Received 5 December 2000 / Accepted 24 January 2001

Abstract. An *XMM-Newton* observation of the plerionic supernova remnant 3C 58 has allowed us to study the X-ray nebula with unprecedented detail. A spatially resolved spectral analysis with a resolution of $8''$ has yielded a precise determination of the relation between the spectral index and the distance from the center. We do not see any evidence for bright thermal emission from the central core. In contrast with previous *ASCA* and *Einstein* results, we derive an upper limit to the black-body 0.5–10 keV luminosity and emitting area of $1.8 \cdot 10^{32}$ erg s^{-1} and $1.3 \cdot 10^{10}$ cm², respectively, ruling out emission from the hot surface of the putative neutron star and also excluding the “outer-gap” model for hot polar caps. We have performed for the first time a spectral analysis of the outer regions of the X-ray nebula, where most of the emission is still non-thermal, but where the addition of a soft ($kT = 0.2$ – 0.3 keV) optically thin plasma component is required to fit the spectrum at $E < 1$ keV. This component provides 6% of the whole remnant observed flux in the 0.5–10.0 keV band. We show that a Sedov interpretation is incompatible with the SN 1181–3C 58 association, unless there is a strong deviation from electron-ion energy equipartition, and that an origin of this thermal emission in terms of the expansion of the nebula into the ejecta core nicely fits all the radio and X-ray observations.

Key words. stars: neutron; supernovae: general; ISM: individual object: 3C 58; ISM: supernova remnants; X-rays: ISM

1. Introduction

3C 58 is a beautiful example of a filled-center (or plerionic) supernova remnant (SNR), probably associated with the historical supernova event in 1181 A.D. (Stephenson 1971). This object has always received much attention because, on the one hand, it shows some characteristics similar to the Crab SNR, while, on the other hand, it seems very different to the Crab itself. For instance, 3C 58 has a compact ($10' \times 6'$) elliptical morphology with a very bright core (Reynolds & Aller 1988) and linear size similar to the Crab; Frail & Moffett (1993) have reported a wisp-like elongated structure at $2.6''$ from the core, which has been observed also in the Crab and which

is probably associated with the pulsar wind termination shock. However, unlike the Crab, there is no clear evidence of a pulsating point source located in the center, as would be expected, since the morphology strongly suggest that the nebula is powered by a spinning neutron star. Despite considerable effort, pulsations have not been detected so far in either radio (see e.g. Lorimer et al. 1998), nor in X-rays (Helfand et al. 1995, H95 hereafter). Moreover, the X-ray to radio flux ratio (f_X/f_r) of 3C 58 is 100 times lower than that of the Crab (H95), its spectral break occurs at 50 GHz (300 times less than the break of the Crab, Green & Scheuer 1992) and its radio luminosity is increasing instead of decreasing as expected (Green 1987). These remarkable differences are also seen in other plerions, and Woltjer et al. (1997) have proposed the introduction of a new sub-class of plerions, the “non Crab-like plerions”, of which 3C 58 can be considered the prototype. For these objects, a non-standard evolution of the pulsar can be invoked, but the details are not yet clear.

* Based on observations obtained with *XMM-Newton*, an ESA science mission with instruments and contributions directly funded by ESA Member States and the USA (NASA).

It is therefore very important to investigate the physical properties which render 3C 58 so peculiar, in order to put this object and its sub-class in the right perspective. In particular, the detection or non-detection of the central source is obviously a key point. Becker et al. (1982) reported the presence of a compact X-ray source in 3C 58 from their Einstein HRI observation, about $10''$ in extent, and contributing to 15% of the detected X-ray flux. Later, Helfand et al. (1995) revisited the X-ray emission of 3C 58 using ROSAT HRI data, confirming the compact source and favored a model in terms of hot polar caps to explain the emission. However, it has not been possible so far to take an X-ray spectrum of the source to study it, and to understand if it is really a point source or an enhancement of the pulsar nebula. Torii et al. (2000) have pointed out that the inclusion of a black-body component in the fit of the ASCA GIS+SIS data of 3C 58 yields an improvement of the χ^2 . They claim that the best-fit black-body component is responsible for $\sim 7\%$ of the unabsorbed flux in the 0.5–10 keV of the whole remnant, and that it is the spectral signature of the central source.

It is also very important to assess the presence of a shell around the pulsar nebula, for it may give compelling constraints on the age of the remnant, the shock velocity and the density of the environment. In the case of the ~ 800 yr old 3C 58 (as other plerions as well), it is expected that the main shock will encounter the stellar ejecta and/or the interstellar medium (ISM) giving rise to a limb brightened shell. However, no sign of a shell has been detected at centimeter wavelengths at distances greater than $5'$ from the core (Reynolds & Aller 1985). However, Reynolds & Aller (1988) have imaged the faint outer emission of the nebula at a distance between $2'$ and $4'$ and have noticed limb brightening at several locations. In this paper, we present a study of the *XMM-Newton* data of 3C 58 obtained during the Calibration and Performance Verification (Cal/PV) phase of the mission. We show that a stringent upper-limit can be imposed on the presence of thermal emission from a central point source, and we also find evidence for a thermal outer shell. The implications of these findings for current models of 3C 58 are also discussed.

2. Data analysis

2.1. Observations

3C 58 has been observed as part of the Cal/PV phase of the *XMM-Newton* satellite (Jansen et al. 2000). In this paper, we focus on the 25 ks on-axis observation performed during orbit 47, on March 12th 2000. Data from the two MOS (Turner et al. 2000) cameras and the PN (Strueder et al. 2000) camera have been used. MOS and PN cameras are CCD arrays which collect X-ray photons between 0.1 and 15 keV and have a field of view of $30'$. The pixel size is $1.1''$ and $4.1''$ for MOS and PN respectively, and this should be compared with the mirror PSF width of $6''$ – $15''$ FWHM-HEW. The data have been acquired

