Abstract. We present simulations of different scanning strategies for the Planck satellite. We review the properties of slow- and fast-precession strategies in terms of uniformity of the integration time on the sky, the presence of low-redundancy areas, the presence of deep fields, the presence of sharp gradients in the integration time, and the redundancy of the scanning directions. We also compare the results obtained when co-adding all detectors of a given frequency channel. The slow-precession strategies allow a good uniformity of the coverage, while providing two deep fields. On the other hand, they do not allow a wide spread of the scan-crossing directions, which is a feature of the fast-precession strategies. However, the latter suffer from many sharp gradients and low-coverage areas on the sky. On the basis of these results, the strategy for Planck can be selected to be a slow (e.g. 4 month-period) sinusoidal or cycloidal scanning.

Key words. cosmic microwave background – methods: observational

1. Introduction

In the last decade there has been a huge increase in the number of experiments dedicated to measurements of the fluctuations of the Cosmic Microwave Background (CMB), e.g. Smoot et al. (1992), de Bernardis et al. (2000), Hanany et al. (2000), Kovac et al. (2002), Benoît et al. (2003), Pearson et al. (2003), Bennett et al. (2003b). These experiments seek to measure a signal whose intensity is very low with respect to the background signal (∼10⁻⁵), over a wide range of angular scales, with the most ambitious experiments aiming at covering the whole sky with an angular resolution of the order of 10′ or better. Such experiments are plagued by a host of systematic effects which arise in the instrument itself (e.g. 1/f detector noise, thermal effects), or in celestial signals which are picked up by the instrument (e.g. straylight due to Galactic emission entering through far sidelobes). A key factor in the success of these experiments is the pattern with which the detector lines-of-sight sweep over the sky, often referred to as the scanning strategy.

The scanning strategy is usually defined on the basis of the instrumental capabilities, e.g. it is designed to allow the suppression of inherent features in the detector behavior by the use of redundancies (or repeated visits to the same part of the sky). This is akin in some ways to the use of hardware chopping, and is therefore largely specific to each experiment. At the same time the scanning strategy introduces symmetries in the data acquisition stream, which has implications for the data reduction process which converts the time sequence of acquired data into a map. Since the data reduction is very computer-intensive (Bond et al. 1999), the scanning strategy design also attempts to enhance (respectively reduce) those symmetries which simplify (respectively complicate) the conversion.

In this paper we concentrate on the scanning strategy aspects of the Planck satellite, a third-generation CMB experiment; however there are generic features in our analysis which are applicable to other experiments with similar objectives.

The Planck satellite (Tauber 2001, http://rssd.esa.int/Planck) is a European Space Agency project designed to map the whole sky at wavelengths ranging from 350 μm to 1 cm with unprecedented sensitivity (∆T/T = 2 × 10⁻⁶) and angular resolution (5′−30′). Its main cosmological objective is to derive a very accurate angular power spectrum of the CMB fluctuations, both for the temperature and the E-mode polarization. It is also considered feasible that it will detect and analyse B-mode CMB polarization signals.

The Planck payload consists of a large offset telescope which collects radiation from the sky and delivers it to a focal plane populated with 70 detectors. The detectors are of two kinds: tuned receivers based on low-noise amplifiers operating in the 20−80 GHz band (Mennella et al. 2003), and wideband bolometers operating in the 90−1000 GHz range (Lamarre et al. 2003). In both cases the detectors are fed by corrugated feedhorns which collect radiation from the telescope and define the angular responsivity of the detectors. Both kinds of detector are very sensitive and stable, allowing them to operate in a “total-power” mode. This was not the case for the earlier CMB experiments which today define the state of the art of CMB anisotropy research (COBE/DMR and WMAP, http://lambda.gsfc.nasa.gov); instead they...
were designed to be differential to overcome inherent instabilities in the detectors (i.e. the measured signals consist of differences of observations of different patches of the sky). The principle of Planck has however been demonstrated on smaller-scale balloon-based experiments, e.g. BOOMERANG (de Bernardis et al. 2000) and Archeops (Benoît et al. 2002).

