Abstract. Using the Effelsberg 100-m telescope, sensitive measurements of the H$_2$O megamaser in NGC 3079 are presented. During 2000–2001, “high velocity” features are seen that are red-shifted up to 225 km s$^{-1}$ with respect to the systemic velocity of the galaxy (V$_{LSR}$ $\sim$ 1120 km s$^{-1}$). Symmetrically bracketing the systemic velocity, the H$_2$O emission covers a velocity range of $\sim$450 km s$^{-1}$ with only one potential narrow gap ($\sim$20 km s$^{-1}$) near the systemic velocity itself. Velocity drifts of individual components are not convincingly detected. It is shown that the presence of red-shifted emission and the absence of detectable velocity drifts are not inconsistent with the existence of a rotating circumnuclear maser disk at the very center of the galaxy. Significant differences in the overall line profile compared to NGC 4258 and a complex morphology of the radio continuum leave, however, space for scepticism.

Key words. galaxies: active – galaxies: individual: NGC 3079 – galaxies: ISM – galaxies: nuclei – radio lines: galaxies

1. Introduction

Recent single-dish and VLBI observations of luminous H$_2$O megamasers have been motivated by the discovery of an edge-on Keplerian sub-pc scale maser disk enshrouding a compact supermassive object at the nucleus of the LINER galaxy NGC 4258 (e.g. Nakai et al. 1993, 1995; Haschick et al. 1994; Greenhill et al. 1995; Miyoshi et al. 1995; Herrnstein et al. 1999). Circumnuclear disk structures traced by H$_2$O are also seen towards NGC 1068, NGC 4045, and the Circinus galaxy (e.g. Gallimore et al. 2001; Greenhill et al. 1997, 2000). H$_2$O megamasers therefore provide a unique probe to study the kinematics and the dynamical structure of the innermost regions of active galactic nuclei.

For the LINER or Seyfert 2 galaxy NGC 3079 (see Sawada-Satoh et al. 2000) that contains one of the most luminous H$_2$O megamasers known to date (e.g. Henkel et al. 1984; Haschick & Baan 1985; Haschick et al. 1990), arguments in favor of a circumnuclear disk have been less compelling. While the known maser components arise in the inner few parsecs of the galaxy, they do not align at right angles to the radio jet(s), almost all the detected emission is blue-shifted relative to the systemic velocity, and any velocity drift of individual H$_2$O features must be small ($\lesssim$4.0 km s$^{-1}$ yr$^{-1}$; Nakai et al. 1995; Baan & Haschick 1996; Trotter et al. 1998; Satoh et al. 1999; Sawada-Satoh et al. 2000).

In this letter we therefore report single-dish observations of the 22 GHz water vapor line from NGC 3079, (1) to look for the missing red-shifted velocity components and (2) to search for velocity drifts in the near systemic features that would indicate centripetal acceleration in a rotating circumnuclear disk.

2. Observations

Observations of the J$_{K_aK_c}$ = 6$_1$–5$_{23}$ H$_2$O maser line (rest frequency: 22.23508 GHz) were made with the MPIfR 100-m radio telescope at Effelsberg between February 1994 and December 2001. Until 1998, a single channel K-band maser receiver was employed in a position switching mode with a system temperature of T$_{sys}$ $\sim$ 225 K on a main beam brightness temperature (T$_{mb}$) scale. An autocorrelator provided bandwidths of 50, 25 or 12.5 MHz with 1024 spectral channels, yielding channel spacings of 0.66, 0.33 or 0.16 km s$^{-1}$. Since 2000, we used a dual channel K-band HEMT receiver in a dual beam switching mode with a beam throw of 2$'$ and a switching frequency of 1 Hz. After averaging the two orthogonally polarized signals, T$_{sys}$ $\sim$180 K. Four autocorrelator backends were employed for each receiver channel. Each spectrum had a bandwidth of 40 MHz and 512 channels, yielding a channel spacing of 1.05 km s$^{-1}$.