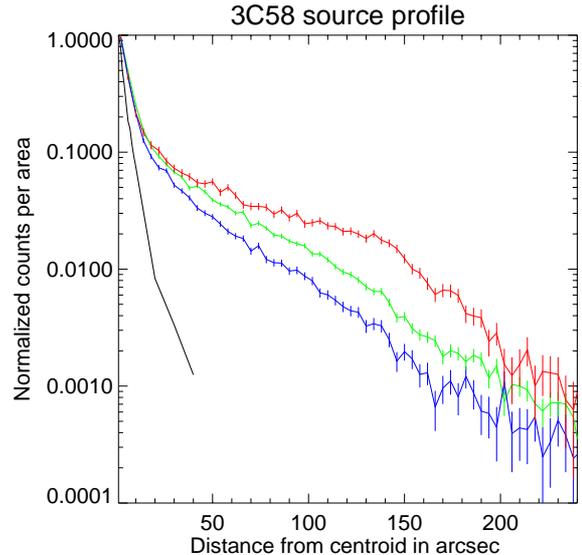

Fig. 1. MOS1+2 source profile, centered at $2^{\text{h}}05^{\text{m}}38.0^{\text{s}} + 64^{\text{d}}49^{\text{m}}37^{\text{s}}$ (J2000). Soft, medium and hard energy band as defined in Fig. 2 are represented as tick marked top, medium and bottom curves, respectively. The solid black line is the Point Spread Function (PSF) of the mirror module 3 at 1.5 keV (Aschenbach et al. 2000)

with the medium filter and in full image mode, and therefore the temporal resolution is low, 2.5 s and 73 ms for MOS and PN, respectively. The worse spatial resolution of the PN is compensated by its greater sensitivity, on the average 20–30% more than the combined two MOS.

The Standard Analysis System (SAS) software we have used (version 5.0 alpha, xmmcas-20001011-1559) takes care of most of the required events screening. However, we have further screened the data to eliminate some residual hot pixels and occasional background enhancement due to intense flux of soft protons in the magnetosphere. In particular, we have extracted the background light-curve from a region free of sources, and we have identified time intervals of unusually high count rates (more than twice the “quiescent” background rate) and removed them from subsequent analysis. Moreover we have also selected events with value of the PATTERN pipeline assigned keywords between 0 and 12. The exposure time of the screened observations is 16 ks for the MOS and 12 ks for the PN detectors.

2.2. X-ray morphology

In Fig. 1, we report the 3C 58 profile as seen by the MOS1+2 computed in 65 annuli with $\Delta r = 4''$ up to a distance of $\sim 4'$ from the centroid, located at $2^{\text{h}}05^{\text{m}}38.0^{\text{s}} + 64^{\text{d}}49^{\text{m}}37^{\text{s}}$ (J2000, $\pm 1''$). The background was collected from a ring with $\Delta r = 30''$ located at $4.5'$ from the center, and has been chosen to fall entirely in the central MOS chip. The comparison with the expected mirror PSF, also shown in Fig. 1 indicates that the central source is extended. The bright core region can be defined up to $\sim 50''$

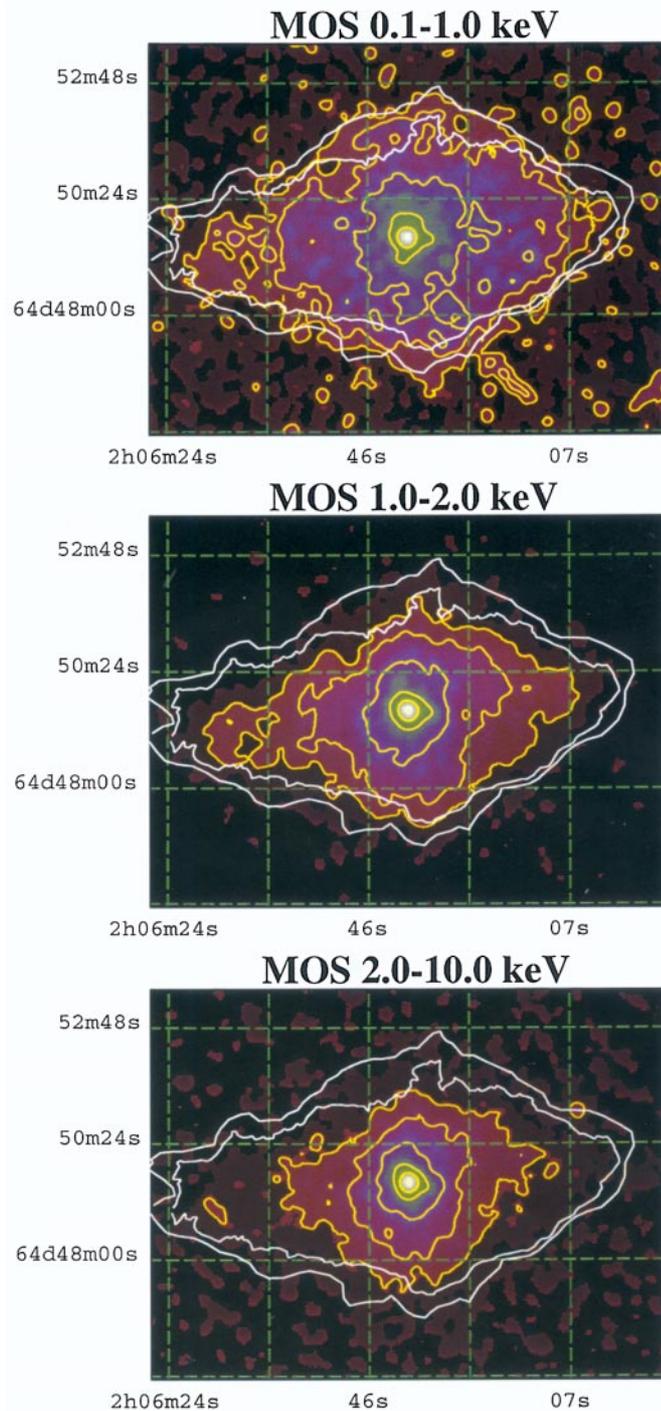

Fig. 2. MOS1+2 images binned at pixels of $2''$ and smoothed using a Gaussian with $\sigma = 3$ pixel to enhance the morphology of the faint nebula edge. *Upper panel:* soft image (0.1–1.0 keV). *Center panel:* medium energy image (1.0–2.0 keV). *Lower panel:* hard image (2.0–10.0 keV). Overlaid are contours representing the weakest ($3\sigma = 0.15$ Jy beam $^{-1}$) 1446 MHz radio contour and the one corresponding to a flux density 4 times higher (both in white, from Reynolds & Aller 1988), and six X-ray contours (in yellow, from 1/100 of the peak to the peak value, logarithmically spaced)

