Abstract. We analyse spectroscopic observations of WR 20a revealing that this star is a massive early-type binary system with a most probable orbital period of ~3.675 days. Our spectra indicate that both components are most likely of WN6ha or O3IIf/WN6ha spectral type. The orbital solution for a period of 3.675 days yields extremely large minimum masses of 70.7 ± 4.0 and 68.8 ± 3.8 M⊙ for the two stars. These properties make WR 20a a cornerstone system for the study of massive star evolution.

Key words. binaries: spectroscopic – stars: early-type – stars: fundamental parameters – stars: individual: WR 20a

1. Introduction

Although it is generally accepted that Wolf-Rayet (WR) stars are evolved descendants of massive O-stars, many open questions remain about the evolution of these objects. Among the most fundamental issues is the importance of mass transfer in the evolution of massive O + O binaries (e.g. Vanbeveren et al. 1998). It is therefore of prime interest to achieve as complete a census of WR binaries as possible and to investigate the fundamental properties of individual massive binary systems.

Among the 227 objects listed in the VIIth Catalogue of Galactic Wolf-Rayet Stars (van der Hucht 2001), there are only 52 known spectroscopic binaries and only 32 of them have reliable orbital solutions. In addition to these confirmed binaries, van der Hucht (2001) provides a list of 30 rather faint and poorly studied objects that are potential WR + OB binaries. Most of these binary candidates were classified as such because of their comparatively weak emission lines that could be the result of the dilution by the continuum light of an OB-type companion. In order to search for a composite spectrum – and hence confirm multiplicity – we performed a snapshot spectroscopic survey of a sample of WR binary candidates. One of the most interesting objects that emerged from our survey was WR 20a.

WR 20a (=THA 35-II-036 = SMSP2) was catalogued by Thé (1966) in an Hα emission line survey, and first discovered to be a WR star by Shara et al. (1991) in the course of a deep narrow and broadband photometric survey for galactic Wolf-Rayet stars in the southern Milky Way. The latter authors also obtained a low-resolution (2 pixel resolution of 7 Å) spectrum of the star and proposed a WN7 spectral type, although they noted the lack of a He II λ 5411 emission line. Shara et al. (1991) suggested that WR 20a had a rather high H/He abundance ratio. Later, the object was re-classified as WN7: h/He by Shara et al. (1999). The star is believed to be a member of the young open cluster Westerlund 2 in the core of the H II region RCW 49 (Moffat et al. 1991). In this letter, we first present our blue/violet observations of WR 20a (Sec. 2). The spectral features as well as the nature of WR 20a are revisited in Sect. 3.1, whilst Sect. 3.2 deals with an analysis of the radial velocities. Finally, we briefly discuss the implications of our results in Sect. 4.

2. Observations

Two snapshot spectra of WR 20a were obtained in March 2002 with the EMMI instrument mounted on ESO’s 3.5 m New Technology Telescope (NTT) at La Silla. The EMMI instrument was used in the BLMD medium dispersion spectroscopic mode with grating # 3 (1200 lines mm−1) providing a wavelength coverage of 460 Å per set-up. The central wavelength was set to 4080 Å (violet setting) or 4530 Å (blue setting). The exposure times were 30 min for each setting and the
corresponding S/N was about 100. The spectral resolution as determined from the FWHM of the lines of the Th-Ar comparison spectra was about 1.25 Å. The data were reduced in the standard way using the Long context of the MIDAS package. The violet spectrum taken on HJD 2452355.60 revealed double absorption lines of hydrogen and helium as well as a moderately strong double-peaked N IV λ4058 emission. On the other hand, the blue spectrum obtained on HJD 2452354.56 showed single absorption lines of hydrogen, He II and N V. These properties suggested that WR 20a could be a short period binary consisting of two very early extreme Of-type stars (Driesens 2003).

We thus organized a follow-up observing campaign to confirm the binarity of WR 20a. The star was monitored over 12 consecutive nights in January–February 2004 with the same instrumentation as in March 2002. The weather conditions were good except for the last two nights where the seeing and the transparency were poor. The data were reduced in the same way as in 2002 and the complete journal of the useable observations is given in Table 1.

