual scatters

of the two relations are $0.14(\pm 0.05)$ and $0.35(\pm 0.22)$, respectively. In both cases they turn out to be consistent with zero (within 3σ), implying that the observed scatter is almost entirely accounted for by the uncertainty of the measurements. Both relations are in good agreement with the last determinations by McLure & Dunlop (2002) and Ferrarese (2002), respectively, once the different cosmology is taken into account. However, at variance with previous findings (Ferrarese & Merritt 2000; Kormendy & Gebhardt 2001), luminosity and central velocity dispersion appear to be almost equally correlated (very similar scatter) with the black-hole mass. A similar result was found by McLure & Dunlop (2002) using a slightly different sample of E-type objects. We note, however, that our scatter (0.39 dex) is larger than that (0.31 dex) found by McLure & Dunlop (2002). Since the data used by these authors are not published it is not possible to further investigate the origin of this difference.

4. Results

4.1. The BH mass of radio galaxies

Here we use the relationships $\text{Log}M_{\text{BH}} - M_{\text{R}}(\text{bulge})$ and $\text{Log}M_{\text{BH}} - \text{Log}(\sigma)$, derived in Sect. 3, (Eq. (1) and Eq. (2)) to estimate the BH mass of the two samples (A and B) of radio galaxies defined in Sect. 2.2. The BH masses derived from σ and from the M_{R} are reported in Cols. 8 and 9 of Table 2. The comparison of the two M_{BH} determinations for the sample A is shown in Fig. 2. We find that the mean values of $\text{Log}(M_{\text{BH}})$ (8.66 ± 0.44 from Eq. (1) and 8.91 ± 0.37 from Eq. (2)) are significantly different. This is mainly attributable to the systematically lower values of σ for the 26 radio galaxies in the sub-samples of SHI90 and FA89 (see Fig. 2). To further emphasize this point we plot in Fig 3 the values of σ versus M_{R} (Faber-Jackson relation) for the RGs in sample A and for normal ellipticals from the Jørgensen et al. (1996, JFK96) sample.

It is clearly apparent that RGs belonging to the SHI90 and FA89 samples deviate systematically from the overall relation derived from fitting the data for the RGs in sample A (excluding the SHI90 and FA89 galaxies) and for normal ellipticals from JFK96 ($\text{Log}\sigma = -0.375 - 0.118 \times M_R$). Note also that the galaxies in these datasets do not well agree with the other RGs of sample A in the Fundamental Plane (Bettoni et al. 2001). Therefore, in the following analysis, we exclude the measurements of these 26 RGs. If we now consider the remaining 45 RGs in sample A (hereafter reduced sample A) we obtain: $\langle \text{Log}(M_{\text{BH}}) \rangle_{\sigma} = 8.81 \pm 0.41$ and $\langle \text{Log}M_{\text{BH}} \rangle_{M_R} = 8.91 \pm 0.40$. For sample B M_{BH} was derived only from M_R

(Eq. (1)). These values are given in Table 3. The mean value of $M_{\text{BH}} < \text{Log}M_{\text{BH}} \rangle_{M_R} = 8.94 \pm 0.34$ is in good agreement with those obtained for the reduced sample A. In Fig. 4 the distributions of M_{BH} for both samples are compared.

4.2. The $M_{\text{BH}} - M_{\text{bulge}}$ relation

McLure & Dunlop (2002) and Laor (2001) investigated the relation $M_{\text{BH}} \propto M_{\text{bulge}}^{\eta}$ for Seyfert galaxies and powerful QSO in order to test its linearity (which means $\eta = 1$). In both papers the above relation is derived from L_{bulge} under the assumption of a mass-to-light ratio having the form $M/L \propto L^{\Gamma}$ but

Table 2. continued.

^a KK – Küehr et al. (1981); G1 – Griffith et al. (1995); G2 – Griffith et al. (1994); BB – Becker et al. (1991).

they reached different conclusions. Laor (2001) claimed that the relation $M_{\text{BH}} - M_{\text{bulge}}$ is not linear, while this was not confirmed by McLure & Dunlop (2002). However, the latter authors showed also that the Laor data may be consistent with linearity if one adopts $\Gamma = 0.31$ (Jørgensen et al. 1996) instead of $\Gamma = 0.18$ (used by Laor).