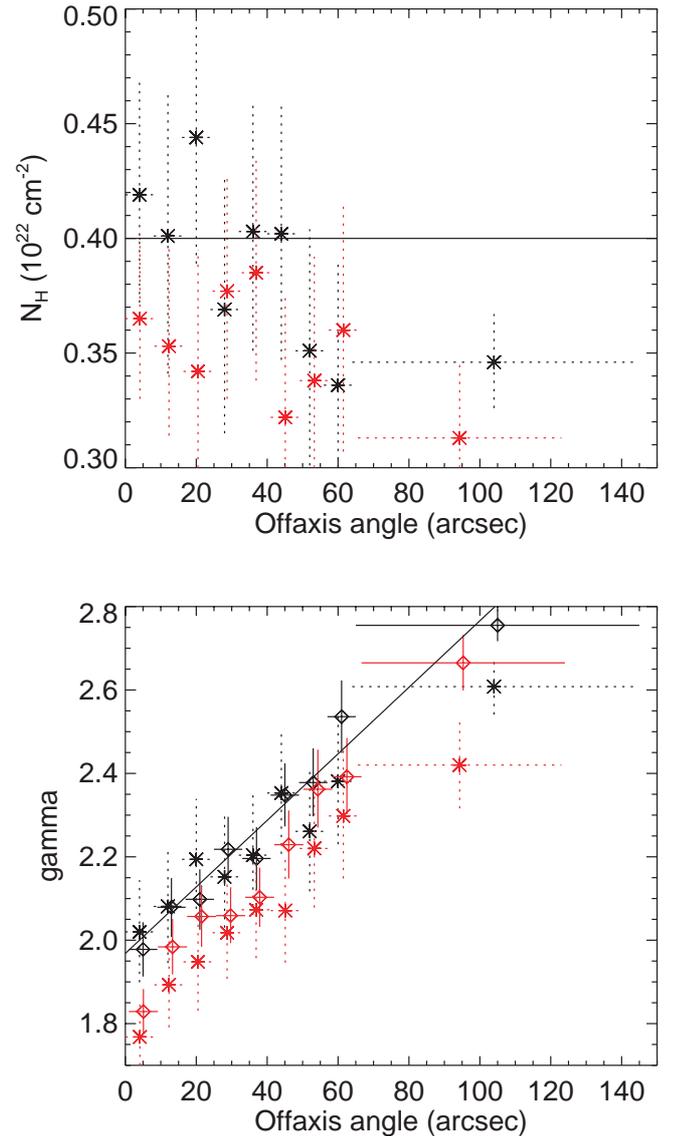

Fig. 3. Spatially resolved spectral analysis with a power-law model of the X-ray nebula associated with 3C 58. We show the results obtained on the 8 annuli and the “edge” regions (the last point) as defined in the text. Black is MOS, red is PN, dotted bars are fit with free N_{H} , solid bars are fit with N_{H} fixed at 4×10^{21} cm $^{-2}$. Regions are centered at $2^{\text{h}}05^{\text{m}}38.0^{\text{s}} + 64^{\text{d}}49^{\text{m}}37^{\text{s}}$ (J2000). A linear fit to the MOS points corresponding to fits with N_{H} fixed at 4×10^{21} cm $^{-2}$ is shown in the lower panel

from the center; Further out, the slope changes and the behavior of the soft curve and hard curve is different. The hard curve declines with the same slope down to the limit of the radio nebula at $\sim 200''$, while the soft curve is clearly flatter than the hard one, with a sudden change of slope occurring at $140''$.

The core is elongated in the N-S direction, with a FWHM of $13.5 \pm 1.5''$ in this direction ($9.0 \pm 1.5''$ in the E-W direction), in agreement with the ROSAT HRI results presented by H95. The centroid of the MOS1 emission is located $4''$ and $8''$ south of the ROSAT and Einstein positions. The data confirm that the radio wisp observed by Frail & Moffett (1993) is located to the East of the

X-ray peak, at $5''$ from the the MOS1 centroid. However, the uncertainties in real attitude reconstruction, which is still not fully implemented, may give an uncertainty in absolute position determination as large as $\sim 5''$.

Figure 2 shows the summed MOS1+2 images of 3C 58 in three different bands, namely 0.1–1 keV, 1–2 keV and 2–10 keV bands, along with the weakest 1446 MHz radio contour at $0.15 \text{ Jy beam}^{-1}$ and the contour at 0.6 Jy beam^{-1} of Fig. 3 in Reynolds & Aller (1988) (both in white in Fig. 2). A small separation of the two contours (e.g. in the SW) indicates limb brightening and therefore confinement in the source. In addition, we also shown the X-ray contours (in yellow), and it is clear that there is correspondence between the radio contours and the X-ray emission of the soft image. In particular, the weakest radio contour matches the outer edge of the weak extended X-ray emission, especially at the north and south edges. Figure 2 also shows that the size of the nebula decreases as the energy increases, an effect also reported by Torii et al. (2000).

2.3. Spectral analysis

The high spatial and spectral resolution of the instrumentation aboard the *XMM-Newton* satellite allows us for the first time to perform spatially resolved spectral analysis of the X-ray nebula associated to 3C 58. To this end, we extracted spectra from 8 concentric annuli with $\Delta r = 8''$ centered at the same position of the X-ray profiles of Fig. 1, covering the core emission up to $1.1'$ from the center. Given the uncertainties in present calibration of the MOS and PN cameras, and the energy dependence of the vignetting correction above 5 keV, we have restricted our spectral analysis to photons in the 0.5–5 keV energy band. The spectra have been background subtracted using the same background region introduced in the previous subsection, and have been rebinned to ensure that a minimum of 30 counts are present in each energy channel. As for response matrices and effective area files, we have used the latest version of standard MOS and PN matrices provided by the calibration team (`mos1_medium_all_qe17_rmf3_tel5_15` and `epn_fs20_sY9_medium`). We have summed the spectra extracted with MOS1 and MOS2, and we have also rescaled the response matrix to reflect this operation¹. Besides the 8 annuli, we have also defined a region (the “edge” region hereafter), represented by the union of two ellipses matching the outer X-ray edge of the nebula², minus a circle with same radius as the 8th annulus. This region is particularly suited for the study of the X-ray emission coming from the outermost fringes of the X-ray and radio nebula.