\textsuperscript{a}) Several tunings and bandwidths were employed during most epochs. As a consequence, noise levels and channel spacings are not uniform across the observed velocity ranges. For noise levels vary from 200 mJy (channel spacing 1.32 km s\textsuperscript{-1}) in September 1996 to 7 mJy (channel spacing 1.05 km s\textsuperscript{-1}) in December 2001. Velocity resolution \approx 1.25 \times channel spacing. For direct access to 64 flux calibrated spectra, contact chenkel@mpifr-bonn.mpg.de.

Amplitude calibration was based on measurements of the 22 GHz continuum flux of 3C286 (see Baars et al. 1977; Ott et al. 1994). Pointing measurements toward nearby sources (in most cases DA 251) were made once per hour. The resultant pointing accuracy was \approx 8\arcsec, that should be compared with the full width to half power beam size of 40\arcsec. Calibration uncertainties are estimated to be \pm 15%.

3. Results

H\textsubscript{2}O spectra were taken during 16 epochs (Table 1; no changes in the maser profiles were seen within any of these observing periods). Several H\textsubscript{2}O features could be traced over the entire monitoring period. The most prominent component, detected at \approx 956 km s\textsuperscript{-1}, showed a peak flux density of 2.5-4.5 Jy. While the peak velocity is observed to drift from about 955.0 to 956.8 km s\textsuperscript{-1} (estimated error of individual measurements: 0.3 km s\textsuperscript{-1}), this drift is not systematic and appears to be caused by a multitude of individual, variable subcomponents. During times with lower peak velocity, the profile tends to show a "shoulder" at the high velocity wing of the line (e.g., on Nov. 5, 1997 and Feb. 1, 1998) and vice versa (Dec. 21, 2000, and Apr. 22, 2001). Notable were two flares of more red-shifted components that exceeded 2 Jy: The 979 km s\textsuperscript{-1} component with 0.7 Jy during Feb. 1994 to Apr. 1997 (see Nakai et al. 1995 for earlier spectra) reached 0.9 Jy in Nov. 1997, 1.5 Jy in Feb. 1998, and 2.2 Jy in May 1998 (Fig. 1a); it then decreased to 1.8 Jy in June 1998, 1.25 Jy in Aug. 1998, and 0.35 Jy since Oct. 2000. The 1017 km s\textsuperscript{-1} velocity component, observed between Sep. 1996 and Nov. 1997 at 0.1-0.5 Jy, reached a peak flux density of 2.5 Jy in Mar. 2000 (Fig. 1b); flux densities decreased to 1.0 Jy in Oct. 2000 and to 0.1 Jy in May 2001. Emission near the systemic velocity of the galaxy (1080 km s\textsuperscript{-1} < V\textsubscript{LSR} < 1160 km s\textsuperscript{-1}) remained faint and not a single narrow velocity component could be traced during several consecutive observing epochs.

Figure 2 shows a spectrum of near systemic (V\textsubscript{sys} \approx 1120 km s\textsuperscript{-1}) and red-shifted (V > V\textsubscript{sys}) features that were detected since March 2000. More than 10 distinct narrow components appear at velocities in excess of 1100 km s\textsuperscript{-1} (Table 2). We conclude that the H\textsubscript{2}O maser emission extends over a radial velocity range of \approx 450 km s\textsuperscript{-1}. The integrated luminosity of the previously known blue-shifted components remains approximately constant. This may also hold for the systemic and red-shifted features shown in Fig. 2. A detection of these prior to 2000 would have been difficult in view of technical improvements that occurred at Effelsberg in 1999. Sensitivity also limits the studies by Nakai et al. (1995; we do not confirm the weak 764 and 791 km s\textsuperscript{-1} components) and Baan & Haschick (1996). However, the 1123 and 1190 km s\textsuperscript{-1} components observed by Trotter et al. (1998) in Jan. 1995, the flaring 1192 km s\textsuperscript{-1} feature (\approx 0.4 Jy) detected by Nakai et al. (1995) in Apr.-May 1995, and a 1201 km s\textsuperscript{-1} feature detected by us in Sep. 1995 (Fig. 3) indicate the presence of isolated red-shifted maser features as early as half a dozen years ago.

