Abstract. The X-ray emission from the supernova remnant DEM L 71 is measured and analysed using the high-resolution cameras and spectrometers on board XMM-Newton. The spectrum from the outer shell is reproduced very well by two plasma components of $kT_e = 0.3$ and $0.8$ keV. The abundance value from this shell is consistent with the average LMC values. More extreme temperature variations are possibly indicated by spatial variations in the O vii forbidden/resonance line ratio, which could imply that in some regions the plasma is cooling dramatically and recombining. However, an alternative and equally interesting possibility is that the variation in forbidden/resonance ratios is due to resonant scattering, which would reduce resonance line emission along lines of sight with a high O vii column density. The inner region is hotter ($kT_e = 1.1$ keV) and shows enhanced Fe and Si abundances. We estimate the Fe and Si ejecta mass to be $0.7 - 1.1 M_\odot$ and $0.1 - 0.15 M_\odot$, respectively. The morphology, mass estimates and abundances strongly suggest that DEM L 71 is the result of a type Ia explosion, as indicated by previous measurements.

Key words. ISM: supernova remnants – ISM: individual objects: DEM L 71 – ISM: abundances – shock waves

1. Introduction

DEM L 71 (SNR 0505-67.9) belongs to a class of Supernova Remnants (SNR) that are dominated by hydrogen emission in their optical spectra with virtually no emission from collisionally excited forbidden lines. Analysis of the optical spectrum of DEM L 71 indicates a shock velocity of 300–800 km s$^{-1}$ which corresponds to a shock temperature of $T_s \approx 0.11 - 0.75$ keV (Smith et al. 1994). This information, combined with a radial size of $\approx 10$ pc, gives an estimated age of $\approx 10^4$ years. ASCA spectroscopy revealed that, despite its age, DEM L 71 still showed emission from ejecta material in the form of enhanced Fe abundance (Hughes et al. 1998). The enhanced Fe abundance indicates that DEM L 71 is the result of a type Ia SNe. The recent Chandra Fe-L images (Hughes et al. 2003; see also Fig. 1) also reveal that the remnant exhibits both shell-like X-ray emission and a centrally filled morphology in this energy range.

In this work, we present the X-ray spectra of DEM L 71 measured by the XMM-Newton suite of scientific instruments, i.e. the Reflection Grating Spectrometers (RGS) (den Herder et al. 2001) and the European Photon Imaging Cameras (EPIC) (Turner et al. 2001; Strüder et al. 2001). In particular, we exploit the high dispersion of the RGS and its unique capability to resolve line emission from extended sources to investigate the conditions of the X-ray emitting plasma in DEM L 71 in unprecedented detail.

2. Observation and reduction

Our analysis is based on XMM-Newton observations of DEM L 71 obtained on 2 April 2001. The observation was performed with the telescope rolled such that the RGS dispersion axis was aligned at 72$^\circ$, clockwise on the sky from celestial North. A large fraction of the observation is affected by high particle background caused by solar activity. For the EPIC instruments periods of high particle background were rejected based upon the 10–12 keV count rate for the entire field of view. After filtering out these high background periods we are left with a net exposure time of 10 ks for the EPIC instruments. The EPIC instruments were all operated in full window mode with the medium filter in place. Good time intervals (GTI) for the RGS were created based on the count rate in CCD number 9 (it is the one closest to the optical axis of the telescope, therefore the most affected by background flares). After applying the GTI filter we are left with an effective exposure time of 40 ks for the RGS. The spectra were extracted by applying spatial filters to the CCD image while a CCD pulse-height filter was applied to select the $m = -1$ spectral order. All the XMM-Newton data were processed using the Science Analysis System (SAS version 5.3).
3. Analysis and results

3.1. Spectra

The spectral analysis was performed using the SRON SPEX package (Kaastra et al. 1996), which contains the MEKAL atomic database (Mewe et al. 1995) for thermal emission. Our model for the X-ray emission of DEM L 71 consists of several plasma components. For each component, we fit for the volume emission measure ($n_e n_T V$), the electron temperature ($T_e$), the ionisation age ($n_e t$) (Kaastra & Jansen 1993), the elemental abundances, the redshift of the source, and the column density $N_H$ of absorbing gas along the line of sight. Here, $n_e$ is the electron density, $n_H$ is the hydrogen density, $V$ is the volume of emitting gas and $t$ is the time since the material has been shocked and heated to its current temperature. A distance of 52 kpc to the LMC is assumed (Feast et al. 2002).