We have used three different emission models to fit the 3C 58 data, namely a power-law model, a power-law model

plus the optically thin plasma model of Mewe et al. (1985) with Fe L calculation of Liedahl et al. (1995), pl+MEKAL hereafter, and a power-law model plus a black-body spectrum, pl+bbody hereafter. These three models encompass what we could possibly expect from an X-ray nebula, the last two representing eventual contributions from a thermal shell (as in the case of known plerion-composite SNR), and from a compact source in the center as pointed out by Helfand et al. (1995). The temperature of the pl+MEKAL model and of the pl+bbody models have been constrained in the 0.1–10 keV and in the 0.1–2.0 keV, respectively. Abundances are those of Anders & Grevesse (1989). All the models have been modified by the interstellar absorption according to cross-sections of Morrison & McCammon (1983), where we have let the equivalent hydrogen column density N_{H} vary. Since we have noted that the non-thermal component provides most of the flux in the *XMM-Newton* bandwidth, and that the residual thermal components of the model pl+MEKAL and pl+bbody are correlated with the value of N_{H} , we have also performed a set of fittings fixing the N_{H} value to $4 \cdot 10^{21} \text{ cm}^{-2}$, which is compatible with previous estimates (Helfand et al. 1995; Torii et al. 2000) and it is also consistent with the result we obtained letting it vary.

2.3.1. The γ vs. radius relation

Figure 3 shows the best-fit value of the absorption and of the power-law photon index (γ) as a function of the distance from remnant center, obtained with a fit to a power-law emission model only. The data clearly show the effect of synchrotron burn-off of high energy electrons as the radius increases. This effect has also been observed in G21.5-0.9 both with Chandra (Slane et al. 2000) and *XMM-Newton* (Warwick et al. 2000) and it is related to inhomogeneity in the particle distribution inside the plerion nebula. The straight line in the lower panel of Fig. 3 represents the linear best-fit to the $\gamma - r$ relation, $\gamma = A + Br$ with $A = 1.97 \pm 0.03$ and $B = 8.0 \pm 0.6 \cdot 10^{-3}$ and r is in arcseconds. The MOS fits to the single power-law reported in Fig. 3 are statistically acceptable³ from ring 1 to ring 6, while not acceptable in rings 7–8 and in “the edge” region. This is true for both N_{H} free and N_{H} fixed fits, and Table 1 reports the χ^2/dof values of the fits. It is interesting to note that the N_{H} value, when left free to vary, is significantly lower than the average value of $4 \cdot 10^{21} \text{ cm}^{-2}$ for the outer nebula regions (Fig. 3). Moreover, the best-fit γ of the shell is off the trend dictated by fit to the spectra of the rings when N_{H} is left free to vary, while it shows lower deviation in the fit with N_{H} fixed. If the X-ray emission of the outer rings is dominated by the non-thermal component of the plerion, we do not expect significative variation of the absorption,

¹ We will refer hereafter to the summed spectra as simply the MOS spectra.

² The E-W and N-S ellipses have large and small semi-axis of $3.3' \times 1.1'$ and $1.7' \times 1.1'$, respectively.

³ We regard a fit as statistically acceptable when the null hypothesis probability computed from the reduced χ^2 and number of degrees of freedom is greater than 5%.

Table 1. Goodness of MOS fits to the 8 annuli of 3C 58. The absorption is fixed to $4 \times 10^{21} \text{ cm}^{-2}$. For each model, we report the value of χ^2 , degrees of freedom (dof), null hypothesis probability. For the pl+MEKAL and pl+bbbody model, we also report the value of the best-fit temperature. The last column is the unabsorbed flux in the 0.5–10.0 keV in units of $10^{-13} \text{ erg cm}^{-2} \text{ s}^{-1}$; its statistical error is ± 0.1

Reg.	Power-law		Pow+MEKAL			Pow+bbbody			flux
	χ^2/dof	Prob.	kT	χ^2/dof	Prob.	kT	χ^2/dof	Prob.	
1	74/73	46	1.0(>0.4)	71/71	48	0.2(>0.1)	73/71	40	15.3
2	69/65	35	6.0(>0.1)	67/63	35	0.9(>0.1)	68/63	30	13.0
3	65/63	41	0.6(>0.1)	65/61	34	0.5 ± 0.3	62/61	44	11.4
4	52/59	71	0.1(>0.1)	51/57	70	0.1(>0.1)	51/57	69	12.3
5	54/61	72	0.7(>0.1)	52/59	72	0.2(>0.1)	53/59	69	12.0
6	52/59	74	0.1(>0.1)	50/57	72	0.6(>0.1)	50/57	72	10.9
7	96/60	0.2	0.2(<0.25)	91/58	0.4	$0.8^{+0.2}_{-0.1}$	91/58	0.4	10.7
8	79/58	3	$0.3^{+0.2}_{-0.1}$	71/56	8	$0.8^{+0.3}_{-0.1}$	73/56	7	10.6

and the data seem to confirm that a fixed N_{H} may be more appropriate. However, the fact that fits of the outer rings and “edge” data are less acceptable than fits to inner rings data strongly suggests a contribution from other components.

2.3.2. Additional thermal components

In order to assess the presence of any additional emission from a central compact source (as suggested by H95) and from any thermal shell, we now consider the results of fits with pl+MEKAL and pl+bbbody models. The inclusion of the additional component (MEKAL or bbbody) does not increase the null hypothesis probability above 5%, except for ring 8. This is also reported in Table 1, in which the reader finds the data needed to evaluate the goodness of the fits we have performed. However, it should be noted that the inclusion of the MEKAL component leads to a reduction of χ^2 (and therefore to a better fit in a relative way) for the outermost rings, and a dramatic reduction in case of the “edge” region, specially for MOS. This is also shown in Fig. 4, where we show the MOS “edge” spectrum along with its power-law only and pl+MEKAL best-fit model and residuals, and in Table 2 where we summarize the results of spectral fitting to the “edge” spectrum. In Fig. 5, we report the ratio of the flux of the second component (f_{mekal} from the pl+MEKAL fit in the upper panel, and f_{bbbody} from the pl+bbbody fit in the lower panel) to the total flux of ring 1–8 and the “edge” region.