In order to achieve its scientific objectives, the scanning strategy of Planck must ensure that:

- the whole sky is covered by all detectors. An ideal survey would provide homogeneous sensitivity across the whole sky (indeed one of the most difficult issues in the data reduction process of large CMB surveys is to understand the behavior of noise across the map), but this is in practice very difficult to achieve by any continuous-sweep experiment. Given that there will be both under- and oversampled regions of the sky, it is generically advantageous to confine them to compact, connected areas, which will offer specific scientific research opportunities (e.g. high-sensitivity and/or high-multipole CMB analysis, but also studies of the Sunyaev-Zeldovich effect);
- there is enough redundancy at all time and angular scales to allow the detection and removal of spurious systematic effects down to the intrinsic sensitivity level of the detectors. The detection and removal process is largely ensured by processing algorithms often dubbed “de-stripers” (e.g. Delabrouille 1998), which are tailored to the specific experimental characteristics. The efficiency of the de-stripper will also depend on the type of spurious noises encountered; in particular map-making algorithms (e.g. Doré et al. 2001; Natoli et al. 2001; Dupac & Giard 2002) are very sensitive to non-stationary noises, and require crossing scans to be present in a large part of the sky.

The Planck satellite will be placed in a Lissajous orbit around the Sun-Earth L2 Lagrange point (see Fig. 1), which guarantees low levels of thermal disturbances and straylight from the Sun, the Earth and the Moon. The focal plane points at an angle of about 85° from the satellite’s spin axis, so that as it rotates, the focal plane footprint (see Fig. 2) traces a large circle on the sky.

The satellite spin axis approximately tracks the direction of the Sun by means of regular repointing manoeuvres, cumulating to an average of 1° per day. These repointing manoeuvres must be such that the sampling density of the sky in the repointing direction obeys the Shannon criterion (i.e. the spacing is at least 2.5 times smaller than the FWHM of the main beam patterns). The scanning strategy is in practice the sequence of repointing manoeuvres that the satellite will carry out over its lifetime. A number of technical factors constrain rather severely the satellite attitude and must be taken into account when designing an optimal scanning strategy. Among these are:

- pointing accuracies;
- manoeuvrability and on-board fuel consumption;
- solar irradiation and thermal transient as well as periodic effects;
- contact with ground antennas and RF interference.

More details on the constraints on the Planck scanning strategy can be found in Tauber (2003).

To determine an optimal scanning strategy for an experiment such as Planck, detailed modelling has to be carried out which simulates:

- the sources of signal (sky, but also spurious);
- the convolution of the instrument response with the signals as a function of time;
- the conversion of the simulated time stream to maps;
- the detection and removal of unwanted signals to recover the CMB anisotropy map;
- ideally, also the compression of the CMB map into an angular power spectrum;

for each possible strategy, followed by a comparison of the noise properties of the recovered maps. Such modelling is at least as complex as the processing foreseen on the acquired data, and prohibitive using traditional schemes at the current time. A much simpler analysis is possible based on “hit maps” (i.e. maps of the redundancy behavior expressed as the number of visits per map pixel, or equivalently as the integration time per pixel) and a relative assessment of these maps in each of the major areas previously mentioned. In this paper we
present such an analysis of the main scanning strategy options for Planck.

2. Simulations of scanning strategies for the Planck mission

For each scanning strategy considered, we have simulated the spin axis coordinates of Planck throughout a year, and based on this we have produced integration-time maps of the whole sky with pixels of size 27′. Strictly speaking, the resolution of these maps is not adequate for sampling the detector beams. However, this does not affect our analysis, since we do not consider strategies which violate the sampling requirements (see e.g. Sect. 2.2), and any spatial structure in the integration time at the scale of the beam size or lower is in reality smoothed out by convolution with the beam. For all maps we use the HEALPix Ring pixelization scheme of the sphere (Górski et al. 1999). All simulations have been performed using home-made Interactive Data Language (IDL) procedures.