The first order RGS spectrum of DEM L 71 is shown in Fig. 2. The spectrum is dominated by emission lines, the most prominent of which are from transitions of highly ionised ions of C, O, Fe and Ne. The O VIII-Lα and O VII-triplet lines are particularly strong. Weaker, but unambiguous, emission from ions of N, Mg and Si are also present. While the second order RGS spectrum has higher spectral resolution, it does not provide any additional information. The second order spectrum is also of lower statistical quality and was therefore not used.

We fitted the RGS 1&2 spectra, extracted from the entire source, simultaneously. A response matrix appropriate to the spatial extent of the source was generated as follows. A spatial mask corresponding to the RGS aperture was imposed on the Chandra ACIS image, and the intensity distribution was integrated over the RGS cross-dispersion direction. The resulting profile was convolved with the RGS point source response matrix, generated with the SAS task RGRMFGEN. We find that one plasma component does not describe the data sufficiently well and that at least two NEI plasma components are needed for obtaining a good fit to the RGS spectrum. A hotter component ($kT_e \sim 0.8$ keV) describes the spectrum below ~20 Å, while a cooler component ($kT_e \sim 0.2$ keV) is needed to model the emission from the O VII-triplet through C VI. When fitting the abundances we used O as the reference atom and, for technical reasons, kept its abundance fixed to solar. We use O because it has the strongest emission and would thus give the least uncertainty in the abundance determination. We allowed the abundance of H, C, N, Ne, Mg, Si and Fe to vary with respect to O. The He abundance was pegged to the H value. The best fit results, given in Table 1, gives a $\chi^2$/d.o.f. ~ 1869/945. We obtain a best fit $N_H = (9.5 \pm 3.1) \times 10^{24}$ m$^{-2}$ and a systematic redshift of 380 ± 120 km s$^{-1}$, which is consistent with the LMC radial velocity (278 km s$^{-1}$). The derived elemental abundances are consistent with the average LMC abundance values. We discuss this more extensively in Sect. 4.2.

The model provides very good fits to the data, though a few discrepancies exist. For the most part, the fit discrepancies in Fig. 2 are a result of the difference between the broad band spatial profile used in the response and the actual spatial profiles of individual emission lines. The images in Fig. 4 and the monochromatic images in Sect. 3.2 show that the remnant’s morphology depends strongly on wavelength.

In addition to the spectral features which are present in the RGS spectra, the EPIC spectra also show more prominent emission from Si and also S. We do not detect any significant Fe-K emission nor emission from Ca and Ar. We extracted and fitted the EPIC-pn spectrum from the entire source. We use the EPIC-pn spectra because they provide the best statistics. As a starting point we used the same model and parameters obtained from the RGS fits. We first allow only the normalisations of the plasma components to vary and subsequently we allowed the absorption, temperature, ionisation age and abundances to vary. The fit results are supplied in Table 1. The derived parameters, except the normalisations, from the fit to the EPIC-pn data remain similar to those obtained from the RGS. The larger normalisations for the EPIC-pn are due to the higher $N_H$ and differences in the RGS and EPIC-pn calibrations (of the order 10%).

We also extracted and fitted the EPIC-pn spectra from both the outer and central region (see Figs. 1 and 3). The spectrum from the inner region is dominated by a broad emission peak around 0.9 keV from Fe-L. The spectrum from the outer rim is softer and shows more pronounced O-K (O VII and O VIII) and Mg-Kα lines. We fitted the spectrum extracted from the rim first. We find that this spectrum can not be well described using only one plasma component. A model composed of two NEI plasma components provides a better fit to the data. The fitting procedure was the same as for the full EPIC-pn spectrum. We then fitted the spectrum from the inner region. As a model we used one NEI component to account for emission from the central shell-like structure. In addition to this, we added the same plasma components and parameters as derived from the fits to the outer region. Only the normalisations from these components were allowed to vary. We do this to account for any projected fore/background shell emission.
The results of the fits are supplied in Table 2. The shell components ($kT_e \sim 0.3$ and 0.8 keV) have lower temperatures than the central component ($kT_e \sim 1.1$). Another significant difference between the two regions is the Fe/O and Si/O abundance ratio. The outer region has a Fe/O $\sim 1.6$ and Si/O $\sim 1.5$, while the inner regions has a much higher Fe/O $\sim 5.9$ and Si/O $\sim 2.3$. The interpretation is discussed in Sect. 4.3.