The fit with an additional black-body component to ring 1 places an upper limit to the unabsorbed flux due to this component of 20% of the total 0.5–2.0 keV flux in this region (i.e. $1.5 \times 10^{-13} \text{ erg cm}^{-2} \text{ s}^{-1}$, or a luminosity $L_{\text{X}} = 1.8 \times 10^{32} D_{3.2}^2 \text{ erg s}^{-1}$, where $D_{3.2}$ is the distance in units of 3.2 kpc, which is the most reliable value according to Roberts et al. 1993) and 10% of the total 0.5–10.0 keV flux of this region (i.e. $1.6 \times 10^{-13} \text{ erg cm}^{-2} \text{ s}^{-1}$, same L_{X} as before). Since the whole remnant 0.5–10 keV flux is $1.6 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$, the upper limit corresponds to 1% of the remnant flux, significantly below the 7% found by Torii et al. (2000). Figure 5 also shows that spectral fit-

Table 2. PN and MOS fit results of the “edge” region of 3C 58. All the fits yield an absorbed flux of $6.1 \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$ in the 0.5–10 keV band

Model	N_{H} cm^{-2}	γ	kT keV	χ^2/dof
MOS1+2				
pow-law	3.5 ± 0.2	2.61 ± 0.06	-	245/170
pl+MEKAL	$7.3^{+0.6}_{-0.9}$	2.89 ± 0.08	0.18 ± 0.01	202/168
pl+bbbody	$5.5^{+0.5}_{-0.8}$	2.75 ± 0.06	<0.11	231/168
pow-law	4.0	2.75 ± 0.04	-	261/171
pl+MEKAL	4.0	2.61 ± 0.05	0.25 ± 0.03	226/169
pl+bbbody	4.0	3.07 ± 0.07	0.78 ± 0.08	243/169
PN				
pow-law	3.1 ± 0.3	2.42 ± 0.11	-	113/138
pl+MEKAL	$7.6^{+0.4}_{-2.5}$	$2.71^{+0.15}_{-0.11}$	0.18 ± 0.03	107/136
pl+bbbody	$5.2^{+1.0}_{-1.7}$	$2.55^{+0.11}_{-0.16}$	<0.13	109/136
pow-law	4.0	2.66 ± 0.06	-	130/139
pl+MEKAL	4.0	2.47 ± 0.10	0.24 ± 0.06	110/137
pl+bbbody	4.0	2.46 ± 0.10	<0.13	110/136

tings of rings 2–6 yields only upper-limits to the presence of an additional MEKAL or black-body thermal emission.

On the other hand, the situation is different for ring 8 and the “edge” region (Tables 1 and 2), where the addition of the thermal component yields a significant decrement of the χ^2 (according to an F-test) and the thermal flux contribution to the 0.5–2.0 total flux is between 5% and 30%. In particular, the pl+MEKAL fit in the “edge” region suggests that between 10 and 20% of the 0.5–2.0 keV flux from this region ($5\text{--}9 \times 10^{-13} \text{ erg cm}^{-2} \text{ s}^{-1}$, or $L_{\text{X}} = 5.8 \text{--} 10.0 \times 10^{32} D_{3.2}^2 \text{ erg s}^{-1}$) is due to the thermal component (8–14% if we consider the 0.5–10 keV band). If compared to the whole remnant 0.5–10 keV flux, the thermal soft excess yields a contribution of 3%–6%. It is important to note that in this region the pl+MEKAL model is to be preferred over the pl+bbbody model (Table 2).

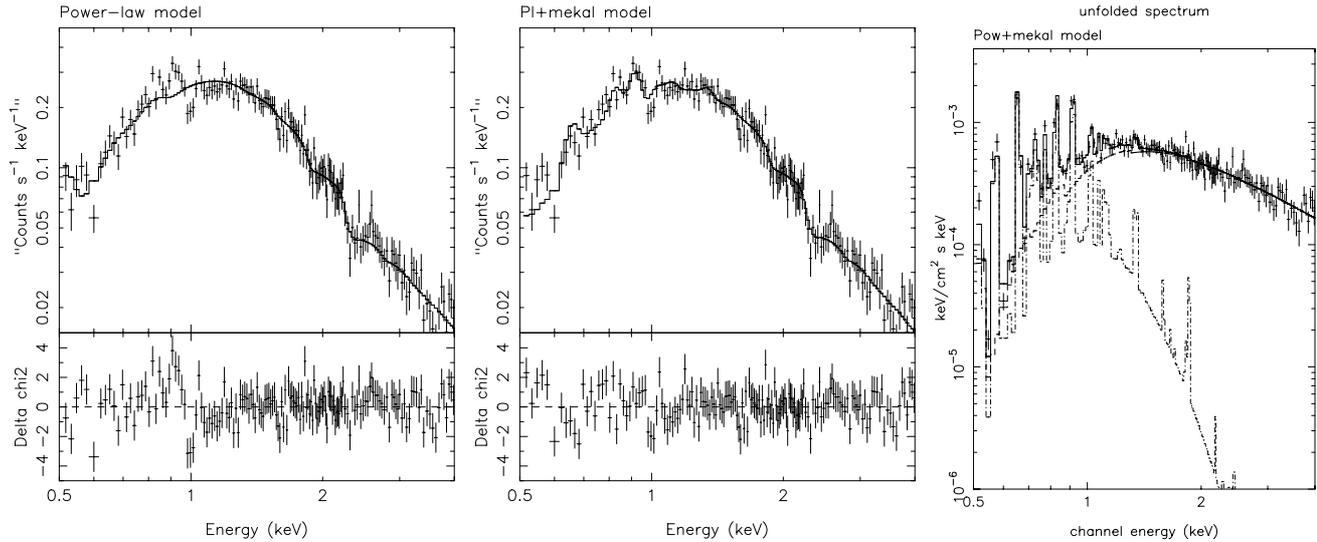

Fig. 4. A close up of MOS spectrum for the “edge” region. *Left panel:* the fit with a simple power-law model does not well represent the spectrum below 1 keV. *Center panel:* the pl+MEKAL model with $kT = 0.2$ keV improves the description of the data. The spectral region near the oxygen edge (between 0.4 and 0.6) is known to have some residual calibration problem. *Right panel:* unfolded best-fit pl+MEKAL model. Dot-dashed line represents the thermal component, which shows emission lines and falls off rapidly above 1 keV, where the power-law component dominates

2.3.3. PSF effects

We have also investigated whether our results are affected by any effect related to the Point Spread Function (PSF) of the *XMM-Newton* mirror. Since only 55% of the photons of a point source are contained within a circle of $8''$ radius, we expect a certain amount of scattering outside the rings. However, this effect is not likely to modify our conclusions. In the central ring, for instance, the strongly peaked morphology keeps the contamination from ring 2 low. Moreover, the scattering can only smooth the $\gamma - r$ relation in Fig. 3, so the observed slope is, strictly speaking, a lower limit to the real slope. Finally, in order to verify whether the soft component detected at large radii is an artifact of the PSF, we have followed this procedure: we have fitted the summed spectrum of rings 1–8 with a power-law model, and we have found $N_{\text{H}} = 3.9 \cdot 10^{21} \text{ cm}^{-2}$ and $\gamma = 2.21$; then, we have fitted the spectrum of the “edge” region with the best-fit model found for ring 1–8 with fixed N_{H} and γ , plus a second absorbed power-law model with free N_{H} and γ . The normalizations of the two models were left free to vary. We have found that the best-fit normalization of the “fixed” power-law is zero, suggesting that negligible contamination from the spectrum of the ring 1–8 is observed in the “edge” spectrum.