2.1. The nominal strategy

The simplest possible scanning strategy for Planck is one whereby it maintains the spin axis pointed as close as possible to the Sun, while keeping strictly to the sampling requirement along the Ecliptic plane. This results in a displacement step of the spin axis along the Ecliptic plane of 2.5′ every hour. With this strategy, each detector observes the same (nearly 85°-wide) circle ∼55 times before moving to the next one (hereafter we shall refer to each spin revolution as a “circle” and to each set of identical circles as a “ring”).

This strategy (referred to as the nominal strategy) has the advantage that the inclination angle of the satellite to the Sun is kept nearly constant and orthogonal, which minimizes Sun-induced thermal variations. It also maximizes the mapping efficiency (i.e. minimizes the time lost in stepping manoeuvres). A clear disadvantage is that most detectors will not survey the two five-degree radius caps around the Ecliptic poles; the fraction of the sky not seen varies from 0.008% (30 and 44 GHz) to 0.5% (143 GHz). Because of its simplicity, the nominal strategy is the one used to assess the technical and operational capabilities of the satellite. It is however not likely that it will be used for Planck, due to the above disadvantage.

Figure 3 shows the scan pattern of the main optical axis for a one-year survey, and Fig. 4 shows the integration-time map corresponding to a one-year observation for one detector assumed to be on the main optical axis. The integration time is distributed in a simple manner with Ecliptic latitude, peaking near the poles.

2.2. Simple generic scanning strategies

An excursion of the spin axis from the Ecliptic plane can be used to overcome the coverage holes left by the nominal strategy around the Ecliptic poles. A second generic by-product of such excursions is to distribute the integration time to lower Galactic latitudes than in the nominal case. This can be of benefit to a number of destriping algorithms (see e.g. Delabrouille 1998) since it distributes the number of re-visits more widely over the sky.

However, the thermal and straylight design of the satellite requires that any excursions from the anti-solar pointing of the spin axis of the satellite must not have larger amplitudes than about 10°. Furthermore, excursions entail the risk of generating thermal fluctuations which may result in systematic effects.

We have simulated two kinds of precession of the spin axis of the satellite:

1. in the first (“cycloidal”) type, the spin axis follows a circular path around the anti-solar axis, which is equivalent to a cycloidal path as a function of Ecliptic longitude. Here the inclination angle of the satellite to the direction of the Sun is constant and therefore Sun-induced thermal variations are kept to a low level;

2. in the second (“sinusoidal”) type, the spin axis path has two components: the first is along the Ecliptic plane, and the second is perpendicular to the Ecliptic plane, with a sinusoidal amplitude in time. Its path is therefore also sinusoidal along the Ecliptic equator.
In both cases the period of the excursion is a free parameter; we have simulated both slow and fast periods for each kind. The slow excursions have a period of 6 months, synchronised to the period of the orbit around L2, which in the cycloidal case offers some advantages for the transmission of data to Earth. It has however been shown by P. Leahy (priv. comm.) that it would be advantageous from the point of view of dipole-based calibration to reduce the period to 4 months. We have performed simulations using a cycloidal precession with periods of 4 months and 2 months in order to characterize the intermediate strategies between the “slow” and “fast” ones. The fast excursions are selected to have the shortest possible period (18 days) while providing a reasonable dwell time on each spin axis pointing (25 min); a shorter period would decrease the observing efficiency to less than 80%.

Figure 5 presents the scan patterns for a one-year observation in the case of the slow and fast cycloidal 7° precessions. For clarity, only one ring in 300 is plotted (one in 600 for the fast precession). The positions of the spin axis are also shown.

![Figure 5. Scan pattern of the main optical axis for a one-year survey with the slow (top) and fast (bottom) cycloidal 7° precessions. For clarity, only one ring in 300 is plotted (one in 600 for the fast precession). The positions of the spin axis are also shown.](image)

The precession angle is 7°. Mollweide projections of the whole sky in Galactic coordinates (the Galactic plane is horizontal, the Galactic north pole is at the top).