Some systematic fit residuals are present in the EPIC-pn fits. The most prominent residual is the underestimation of the spectra at $\approx 1.2$ keV. This is a known problem and is probably due to missing high excitation lines of Fe XXVIII-XXIX in the plasma code (see Brickhouse et al. 2000).

3.2. Monochromatic images and single ion spectroscopy

We extracted monochromatic images for various lines to probe variations in temperature and ionisation ages over the remnant and to further investigate the morphological differences between O and Fe emission. In order to compare RGS line images to one another one has to take into account an important systematic effect, which is the chromatic magnification that makes long wavelength images more “squashed” than the shorter wavelength images. We correct for this effect, to first order, by using the grating equations. The extent of the source...
Table 1. Best fit parameters for fits to the RGS and EPIC-pn spectra, extracted from the entire remnant. The abundance values are all normalised to O and relative to solar (Anders & Grevesse 1989). Note that C and N emission can not be determined from the EPIC-pn data, while the S-K emission is too weak to be detected by the RGS.

Fig. 4. RGS monochromatic images for Fe XVII (at 17.05 Å) (upper left) O VIII Ly-α (upper right), O VII-resonance (lower left) and O VII forbidden (lower right) lines. The images are plotted with the dispersion and cross-dispersion on the X and Y axis respectively. North is 18° clockwise, as indicated. The RGS dispersion direction is such that wavelength increases from right to left in the images.

of the source produces a maximum broadening of ±0.08 Å (O VII-r line), equivalent to a Doppler shift in either direction of 1100 km s\(^{-1}\). For comparison, the intrinsic wavelength resolution of the RGS is ~0.06 Å (FWHM) at 21.6 Å. However, any Doppler broadening is also convolved along the dispersion direction and, depending on its magnitude, could distort the RGS images. We present images for the O VIII Ly-α, O VII-resonance (r) and O VII-forbidden (f) line in Fig. 4. We choose these lines because they are the strongest features in the spectrum and because the O VII line ratios are valuable plasma diagnostics. We also extracted an Fe XVII image for the purpose of investigating the Fe emission morphology. The images are all on a on 2 × 2′ size. The images have been smoothed with a gaussian filter (FWHM of 4″ for O VIII Ly-α and 8″ for the rest).

First we turn our attention to the Fe/O emission morphology. The Chandra images (Hughes et al. 2003) suggest that most of the O emission originates from the outer shell, while the central region is (as compared to the rim) Fe rich. The Chandra observations, however, cannot resolve line blends so these images are possibly contaminated with underlying continuum emission as well as emission from different ion species (e.g. Ne). For this reason we turn our attention to the monochromatic images supplied by the RGS. The RGS O images and the Fe XVII image (see Fig. 4) confirm the Chandra results. The Fe XVII image shows a central filled morphology.
with some emission from the outer region. The O images show more emission from the outer rim with less emission in the central region. We also examined the cross-dispersion profiles, displayed in Fig. 5, to ensure the statistical significance of these results. We use the cross-dispersion since we have no velocity distortion in this plane, as opposed to the dispersion direction. Here, again, we see that the Fe emission profile is more centrally peaked as compared to the O emission.

Next we turn our attention to the differences between the morphology of the O VIII Ly-α, O VII-r and O VII-f emission. The images show significant differences between the three lines. The O VIII Ly-α emission predominantly comes from the rim. The O VII-r emission shows a brighter emission spot in the northwestern region while the O VII-f line shows a bright emission spot on the East rim. To ensure the statistical significance of these results we consider the dispersion profiles, displayed in Fig. 6. We now use the dispersion profiles because the differences in the lines show up more clearly in this plane. These lines should originate from the same location and have the same velocity structure since they are from the same ion. Any velocity distortion between these images should thus be insignificant as compared to the resolution of our instrument. These profiles confirm the variations in the O VII–f and O VII–r images.

One concern could be the possible contamination of O VII–r by its neighbouring O VII–i line. Due to the extent of the source, the O VII–i line emission from the West rim could show up at the long wavelength shoulder of the O VII–r emission line (i.e. the East rim in the O VII–r image). So any possible contamination would cause an increase in the O VII–r line in the East, we instead see the opposite. The intercombination line is, in any case, weak. We checked the spectra from various cross-dispersion regions, but did not see any evidence for an enhanced i line.