Here we investigate the $M_{\text{BH}} \propto M_{\text{bulge}}^{\eta}$ relation for our samples of RGs. We have computed the two involved quantities (M_{BH} and M_{bulge}) from σ , M_R and the effective radius of the galaxy (R_e) avoiding possible spurious effects introduced in the analysis by the use of the same variable to derive the two masses. We first derive M_{BH} from M_R (Eq. (1)) and M_{bulge}

from R_e and σ using the formula $M_{\text{bulge}} = 5G^{-1}\sigma^2 R_e$, proposed by Bender et al. (1992). These two determinations are reported in Cols. 9 and 10 of Table 2. Figure 5 shows the linear fit to the $M_{\text{BH}} - M_{\text{bulge}}$ relation for objects in the reduced sample A and for normal ellipticals (JFK96), together with the data relative to the sample of inactive galaxies for comparison. We find:

$$\text{Log}(M_{\text{BH}}) = 0.96(\pm 0.03) \times \text{Log}(M_{\text{bulge}}) - 2.56(\pm 0.34). \quad (3)$$

This relation has $\text{rms} = 0.14$, while the residual scatter (i.e. the scatter not accounted for by the errors) is $s_r = 0.03 \pm 0.012$, which is consistent with zero. The slope ($\eta = 0.96$) is

practically coincident with an almost perfect linearity ($\eta = 1$; see the dotted line in Fig. 5). This suggests that a fundamental link is present in the combined formation of BHs and spheroids that holds for various types of active and inactive galaxies. We also note that, given the coefficients of the fundamental plane (FP), the linearity of the $M_{\text{BH}}-M_{\text{bulge}}$ relation turns out to be directly linked to the particular value of the slope (A) of the relation ($\text{Log} M_{\text{BH}} = A \times M_R + B$). In fact the exponent η of the $M_{\text{BH}} - M_{\text{bulge}}$ relation can be written in the form: $\eta = -A\alpha/2\beta$, where α and β are the coefficients of the FP. Using $\alpha = 1.242$, $\beta = 0.33$ (Bettoni et al. 2001) and $A = -0.5$ it follows that,

$\eta = 0.94$. Vice versa, if perfect linearity is assumed using the same α, β one obtains $A = -0.53$.

The distribution of the black-hole to bulge mass ratio is shown in Fig. 6 (panel a). The average value of the mass ratio is $\langle \text{Log}(M_{\text{BH}}/M_{\text{bulge}}) \rangle = -3.11$, with rms ~ 0.17 . The dispersion expected from just the uncertainties on the measurements (~ 0.26) is consistent with that observed, suggesting that the intrinsic variance of the ratio $M_{\text{BH}}/M_{\text{bulge}}$ is very small.

Alternatively we can derive the $M_{\text{BH}}/M_{\text{bulge}}$ ratio using M_{BH} derived from σ and assuming $M_{\text{bulge}} = 0.0021L^{1.30}$ (the coefficients are derived by fitting the $M-L$ relation, in the

R band, for our RG data together with the ellipticals in JFK96). In this case we obtain $\langle \text{Log}(M_{BH}/M_{bulge}) \rangle = -3.16$ with a dispersion of 0.43 (Fig. 6b). These are in good agreement with those derived for the inactive galaxy sample: -3.07 (rms = 0.19) and -3.05 (rms = 0.50) for the two procedures respectively. They are also similar to previous determinations by Merritt & Ferrarese (2001) who found -2.90 ± 0.45 using the Magorrian et al. (1998) galaxy sample and the $M_{BH}-\sigma$ relation, and by McLure & Dunlop (2002) who report -2.87 ± 0.47 from their study of the host galaxies of powerful quasars and use virial black-hole masses.