4. Discussion

In NGC 4258, Nakai et al. (1993) detected red- and blue-shifted H\textsubscript{2}O "satellites" symmetrically displaced by approximately \pm 900 km s\textsuperscript{-1} from the systemic velocity. This suggested the presence of a circumnuclear disk that was later confirmed (see Sect. 1). Is the discovery of a multitude of near systemic and red-shifted features in NGC 3079 also hinting at a circumnuclear disk? Emission is seen at least between 928 and 1352 km s\textsuperscript{-1} (Fig. 3).
Fig. 2. Near systemic and red-shifted H$_2$O maser features toward NGC 3079. Channel spacing: 2.1 km s$^{-1}$ (main spectrum), 4.2 km s$^{-1}$ (inserts b and c), and 8.4 km s$^{-1}$ (insert a). The inserted spectra (insert c) includes a few bad channels at the edge of the band show an initially dominant fading 1222 km s$^{-1}$ component, while the flux of the 1192 km s$^{-1}$ component increases. The brightest components have an isotropic luminosity of ≈0.5 $L_\odot$. Since the zero level is determined by a linear baseline derived from velocities $V < 920$ and $>1360$ km s$^{-1}$, the absence of H$_2$O emission near 1100 km s$^{-1}$ is not entirely certain.

Table 2. Velocities of distinct near systemic or red-shifted features observed on December 5, 2001 (see Fig. 2).

Assuming the presence of a symmetric edge-on circum-nuclear disk, the systemic velocity of the nuclear region then is $\approx 1140$ km s$^{-1}$. Including the 896 km s$^{-1}$ feature apparent in the early spectra of Henkel et al. (1984) and Haschick & Baan (1985) and tentatively also seen in Dec. 2000 and Dec. 2001, $V_{sys} \approx 1124$ km s$^{-1}$. Is this consistent with the systemic velocity of the galaxy?

From the nuclear molecular gas traced by the CO $J = 1-0$ line, Irwin & Sofue (1992) deduced a systemic velocity of $V_{sys} = 1050 \pm 10$ km s$^{-1}$. From an H I line profile, Irwin & Sofue (1991) obtained a midpoint at the 20% peak level of 1123 ± 10 km s$^{-1}$ and 1126 km s$^{-1}$ from a fit to the moment map. Three dimensional modeling of their H I data cube yields $V_{sys} = 1116$ km s$^{-1}$. The rough agreement of CO, H I, and H$_2$O velocity centroids implies a nuclear systemic velocity of $\approx 1120$ km s$^{-1}$ and suggests that we have seen, for the first time, all the stronger 22 GHz H$_2$O maser components in NGC 3079. A nuclear systemic velocity of 1230 km s$^{-1}$ as suggested by Satoh et al. (1999) is not supported by our H$_2$O data.

Nevertheless, the maser emission is far from perfectly symmetric: (1) All bright components (>0.5 Jy) are blue-shifted with respect to the systemic velocity which is inconsistent with the situation in NGC 4258 and NGC 1068 as well as with the spiral shock model proposed by Maoz & McKee (1998). (2) The systemic velocity obtained from model fits (Irwin & Sofue 1991) lies at the edge of that narrow velocity interval ($\Delta V \approx 20$ km s$^{-1}$, see Fig. 2) that appears to be devoid of H$_2$O emission (the only such interval over the entire H$_2$O velocity range observed by us). Interpreted in terms of the paradigm established for NGC 4258, this may hint at a lack of nuclear 22 GHz radio continuum emission at the very center of the putative masinger torus. (3) In a well ordered edge-on circumnuclear disk, small line-of-sight velocity gradients that stimulate maser emission should only be present near the tangential points and near the front and back side of the disk. A continuous coverage of the velocity range as observed in NGC 3079 is not expected. (4) None of the four systemic velocities quoted above provides a particularly high number of red- and blue-shifted components that match each other with respect to velocity ($|V_{red} - V_{sys}| \approx |V_{blue} - V_{sys}|$). Note that the following discussion, does not sensitively depend on the exact choice of $V_{sys}$ as long as it is in the range 1100–1150 km s$^{-1}$.