4. Discussion

4.1. Single ion spectroscopy

The O VII f/r line ratios, displayed in Fig. 7, indicate considerable temperature and ionisation age variations in the outer shell. To further investigate the implications of these variations we computed the O VII f/r for a NEI plasma using numerous combinations of temperatures and ionisation ages. The average ratio of ~0.65 corresponds to a plasma in the temperature range $kT_e \sim 0.1$–$0.4$ keV with $n_{e,T} > 3 \times 10^{17} \text{ m}^{-3} \text{ s}$. The ratio of ~0.4 in the northwest indicates an ionisation age and temperature combination ranging from ($n_{e,T} \sim 1 \times 10^{16} \text{ m}^{-3} \text{ s}, kT_e \sim 0.3$ keV) to ($n_{e,T} \sim 1 \times 10^{17} \text{ m}^{-3} \text{ s}, kT_e \sim 0.6$ keV).
The high f/r value in the East could indicate a low ionisation age \((n_e t \sim 1 \times 10^{15} \text{ m}^{-3}\text{s})\) plasma. However, such a low ionisation age plasma should produce strong O VII- intercombination \((i)\) line emission and we do not see any evidence for this in our data. The observed line ratio can also be obtained if the gas in this region is slowly cooling down to a temperature of \(~0.1\ \text{keV}\). Such a situation would produce a recombination spectrum with the observed f/r ratio and without a particularly strong O VII-\(i\) line. The next question, if we do indeed have a recombining plasma, is the feasibility of cooling in DEM L 71. Recombination effects would become notable if there were some energy draining mechanism operating at the shock front, e.g., particle acceleration (Dorfi & Börhringer 1993) or radiative shocks. If we assume an initial explosion energy of \(E_0 = 1 \times 10^{44} \text{J}\) and an electron density \(n_e \sim 3.2 \times 10^6 \text{ m}^{-3}\), as obtained in Sect. 4.3, then we estimate (according to Falle 1981) that the radiative cooling phase could commence at an age of \(~1.4 \times 10^3\ \text{yrs}\) and this time could be reduced if the blastwave encounters higher density ISM material in this region. If we consider that the estimated age of DEM L 71 is \(~1 \times 10^4\ \text{yrs}\) then this, together with the fact that radiative shocks have also been observed by Ghavamian et al. (2000), makes it possible that we have detected the effects of recombination. We attempted to model the EPIC-pn spectrum from the East rim with a recombination model. This model gave a good description of the data, but required a Fe abundance of greater than 20 times solar while the other elements had sub-solar abundances. We regard this model as being unphysical. It is probably incorrect to model emission from the entire rim with a recombination model since recombination could only be occurring at a localised region(s) along the rim, as suggested by the bright f line emission spot in Fig. 4 and the results of the Fabry-Perot observations of Ghavamian et al. (2000).

Alternatively, an increase in the f/r line ratio could be introduced by the presence of resonance scattering of the O VII-\(r\) photons. In the case of resonance scattering the effective velocity broadening needed to calculate the optical depth is determined from the maximum differential velocity over the region with optical depth \(\tau = 1\). We estimate a differential velocity of \(30 \text{ km s}^{-1}\), given an overall expansion velocity of \(800 \text{ km s}^{-1}\). This differential velocity includes both the gradient in the radial velocity component of the shocked gas as well as the effective azimuthal velocity difference due to the finite (azimuthal) extent of the last scattering surface \(\tau = 1\). If we assume a uniform spherical shell of thickness \(R_e/12\) and a velocity broadening of \(30 \text{ km s}^{-1}\), then we could expect an optical depth of \(\tau \sim 2.2\) and \(\tau \sim 1.0\) in the O VII-\(r\) and O VIII Ly\(r\) lines, respectively. Following the arguments put forward by Kaastra & Mewe (1995), an optical depth of \(\tau \sim 2.2\) could produce a factor of 2 reduction in the O VII-\(r\) line, which would then produce the observed f/r ratio. If the O VII emission originated in a homogeneously filled spherical shell then one would expect that, in the presence of resonance scattering, the O VII-\(r\) line image would be more centrally peaked as the photons would escape along the path of shortest optical length. This morphology is not observed. However, the effects of resonance scattering are highly dependent on the morphology and geometry of the system and resonance scattering could be limited to localised regions. The observed f/r ratio in the East could come about if the shock front encountered a dense inter-stellar medium (ISM) clump there. The O VII-\(r\) photons would then be scattered out of the line of sight, thus producing the observed f/r ratio. We neglected the broadening of the line profile due to microturbulence in the estimation of the optical depth. Microturbulence velocities of a few hundred \(\text{km s}^{-1}\) could reduce the optical depth quite considerably. However, such high microturbulent velocities in DEM L 71 are unlikely.