4.3. Relationship between M_{BH} and radio emission

Based on a small number of nearby galaxies with known BH masses it was suggested by Franceschini et al. (1998) that M_{BH} scales with the total radio luminosity L_{radio} at 5 GHz ($L_{radio} \sim M_{BH}^{2.5}$). This is what would be expected by Accretion-Dominated Accretion Flows (ADAF, see Abramowicz et al. 1995; Narayan & Yi 1996) models. This correlation appears to hold over at least 3 order of magnitudes for M_{BH} and, given its steepness, it was proposed as a tool to predict M_{BH} from the simple observation of the radio flux. Additional support for a

Fig. 2. The BH mass determinations obtained from $M_{\text{BH}} - M_{\text{R}}$ and $M_{\text{BH}} - \text{Log}(\sigma)$ for the sample A of RG. A good agreement is found for the reduced sample A (filled circles), while the objects from SHI90 and FA89 (big open circles) exhibit a systematic deviation. For comparison we also plot M_{BH} for the sample of 20 normal galaxies (asterisks). The solid line illustrates the best fit obtained for the reduced sample A: $\text{Log}[M_{\text{BH}}(\sigma)] = 0.28 + 0.94 \times \text{Log}[M_{\text{BH}}(M_{\text{R}})]$. The dotted line is the one-to-one relation.

Fig. 3. Faber-Jackson relation for RGs in sample A and normal ellipticals. RGs from SHI90 and FA89 (open circles) have systematically lower σ than the other RGs in the sample (filled circles). For comparison we also plot the 20 inactive Es (asterisks) and data for early-type galaxies from JFK96 (crosses). The solid line is our fit $\text{Log} \sigma = -0.375 - 0.118 \times M_{\text{R}}$ to the data of reduced sample A and normal ellipticals in the JFK96 samples.

Fig. 4. a) The distribution of M_{BH} for 46 low z RGs derived from measurements of σ (Eq. (2), reduced sample A); b) The distribution of M_{BH} for 46 low z RGs derived from measurements of the bulge luminosity (Eq. (1), reduced sample A); c) The distribution of M_{BH} for 79 radiogalaxies derived from the bulge luminosity (Eq. (1), sample B).

link between L_{radio} and M_{BH} in various type of active galaxies was lead by Laor (2001) and Lacy et al. (2001).

However, a recent analysis by Ho (2002) of this relationship, for objects with a wide range of nuclear activity, argued that M_{BH} is only loosely related to the radio power (both total and core emission). The poor correlation observed between the two quantities could therefore arise from indirect relations between radio luminosity, bulge mass and M_{BH} and has no practical power to predict M_{BH} from the radio luminosity.

We have investigated this issue using our samples of radiogalaxies for which radio power (P_{tot}) at 5 GHz and M_{BH} are available (Table 2). In Fig. 7 we show the data for our radio galaxies in the plane $M_{\text{BH}} - \text{Log} P_{5\text{GHz}}(\text{total})$. The two quantities are not correlated: Spearman correlation coefficient -0.174 , with significance of nonzero correlation 0.038. The same result is found using the core radio power. Similarly, no significant correlation is found between the host galaxy mass M_{bulge} and the radio power, in agreement with the fact that M_{BH} is tightly related to M_{bulge} .

Fig. 5. The relation between M_{BH} and M_{bulge} for RGs in the reduced sample A (filled circles), for the nearby inactive galaxies with BH mass determination (asterisks) and for JFK96 normal ellipticals (crosses). The solid line illustrates the fit obtained for galaxies in the reduced sample A and in JFK96 sample (see Eq. (3)). The dotted line represents the case of perfect linearity ($\eta = 1$) with $\langle \text{Log}(M_{\text{BH}}/M_{\text{bulge}}) \rangle = -3.11$.

Fig. 6. The distribution of the ratio $M_{\text{BH}}/M_{\text{bulge}}$ for the reduced sample A of radiogalaxies: (a) M_{BH} from Eq. (1) and M_{bulge} from σ and R_e ; (b) M_{BH} from Eq. (2) and M_{bulge} from L_{bulge} assuming $M/L \propto L^{0.30}$. The solid lines represent Gaussian distributions with the same average values and rms of the corresponding dataset (see text).