2.4. Timing analysis

In order to search for pulsed X-ray emission from the central source which is powering 3C 58, we have calculated the power spectrum density of the time series of events of the central ring used for spectral analysis. Unfortunately, the time resolution of the EPIC cameras when operated

in full image mode is low, and we were not able to sample frequencies above 1 Hz. For timing analysis, we have collected MOS1 and PN photons in ring 1 between 0.5 and 10 keV, and we have analyzed the two independently. Furthermore, we have also analyzed a more restricted energy range, 2–10 keV.

None of the power spectra show features significant at the 99% confidence level. The corresponding MOS1 upper limits to relative amplitude of a sinusoidal pulsed signal in the $5 \cdot 10^{-3} - 0.1$ Hz are 6.2% and 10.0% for the 0.5–10 keV and 2–10 keV respectively, while the PN upper limits in the $10^{-2} - 1$ Hz are 2.0% and 3.1% in the broad and hard band, respectively.

3. Discussion

The good spatial and spectral resolution *XMM-Newton* data on 3C 58 has allowed us to perform a detailed spatially resolved spectral analysis of this remnant, and in particular, to address the topic of the spectra of the compact core at its center and the presence of an X-ray shell.

3.1. The compact core

The possible emission mechanisms for the compact core of 3C 58 have been reviewed by H95, and a preference has been given to a thermal model for the emission from hot polar caps, mostly on the basis of a review of ROSAT and Einstein HRI data. Torii et al. (2000) have confirmed the detection of an additional component in the remnant spectrum, which they have modeled with a black-body of $kT = 0.40 - 0.45$ keV and a flux of $1.5 \cdot 10^{33} D_{3.2}^2 \text{ erg s}^{-1}$ in the 0.5–10 keV band. While the Torii et al. (2000) flux

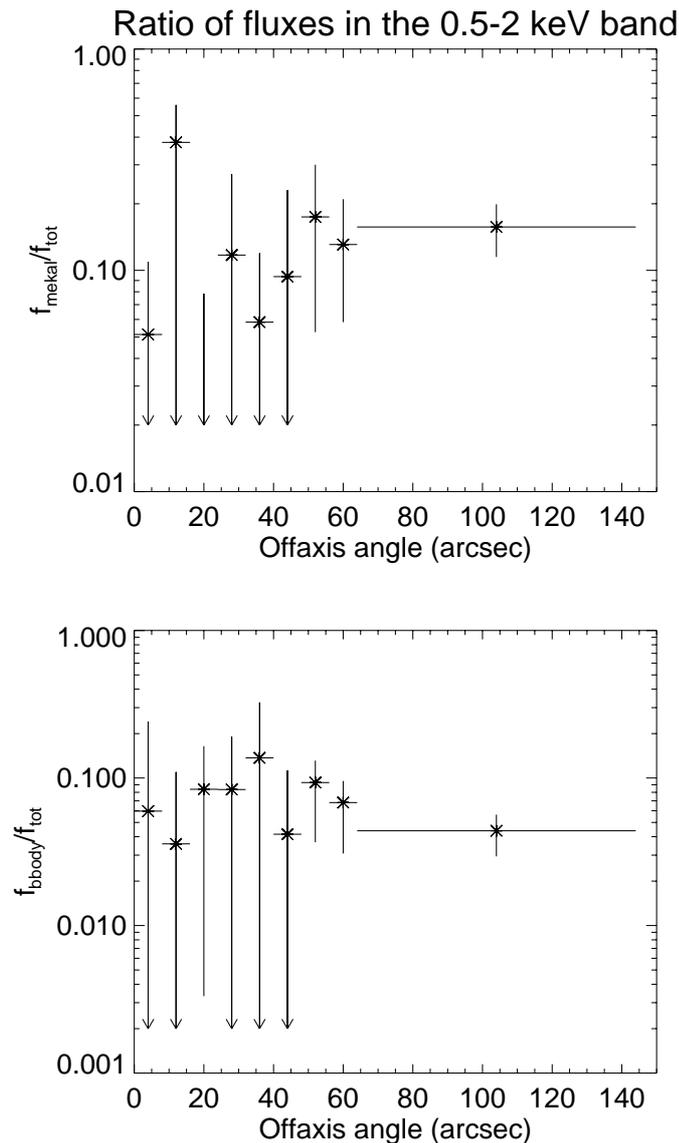

Fig. 5. Same as in Fig. 3, but here we report the ratio between the 0.5–2.0 keV flux due to the additional component (MEKAL in the upper panel, and bbody in the lower panel) to the total 0.5–2.0 keV flux versus the distance from the center. Arrows indicate upper limits. Goodness of fits are reported in Table 1

estimate is within 20% of the H95 one, we have found in ring 1 an upper limit to the flux of the $kT = 0.25$ keV black-body component a factor of 10 less than the H95 estimate. The inferred upper limit on the emitting area is $1.3 \cdot 10^{10} \text{ cm}^2$ (corresponding to a radius of ~ 650 m), more or less the value found by Torii et al. (2000), and this is expected since our best-fit temperature is a factor of two less than the one derived by ASCA. By forcing the temperature at the value of Torii et al. (2000), the corresponding upper limits are $9.4 \cdot 10^{-14} \text{ erg cm}^{-2} \text{ s}^{-1}$ ($L_X = 1.1 \cdot 10^{32} D_{3.2}^2 \text{ erg s}^{-1}$) and $8 \cdot 10^8 \text{ cm}^2$. While this large difference in the inferred black-body flux may seem puzzling, it may be explained by the dramatic improvement of the *XMM-Newton* spatial resolution compared