Further evidence for resonance scattering is provided by the O line profiles in Fig. 6. Since the estimated optical depth in the O VIII Ly\(r\) line is unity, the expected reduction in this line is a factor \(~3\) less than for O VII-\(r\). The O VIII Ly\(r\) and O VIII-\(f\) line profiles in Fig. 6 are quite similar, while most of the deviation is seen in O VII-\(r\). This suggests that the high f/r ratio is brought about by a reduction in the O VII-\(r\) line rather than an enhancement of the O VII-\(f\) lines. This is exactly what we would expect in the presence of resonance scattering.

### 4.2. Abundances and morphology

Figure 8 displays the elemental abundance ratios as derived from fits to the RGS data. The abundances are all relative to solar (Anders & Grevesse 1989) and normalised to O. The derived abundances are also compared to the average LMC abundance values (open circles). The ratios are all relative to solar (Anders & Grevesse 1989) and normalised to O. The LMC values are from Hughes et al. (1998).

![Fig. 8. Elemental abundance ratios as derived from fits to the RGS data](image-url)
is Balmer-dominated. Balmer-dominated optical spectra can be interpreted well in the context of a model in which a high-
velocity interstellar shock overtakes at least partially neutral
interstellar gas (Chevalier & Raymond 1978). Analysis of the
high spatially resolved Chandra ACIS-S CCD image shows that
the X-ray outer rim matches the optical Hα image nearly
perfectly (Hughes 2001).

The inner region is Fe rich. This is evident from the fits to
the EPIC-pn spectra which give Fe/O ∼ 1.6 and Fe/O ∼ 6.0 for
the shell and inner regions respectively. This Fe enrichment is
also visible in the RGS results, which show a higher Fe/O ratio
as compared to the LMC value. The higher Fe abundance has
also been noted in previous ASCA observations (Hughes et al.
1998). This indicates that the inner shell structure seen in the
Chandra images is (reverse shock heated) Fe-rich SN ejecta.
Fe-rich SN ejecta in the inner regions of SNRs is typical for
images is (reverse shock heated) Fe-rich SN ejecta.

1998). This indicates that the inner shell structure seen in the
Chandra images is (reverse shock heated) Fe-rich SN ejecta.
These results are consistent with shock temperatures of
∼ 0.11–0.75 keV) obtained from optical results (Smith et al.
1994). Temperature and ionisation age variations are also evident from the difference in
morphology between the O VII f and r lines. These lines show
an anomalously high ratio (f/r ∼ 1.2) in the East. This ratio
could imply that in this region the plasma is cooling and recombining. However, an alternative, and equally interesting, possibility is that the variation in f/r ratios is due to resonance scattering,
which would reduce O VII–r line emission along lines of
sight with a high O VII column density.

The Chandra images reveal a double shock structure in
DEM L 71. The EPIC-pn spectral analysis of these two regions
indicates that the inner region (kT e ∼ 1.1 keV) is hotter than
the shell (kT e ∼ 0.2–0.8 keV). The abundance ratios of the
outer shell is consistent with the average LMC values, while
the inner region shows a much higher Fe/O abundance ratio.
The outer shell has a much higher mass (∼80 M⊙) compared to
the inner shell (∼2 M⊙). The image and spectral analysis of
DEM L 71 thus suggests that the remnant has a structure consist-
ing of a hot centre surrounded by a cooler shell. This is in
agreement with shock models like Truelove & McKee (2001),
which predict a hotter interior. The outer rim represents a blast
wave moving out into the ISM, while the interior emission is
from reverse-shock-heated Fe-rich stellar ejecta material.
The morphology, mass estimates and abundances strongly suggest
that DEM L 71 is the result of a type Ia explosion as previ-
ously thought. Our analysis also confirms the recent results of
Hughes et al. (2003).

DEM L 71 is a good candidate object to study in order to
discriminate between the various type Ia supernovae models
(e.g. Nomoto et al. 1997). However, the current data do not
allow for this. Deeper observations would provide better statistics
to study the ejecta material in more detail, particularly the
density profile of the ejecta plasma and the possible detection
of Ar, Ca and Fe-K emission.