Most blue-shifted 22 GHz H$_2$O velocity components of NGC 3079 are already known to show no significant velocity drift (e.g. Fig. 7 of Nakai et al. 1995; Fig. 6 of Baan & Haschick 1996). The slow drift of $\sim 0.4$ km s$^{-1}$ yr$^{-1}$ suggested by Baan & Haschick (1996) for the 945, 951, and 1015 km s$^{-1}$ components ($V$ refers to epoch 1994.0) is not expected if a circumnuclear torus is present (e.g. Miyoshi et al. 1995). Our data for the 945 km s$^{-1}$ component (945.7 and 946.2 km s$^{-1}$ in Feb. 1994 and 1998, and 946.6 and 946.5 km s$^{-1}$ in May and June 1998; errors derived from Gaussian fits are $\sim 0.3$ km/s) are not contradicting Baan & Haschick (1996), although a group of features with varying amplitudes could also simulate the drift. The 1017 km s$^{-1}$ component (Fig. 1b) fluctuates between 1014 and 1018 km s$^{-1}$ and does not support a regular drift, although it is likely related to the 1015 km s$^{-1}$ component of Baan & Haschick (1996). The 951 km s$^{-1}$ component was not seen by us. Satoh et al. (1999) and Sawada-Satoh et al. (2000) report a drift of $3.7 \pm 0.6$ km s$^{-1}$ yr$^{-1}$ for a maser feature near 1190 km s$^{-1}$. We find a group
Fig. 3. Individual velocity components of the 22 GHz H$_2$O spectrum obtained with an accuracy $<1$ km s$^{-1}$ for the blue-shifted components and $1$ km s$^{-1}$ for the redshifted ones.

of features (total width: $V_{\text{tot}} \sim 5$–$6$ km s$^{-1}$) centered at 1192.9 km s$^{-1}$, both on Mar. 3 and Dec. 5, 2001. Thus the drift appears to be well below our estimated detection level of 1.5 km s$^{-1}$ yr$^{-1}$ for a time interval of 9 months. In view of the long lifetime inferred for some of the blue-shifted maser lines (Sect. 3 and Fig. 3), the 1192 km s$^{-1}$ feature reported by Nakai et al. (1995) is likely part of this component, reducing the velocity drift to well below 1.0 km s$^{-1}$ yr$^{-1}$.

The overall lineshape of the H$_2$O profile is quite distinct from that of NGC 4258 and the morphology of the radio continuum (T. Krichbaum, priv. comm.) is more complex. In spite of the presence of a roughly linear ridge of blue-shifted H$_2$O masers, the existence of an associated nuclear disk is thus not certain (see e.g. Trotter et al. 1998 for alternative scenarios). Sawada-Satoh et al. (2000) proposed a thick maser disk with continuum source “B” at the nucleus and the 1190 km s$^{-1}$ feature on its near side (their Fig. 6). Since we see no velocity drift near 1190 km s$^{-1}$ and since this is not the systemic velocity, however, there is no need to put this component at the near side of the putative disk. We therefore tend to favor the disk scenario outlined by Trotter et al. (1998) with the nucleus of the galaxy being located between continuum components A and B (their Fig. 7). In this latter scenario, expected velocity drifts would be consistent with our upper limits. The nucleus would contain a few $10^6 M_\odot$ within $R \sim 10$ mas (0.7 pc; assumed rotation velocity $V_{\text{rot}} \sim 100$–225 km s$^{-1}$), the centripetal acceleration and proper motion of the near-systemic components would be difficult to detect ($<0.1$ km s$^{-1}$ yr$^{-1}$ and $\sim 1$ $\mu$as yr$^{-1}$), and most of the red-shifted masers would be located 10–15 mas south of the blue-shifted ones (some masers may be associated with the jet (e.g. Trotter et al. 1998)). Sensitive VLBI data are needed to examine this picture and to obtain definite information on the relative location of blue- and red-shifted maser features and continuum sources in the very center of NGC 3079.