3. Results

3.1. The spectrum of WR 20a

Our data reveal that WR 20a is indeed a short-period binary system (see below). All prominent spectral features appear double with nearly identical intensities on most of our spectra (see e.g. Fig. 1) indicating that the components of WR 20a must have identical spectral types and a visible brightness ratio of ~1. The spectrum of WR 20a displays many absorption lines of H I, He II and N V unlike what we would expect if WR 20a were indeed a “classical” WN7 star (see however below). Only a few (rather narrow) emission lines are seen in the blue/violet spectrum: N IV λ4058, He II λ4686 as well as a broad complex probably due to N III λλ4634-41, C III λλ4647-50 and possibly C IV λ4658. The Balmer absorption lines also display some broad underlying emission wings on several spectra. The emissions seen around the Hδ absorption in Fig. 1 could actually be due to Si IV λλ4089, 4116, but the spectra obtained on other nights do not allow us to unambiguously confirm this identification. In addition to the strong diffuse interstellar bands, we note the presence of the interstellar He I λ3889 absorption line. This latter feature was also observed in the spectra of several early-type stars of the Carina Nebula (Walborn & Hesser 1975). This line is not usually seen in interstellar sightlines (cf. ζ Oph, Shulman et al. 1974) and may be formed locally as in the case of the Carina stars.

No stellar He I lines are clearly seen in the spectrum. Together with the presence of rather strong N V absorption lines, this would suggest a very early O-type classification for the components of WR 20a. The presence of He II λ4686 in strong emission further suggests a supergiant luminosity class. Comparing our spectra to the classification scheme of Walborn et al. (2002, see also Walborn 2001), we would propose an O3 If∗ spectral type for both stars. However, distinguishing an extreme Of star from a weak-lined WNL star is a very tricky issue. In this context, Crowther & Dessart (1998) proposed $\text{EW(He II } \lambda4686) = 12 \, \text{Å}$ as a boundary between O3 If*/WN and WN5-6 stars. For WR 20a, we determine $\text{EW(He II } \lambda4686) = 13.1 \, \text{Å}$ with a 1-σ dispersion of 1.3 Å, right at the borderline proposed by Crowther & Dessart. Since
the He II λ 4686 emission could contain a contribution from a wind interaction process, we consider this an upper limit on the actual strength of the line. Comparing the spectrum of WR 20a obtained near conjunction with the spectra of several extreme O stars and weak-lined WN stars, we find that the components of WR 20a are indeed intermediate between Mk 42 (O3If′/WN) and HD 97950C (=WR 47c, WN6ha). Finally, the spectrum of WR 20a presented by Shara et al. (1991) indicates that the H β line is in weak emission. The latter feature favours a WN6ha spectral type. We shall thus adopt a WN6ha classification for both components of WR 20a, though we cannot fully exclude an O3If′/WN6ha type. The Shara et al. (1991) spectrum of WR 20a suggested the presence of a C IV λ 15808 emission with a normalized intensity stronger relative to He I λ 5876 than in normal WN stars, thus leading to the WN/WC classification proposed by Shara et al. (1999). Note that our blue/violet spectra do not provide support for such a hybrid type.

3.2. Orbital solution

We have measured the radial velocities (RVs) of the components of WR 20a by fitting Gaussians. The typical uncertainties on individual RV measurements are of order 10–15 km s$^{-1}$ for those phases when the components are resolved$^1$.

A major issue in determining the orbital period arises from the fact that the spectral types of both stars are identical. In fact, the spectra do not allow us to distinguish the components a priori. Therefore, we performed a period search on the absolute values of the radial velocity differences |RV$_1$ – RV$_2$|. In this way, we expect to find the highest peak in the periodogram at $v_t = 2/P_{\text{orb}}$. Using the Fourier technique of Heck et al. (1985, see also Gosset et al. 2001), we find that the most likely value of $v_t$ is 0.544 ± 0.009 day$^{-1}$. However, there is a strong ambiguity with the 1 – $v_t$ alias at 0.453 ± 0.009 day$^{-1}$ which produces only a slightly smaller (formal) peak in the periodogram (see Fig. 2). Our preferred value for the orbital period is therefore 3.675 ± 0.030 days, but we cannot discard the alternative value of 4.419 ± 0.044 days. Alternatively, if (the slightly smaller) peak at the 1 + $v_t$ alias (1.547 day$^{-1}$) were to be selected, the orbital period would be ~1.29 days, i.e. even shorter than the 1.64 day period of CQ Cep, the shortest period WN binary system known to date (see e.g. van der Hucht 2001).

As a next step, we determined the apparent systemic velocity of each spectral line from an orbital solution obtained for the RVs of the specific line. In this way, we found apparent systemic velocities of −75, −18, −77, −42, −51 and −26 km s$^{-1}$ for the H$_\gamma$, He II λ 4542, N V λ 4604, N V λ 4620, N IV λ 4058 and H$\delta$ lines respectively. Finally, we averaged the RVs of the different lines listed above after subtracting their systemic velocities. The results are listed in Table 1.

Due to the ambiguity about the right alias in the periodogram, we caution that the orbital phases as well as the primary/secondary identifications in Table 1 are only valid if the orbital period is indeed 3.675 days. Adopting this period, we have derived the orbital solution of WR 20a using the technique described by Sana et al. (2003). Since the RVs show no indication of a significant orbital eccentricity, we assumed a circular orbit. The results are provided in Table 2 and the RV curve is illustrated in Fig. 3. We emphasize that orbital solutions derived from the RVs of individual spectral lines overlap within the errors with the results in Table 2.