4.3. Mass estimates
The results of the line ratios show that the two NEI compo-

dent model used to fit the entire spectrum is highly simplified.
These temperature and ionisation age variations in the plasma
are probably also the reason why we need at least two com-
ponents to model the spectra. Despite our simplified model,
we can still use the results of the full spectral fits to estimate
parameters such as the mean electron densities and emitting
masses. We can infer these parameters from the emission mea-
sures, but to do this we need to make a volume estimate. The
Chandra images show that the X-ray emission from both re-

gions originate from limit brightened shells. The inner shell has
an average radius of ∼23″ while the outer shell has an average
radius of ∼37″. We assume that the outer shell has a thickness
of R/12. We use the radius and shell thickness assumption to
estimate the volume, which in turn is used to calculate the
electron density and masses. We estimate the outer shell to have an
electron density n e = 3.2 × 106/√T m−3 which yields a swept
up mass of M shell ∼ 80 M⊙ √T, where f is the (shell) volume
filling factor.

The mass estimate of the ejecta (central) region depends on
the amount of H mixed into the ejecta during its evolution (see
Hughes et al. 2003 for complete explanation). We thus, follow-

ing the example of Hughes et al. (2003), compute the masses
for two astrophysically plausible scenarios; 1) We assume that
metals are the sole source of electrons 2) assume that a com-
parable amount (in mass) of hydrogen has been mixed into the
metal rich ejecta. We use the volume estimate for a spherically
symetric shell. The Chandra images indicate an average radius of
∼23″ and a shell thickness of ∼11″ for the central region. A
pure metal composition yields 1.1 M⊙ of Fe and 0.15 M⊙ of Si,
while an admixture of H yields 0.7 M⊙ of Fe and 0.1 M⊙ of Si.
These values are similar to and confirm the results of Hughes
et al. (2003).

There are observational and theoretical indications that
type Ia SNe are thermonuclear explosion of accreting white
dwarfs (e.g. Nomoto et al. 1994), however, the exact bi-
nary evolution has not been identified. Nomoto et al. (1997)
provided some constraints on the progenitor system from the
viewpoint of nucleosynthesis. They presented nucleosynthesis
results for various deflagration speeds to constrain the rate of
accretion from the companion star. The measurement of the
Si/Fe, S/Fe, Ar/Fe and Ca/Fe mass ratios would be useful to
distinguish the type Ia models (Nomoto et al. 1997). We are
only able to derive mass estimates for Fe and Si. Nomoto
et al. (1997) predicts a Si/Fe mass ratio of ∼0.25 for the clas-
sical (W7) type Ia model and ∼0.44 for a delayed detonation
(WDD2) model. The present data do not allow us to discrimi-
nate between models. Deeper observations of DEM L 71 could
detect S, Ar and Ca emission which would be useful in identi-

fiying the type Ia SNe model.

5. Summary and conclusions
The high resolution XMM-Newton emission line spectra of
DEM L 71 can be fitted with two NEI plasma components. The
RGS spectra are dominated by emission from the SNR shell,
so the two NEI components needed to fit these spectra indi-
}cate a range of temperatures and ionisation ages present in
the shell. The temperatures (kT e ∼ 0.2 and 0.8 keV) are consistent
with the shock temperature (kT s = 0.11–0.75 keV) obtained from
optical results (Smith et al. 1994). Temperature and ion-
isation age variations are also evident from the difference in
morphology between the O VII f and r lines. These lines show
an anomalously high ratio (f/r ∼ 1.2) in the East. This ratio
could imply that in this region the plasma is cooling and recombining. However, an alternative, and equally interesting, possibility is that the variation in f/r ratios is due to resonance scattering,
which would reduce O VII–r line emission along lines of
sight with a high O VII column density.

The Chandra images reveal a double shock structure in
DEM L 71. The EPIC-pn spectral analysis of these two regions
indicates that the inner region (kT e ∼ 1.1 keV) is hotter than
the shell (kT e ∼ 0.2–0.8 keV). The abundance ratios of the
outer shell is consistent with the average LMC values, while
the inner region shows a much higher Fe/O abundance ratio.
The outer shell has a much higher mass (∼80 M⊙) compared to
the inner shell (∼2 M⊙). The image and spectral analysis of
DEM L 71 thus suggests that the remnant has a structure consist-
ing of a hot centre surrounded by a cooler shell. This is in
agreement with shock models like Truelove & McKee (2001),
which predict a hotter interior. The outer rim represents a blast
wave moving out into the ISM, while the interior emission is
from reverse-shock-heated Fe-rich stellar ejecta material.
The morphology, mass estimates and abundances strongly suggest
that DEM L 71 is the result of a type Ia explosion as previ-
ously thought. Our analysis also confirms the recent results of
Hughes et al. (2003).