with the ASCA one. In fact, if we compute the sum of our best-fit values for the flux of the black-body component of the pl+bbody fit over all the rings and the “edge” region, we obtain a 0.5–10 keV flux of $1.2 \cdot 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$, or a luminosity of $1.3 \cdot 10^{33} D_{3.2}^2 \text{ erg s}^{-1}$, in very good agreement with the value reported by H95 and Torii et al. (2000). More than 50% of this flux comes from ring 7–8 and the “edge” region: it is therefore probable that the ASCA data correctly detected a soft excess in the integrated spectrum of 3C 58, but this was incorrectly attributed to the thermal component of the central compact object, whereas Fig. 5 suggests that it comes from the *external* parts of the nebula. The more stringent *XMM-Newton* upper limit to the black-body component also heavily constrains its interpretation. Our value of the emission area is too low to assume that the whole surface of neutron star is losing the residual heat of formation, and therefore would suggest the hot polar caps mechanisms. A review of the polar caps heating mechanisms can be found by Yancopoulos et al. (1994). H95 favors the “outer-gap” model, and in this case we expect $L_X = 10^{30} B_{12} P^{-2} \text{ erg s}^{-1}$, where B_{12} is the magnetic field in units of 10^{12} G and P is the period in seconds. As shown in Fig. 6, our L_X upper limit yields a magnetic field higher than the highest value known for allowed B and P values of an 810 yr old pulsar. For this model to be compatible with the L_X upper limit, either an older pulsar must be present or, unlike the Crab, the pulsar has not suffered high energy losses, in which case all the points below the isochrone lines of Fig. 6 are allowed. Other mechanisms invoked to explain the hot polar caps yield estimates of L_X lower than the “outer-gap” model and in principle may be compatible with the observations. However, other observed pulsar nebulae—thermal pulsar pairs reported by Seward & Wang (1988) show a ratio between compact object luminosity and total (pulsar+nebula) luminosity L_c/L_{tot} of ~ 0.1 – 0.2 (the Crab has $L_c/L_{\text{tot}} = 0.04$), while, using the observed total 3C 58 luminosity of $1.8 \cdot 10^{34} \text{ erg s}^{-1}$ and the upper limit we have derived, we derive a ratio < 0.01 . Figure 6 also shows that we expect a period less than 1 s for reasonable values of B , and therefore, to properly detect a pulsation, we would need a better time resolution than those of the EPIC camera in full image mode.

3.2. Thermal emission at the edge of the nebula

The interpretation of the additional component in terms of expansion of the main shock in the environment of the SNR cannot be excluded a priori: recently, there have been some cases of SNRs reclassified as composite (e.g. G11.2-0.3, Vasisth et al. 1996; G327.1-1.1, Sun et al. 1999). The observed temperature of the MEKAL component corresponds to a shock speed of $\sim 450 \text{ km s}^{-1}$, while the emissivity corresponds to a post-shock density of $(0.60 \pm 0.15) D_{3.2}^{-1/2} \text{ cm}^{-3}$ and a pre-shock density four times smaller (assuming the emission comes from a thin shell at $r = 2.5'$, where the soft profile in Fig. 1 drops

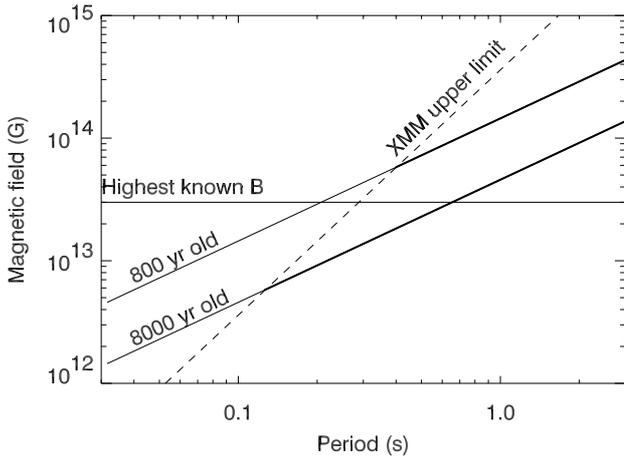

Fig. 6. The plot shows that allowed regions of the $B - P$ plane according to the classical model for pulsars (e.g. Manchester & Taylor 1977) in solid lines (assuming the initial period was much less than the present period). We show the case for an 800 yr old pulsar (i.e. assuming that 3C 58 is related to SN 1181) and for a pulsar with an age a factor 10 larger. The dashed line represent the $B - P$ values allowed by the “outer-gap” polar heated caps model of Cheng et al. (1986) and our derived upper limit to the black-body luminosity of the central source. The intersection of the observational and theoretical curves gives the allowed $B - P$ values (thicker part of the isochrone lines). If 3C 58 is the remnant of SN 1181, the model would provide an unreasonably high B . Older pulsars and/or low rotational energy losses may yield more reasonable B values

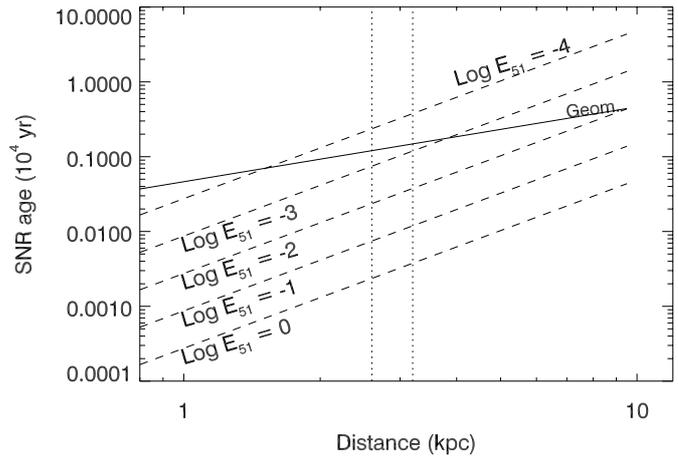

Fig. 7. Loci of allowed SNR age and distance according to a simple Sedov analysis of the thermal component of outer rim X-ray emission of 3C 58. The solid line labeled “Geom.” gives the loci allowed by the simple geometrical relation between the real radius of the shell and the SNR age (Eq. (2) of Kassim et al. 1993). The radius is linked to the distance via the apparent shell radius, and we have used $2.5'$ to derive the relation. The dashed lines represent the loci of the solutions allowed by the Sedov relation $R = 14(E_{51}/n_0)^{1/5}t_4^{2/5}$, where n_0 is derived from the emission measure of the MEKAL component assuming a spherical emitting volume with a radius of $2.5'$ and a filling factor of 25%. The intersection between the dashed lines and the solid line gives a solution. Vertical dashed lines mark the distance estimate of 2.6 and 3.2, due to Green & Gull (1982) and Roberts et al. (1993), respectively