In Fig. 8 we compare the distribution of our RGs over the plane M_{BH} – radio power with that of other samples of galaxies at various levels of nuclear activity investigated by Ho (2002) and Oshlack et al. (2002). Note that the latter data refer to flat spectrum radio-sources whose flux is likely enhanced by

Fig. 7. M_{BH} – $\text{Log}P_{\text{tot}}(5 \text{ GHz})$ plane for RGs in sample A (filled circles, reduced sample A, open circles data from SHI90 and FA89) and sample B (filled squares). M_{BH} is derived from σ (see data in Tables 2 and 3). The two quantities are clearly not correlated.

Doppler boosting (beamed sources). Their observed luminosity therefore tends to occupy the higher region of the $P_{\text{tot}} - M_{\text{BH}}$ plane (see also Jarvis & McLure 2002). Our data for RG are in agreement with the analysis by Ho (2002) and enforce his conclusion that radio power is poorly correlated with the mass of the central BH and therefore that the latter cannot practically be predicted by the measurement of the radio flux. If instead of the total radio luminosity we use the radio power of the core this picture remains basically unchanged. Together, the points in Fig. 8 appear to follow the trend of increasing M_{BH} with higher radio luminosity. This behavior is consistent with the suggestion by Dunlop et al. (2002) that both active and inactive galaxies fall between two envelopes (following the $P_{\text{tot}} \propto M_{\text{BH}}^{2.5}$ law) in the $M_{\text{BH}} - P_{\text{tot}}$ plane. On the other hand the scatter of the points is rather large and do not produce a significant correlation of the two quantities. Our objects cover the top-right part of the diagram where more massive BH and powerful radio sources are expected. Most of our points and those of Ho (2002) lie above the relation proposed by Franceschini et al. (1998) by 2–3 order of magnitude. At low accretion rates ADAF models foresee that radio power depends on M_{BH} as $P_r \propto M_{\text{BH}}^{2.5}$. The location of points well above such relation may simply reflect the much higher level of activity (and likely of accretion).

5. Summary and conclusions

We used empirical relations between M_{BH} and either the velocity dispersion (σ) or the bulge luminosity $M_R(\text{bulge})$ derived for nearby early type galaxies to infer the mass of the central BH of low redshift radio galaxies.

The main conclusions of this study are:

1) Using only nearby galaxies of E-type morphology, for which BH masses are available, the two relationships $M_{\text{BH}} - \sigma$

Fig. 8. $M_{\text{BH}} - \text{Log}P(\text{total})$ relation for the samples A (filled circles, reduced sample A, open circles data from SHI90 and FA89) and B (filled squares) of radiogalaxies, compared with the objects (open squares and triangles) studied by Ho (2002) and with radio loud quasars (crosses) investigated by Oshlack et al. (2002). The dashed line is the Franceschini et al. (1996) relation ($P_{\text{tot}} \propto M_{\text{BH}}^{2.5}$).

and $M_{\text{BH}} - M_{\text{bulge}}$ exhibit a similar scatter (~ 0.4 in $\text{Log}M_{\text{BH}}$) which is also consistent with that expected from the estimated errors on the involved parameters.

2) We showed that when the dependence on the adopted cosmology (for the $M_{\text{BH}} - M_{\text{bulge}}$ relation) is properly taken into account, the two relations predict the same value of the central BH mass (within the expected uncertainties). This means that the BH mass can be reliably estimated from the observable parameter $M_{\text{R}}(\text{bulge})$ which is more easily measured than σ .

3) The inferred BH mass of low redshift radio galaxies is in the range 5×10^7 to $5 \times 10^9 M_{\odot}$.

4) We found that the central BH mass is linearly correlated with that of its host galaxy; the average Black Hole to bulge mass ratio is $\langle \text{Log}[M_{\text{BH}}/M_{\text{bulge}}] \rangle \sim -3.1$.

5) The total (or core) radio power at 5 GHz is not correlated either with the mass of the central BH nor with that of the galaxy; the radio power is always in excess by 2–3 order of magnitude with respect to what would be expected from low accretion rate models (ADAF).