The most important results are the large minimum masses of 68.8 ± 3.8 and 70.7 ± 4.0 $M_\odot$ derived for the secondary and primary component respectively. It should be emphasized that these values strongly depend on the adopted orbital period. In fact, the alternative orbital period (4.419 days) would lead to even larger minimum masses of 80.8 ± 5.1 and 84.0 ± 5.3 $M_\odot$ respectively. If, on the contrary, the 1 + $v_t$ alias corresponding to an orbital period of 1.293 days were selected, the minimum masses would be much lower (24.9 ± 1.4 and 25.9 ± 1.4 $M_\odot$). We note however, that in the latter case, the orbital solution is of significantly lower quality than the one obtained for an orbital period of 3.675 days.

4. Discussion and future perspectives

The WN6ha or O3 If′/WN6ha spectral type of the components of WR 20a is significantly earlier than those of the earliest members (O6 V–O7 V) of Westerlund 2 analysed by Moffat et al. (1991).

Several authors have estimated the distance of Westerlund 2: 7.9$^{+1.0}_{-0.5}$ kpc (Moffat et al. 1991); 5.7 ± 0.3 kpc (Piazzii et al. 1998); 6.4 ± 0.4 kpc (Carraro & Munari 2004). Adopting a visual brightness ratio of 1 together with the photometry of Moffat et al. (1991; $V = 13.58, B - V = 1.51$) the various distance estimates yield absolute magnitudes $M_V$ in the range −5.0 to −6.1. This is fainter than the average of
The first and second columns provide the heliocentric Julian date (in the format HJD−2 450 000) and the orbital phase assuming a period of 3.675 days and adopting phase $\phi = 0.0$ as given in Table 2. The third column indicates whether the blue ($B$) or violet ($V$) spectral range was observed. The recentred and averaged primary and secondary radial velocities are given inCols. 4 and 5 respectively (see text). Finally, the last column yields the weight that we assigned to the various RV data in the orbital solution.

Table 1. Journal of our spectroscopic observations of WR 20a. The recentred and averaged primary and secondary radial velocities are given inCols. 4 and 5 respectively (see text). Finally, the last column yields the weight that we assigned to the various RV data in the orbital solution.

</table>

Three WN6ha stars in NGC 3603, namely $−6.9$ to $−7.7$ mag$^2$, such that only the largest published distance of Westerlund 2 would be in marginal agreement with the photometry of WR 20a, for allowing a cosmic scatter of $0.5−0.7$ mag on $M_V$. This problem would be less severe if the absolute magnitudes of the components of WR 20a were more typical of O31 stars ($M_V = −5.9$ according to Crowther & Dessart 1998). Alternatively, WR 20a could actually be unrelated to Westerlund 2 (though the rarity of early-type stars and the angular proximity of WR 20a to the cluster strongly suggest membership) or the photometry of Moffat et al. could be affected by photometric eclipses. Concerning the last possibility, we note that given the extremely large minimum masses of

$^2$ Moffat et al. (1994) derived an average $M_V$ of $−7.7$ for the three H-rich WN stars in NGC 3603, whilst Crowther & Dessart (1998) re-evaluated their distance and reddening and obtained an average of $−6.9$ mag.

Three of the components in WR 20a, it appears very likely that the system could display eclipses. A photometric monitoring of this binary is therefore of the utmost importance in order to help derive its absolute magnitude, to get rid of the aliasing problem of the RV data and to constrain the orbital inclination. We intend to organize such a campaign in the near future.

An important issue in the context of the formation and the evolution of very massive stars is that of the mass of the most massive ones. Masses up to $≈200 M_\odot$ have been inferred for the most luminous O2 stars from a comparison with evolutionary tracks (Walborn et al. 2002). However, to date, none of the O2 stars is known to belong to a binary system that would allow to determine its mass in a less model dependent way. The most massive main-sequence stars in binary systems known so far were found in R 136-38 (O3 V + O6 V) and R 136-42 (O3 V + O3 V). Massey et al. (2002) determined
masses of 57 and $40M_\odot$ respectively for the O3 V primary stars of these systems. Another extremely massive object is the WN7ha primary in the 80-day period binary WR 22 (Rauw et al. 1996; Schweickhardt et al. 1999) with a minimum mass of $55M_\odot$. WR 20a thus probably consists of two of the most massive stars with a direct mass determination known so far. Therefore, WR 20a is certainly a cornerstone system for future investigations of massive star evolution.

Finally, we note that the emission lines in the spectrum of WR 20a display strong phase-locked profile variability. This aspect will be discussed along with an analysis of the spectrum with a model atmosphere code in a forthcoming paper.