rapidly, and $\Delta r = r/12$). The emitting mass is of the order of $0.1D_{3.2}^{5/2} M_{\odot}$. The inferred density is very reasonable for typical low galactic latitude Sedov SNRs, but on the other hand it can hardly be reconciled with the association between SN 1181 and 3C 58. This is shown in Fig. 7, which reports the allowed values of the SNR age and of the distance according to a simple Sedov analysis following the outline given in Kassim et al. (1993). It is clear that from a pure geometrical point of view, the measured X-ray temperature may represent a Sedov shock of an ~ 800 yr old SNR located at a distance of 3.2 kpc (“Geom.” solid line in Fig. 7), but the measured emission measure of the MEKAL component yields a solution with a distance well above 10 kpc and a remnant age well in excess of $\sim 10^4$ yr, if we assume that the explosion energy is of the order of the “canonical” value 10^{51} erg ($\log E_{51} = 0$ in Fig. 7, where E_{51} is in units of 10^{51} erg). Among the lowest values of the explosion energy quoted in the literature, we have $E_{51} = 0.1$ for Vela (Bocchino et al. 1999) and $0.02 - 0.3$ for G292.0+1.8 (Hughes & Singh 1994), and we note that, for $E_{51} = 0.01$, Fig. 7 gives a solution of a remnant at 8–10 kpc and an age of 3000–6000 yr. The association 3C 58–SN 1181 suggests an explosion energy of the order of 10^{48} erg, roughly ten times lower than the lowest inferred. We recall that the association have been questioned by Huang (1986), but re-

cently Stephenson & Green (1999) have pointed out that, on the basis of an update of historical information, the association should be reliable. If so, the Sedov model does not provide a proper description of all the observational evidence.

In order to understand the interaction between 3C 58 and its environment, and to understand the origin of the soft X-ray component, it is useful to compare its radio and X-ray emission. The soft X-ray maps of Fig. 2 show that the X-ray emission is in any case confined within $2' - 4'$ from the center, and therefore the presence of the shell is in agreement with the lack of detection of a radio shell at $r > 5'$ of Reynolds & Aller (1985). It is interesting to note that there is a close correspondence between the radio morphology of the outer regions of the nebula and the soft X-ray maps (Fig. 2, upper panel). This is also observed in other shell-like young SNR like Kepler (Matsui et al. 1984) and Cas A (Keohane et al. 1996), while, on the other hand, the radio emission of the Crab nebula is four times greater than its X-ray counterpart. Reynolds & Aller (1988) have pointed out that the radio image of the remnant at 1446 MHz shows confined-edge emission at some locations of the outer regions of the nebula, and some of these also show limb-brightening. According to them, this may be explained if the edge of the nebula is sweeping up moving

material, e.g. ejecta, like in the “inhomogeneous” model of Reynolds & Chevalier (1984), or the shock model invoked by Sankrit & Hester (1997) to explain the [O III] emission seen at the boundary of the Crab. This may explain the small amount of limb brightening and is also in agreement with the relatively slow shock speed measured in X-rays. In fact, the expected shock speed in the moving ejecta material is $\sim 300 \text{ km s}^{-1}$ (Reynolds & Chevalier 1984; $150\text{--}200 \text{ km s}^{-1}$ in the Crab according to Sankrit & Hester 1997), and we observe $v_s = 450 \text{ km s}^{-1}$. Therefore, the thermal component we observe in the outer rim of 3C 58 may be associated with the expansion of the nebula in the inner ejecta core. Note that this is also in agreement with the discrepancy between the large speed measured in 3C 58 filaments ($\sim 900 \text{ km s}^{-1}$, Fesen 1983) and the X-ray derived speed. In fact, the filaments are composed of material ejected in the explosion itself, pushed on and accelerated by the synchrotron nebula, while the X-ray emission is due a shock expanding into moving ejecta. However, the low value of the X-ray emitting mass would imply that the interaction is only at its beginning.

Finally, it should be noted that the above conclusions rely on the hypothesis of fast electron-ion equipartition. Unfortunately, it is not possible to independently measure the proton temperature T_p of the 3C 58 shock. Bocchino et al. (1999) have shown that $T_e < T_p < 2T_e$ for a shock region of the old Vela SNR, but Hughes et al. (2000) found evidence for $T_p \sim 45T_e$ in the 1000 yr old SNR E0102.2-7219, suggesting that non-equipartition may be common among young SNRs. If also in case of 3C 58 T_p is ~ 45 times higher than the X-ray derived electron temperature, than a Sedov solution with $E_0 \sim 3 \cdot 10^{49}$ erg, would be compatible with a distance of 3.2 kpc and the association with SN 1181.

4. Summary and conclusions

The high spatial resolution of the EPIC camera onboard *XMM-Newton* has allowed us to look with unprecedented detail at the X-ray emission from the filled-center SNR 3C 58. We have presented soft (0.1–1 keV), medium (1–2 keV) and hard (2–10 keV) energy images, and we have found a close correlation of the soft image with radio emission at 1446 MHz. A quantitative study of the source profile shows the effect of synchrotron burn-off and indicates a different slope of the soft X-ray radial profile compared to that obtained in the hard band. Spatially resolved spectral analysis carried on in rings with $\Delta r = 8''$ has allowed us to derive the relation between the spectral index and the distance from the core. In contrast with previous ASCA results, we have not found evidence for thermal black-body emission from a central source, and we have placed an upper limit to this component of $L_X = 1.8 \cdot 10^{32} \text{ erg s}^{-1}$. This stringent upper-limit rules out thermal emission from the whole surface of the putative neutron star at the center of 3C 58, and also rules out the “outer-gap” model for hot polar caps of

Cheng et al. (1986), unless the pulsar has very low rotational energy losses.

The large effective area of the *XMM-Newton* mirrors has allowed us to perform, for the first time, a spectral analysis of the outer edge of the 3C 58 X-ray nebula, excluding the inner and brighter regions. We have found that non-thermal emission is still responsible for most of the emission there, but a soft thermal component is required to better fit the spectrum below 1 keV. If represented with an optically thin emission model, this component gives $kT = 0.2\text{--}0.3 \text{ keV}$. If it is associated to the Sedov expansion of the 3C 58 shell, it is incompatible with the association between 3C 58 and SN 1181, unless there is strong deviation from electron-ion equipartition. If it is due to the expansion of the nebula into the inner core of moving ejecta, the X-ray spectra characteristics and the radio morphology of the outer nebula can be more easily reconciled.

Acknowledgements. We thank the whole *XMM-Newton* team for its effort in producing well-calibrated data at this early stage of the mission. We also thank the referee, R. Strom, for his useful suggestions. F. Bocchino acknowledges an ESA Research Fellowship and thanks R. Bandiera for helpful discussions.