### 2.3. Complex scanning patterns

In principle any number of variations on the above simple types can be considered, as long as the basic attitude and sampling requirements are obeyed. Some of these variations are:

- large step-like variations in the spin-axis orientation;
- half-sine scans: sequential positive half-sine scans followed by negative ones;
Therefore we confine ourselves to an analysis of the latter. Our investigations into a few of these options indicate that they do not offer significant advantages over the simpler strategies. Therefore we confine ourselves to an analysis of the latter.

3. Results of the simulations

We have analysed the various scanning strategies in terms of properties of the distribution of the observation time on the sky. Our main criteria are:

- the completeness and homogeneity of the coverage;
- the surface, depth and connectedness of deep fields;
- the characteristics of sharp gradients in the integration-time maps;
- the redundancy in the scanning directions.

In the following, we detail the characteristics of the different scanning strategies investigated towards these criteria, in terms of the response of a single detector located along the focal axis. In Table 1, quantified characteristics are provided. The (minor) effects of including all detectors in the analysis are addressed in Sect. 3.2.

#### 3.1. Completeness and large-scale homogeneity

The nominal strategy (Fig. 3) exhibits good uniformity and smooth coverage, except that the Ecliptic poles are not covered at all for some detectors, which is a shortcoming for this strategy. However, the non-covered area is relatively small (0.3% for a detector at the main optical axis), and it could be filled in by specific short-duration (a few days) observations.

As Figs. 6 and 7 show, the slow precession strategies exhibit good uniformity of the integration time on the sky, except around the Ecliptic poles where we find deep-field candidates. The fast-precession simulations show non-uniformities and sharp gradients over the whole map. The fast-precession strategies have two significant weaknesses compared to the slow precession: the proportion of the sky which is not well covered is high (see Fig. 8), and there are no significant deep fields (see Sect. 3.3). The differences in terms of average integration time on the whole sky are due to the fact that more time is lost in manoeuvres in the case of the fast-precession strategies.

There are few differences between the cycloidal and sinusoidal strategies; one is that the sinusoidal strategies are perfectly symmetrical with respect to the Ecliptic equator, which is not the case for the cycloidal strategies.

The main difference that arises when changing the precession angle (see Fig. 7) is that the size and depth of the long-integration patches change. Although not shown, this applies to sinusoidal strategies as well.

---

**Fig. 7.** Integration-time maps for one detector and a one-year survey for the slow cycloidal strategy. The precession angles are respectively 5° and 10° from top to bottom. Mollweide projections of the whole sky in Galactic coordinates (the Galactic plane is horizontal, the Galactic north pole is at the top).
3.2. The effect of co-adding several detectors

Most detectors in the Planck focal plane are co-aligned along the scanning direction (Fig. 2), and for these the integration time maps scale up simply from that of a single detector. For many frequency channels, however, the detectors are spread more widely across the scan direction and therefore some smoothing effect can be expected when co-adding all detector maps at a given frequency. In Table 2 we illustrate this effect in the case of the slow cycloidal strategy. The generally small differences seen do not change the conclusions drawn from the analysis of one detector. Although not explicitly shown, for other types of strategy the situation is similar.

3.3. Deep fields

As discussed previously, areas with very high signal-to-noise are of special scientific interest. It should however be noted that the Planck design implies that these fields will inevitably be located at high (positive and negative) Ecliptic latitudes, which are certainly not the cleanest parts of the sky in terms of foregrounds.

We define “deep fields” as areas that have at least 9 times more integration time than the sky average (i.e. 3 times more sensitivity). It is clear that almost any slow scanning strategy allowed for Planck will produce deep fields. As can be seen in Table 1, the two slow-precession strategies make it possible to obtain two relatively large deep fields (about 90 deg$^2$ each) around the Ecliptic poles. It is also important that the areas with high signal-to-noise do not consist of many disconnected patches. This is the case for the slow strategies (see Fig. 9). The effect of changing the amplitude of the excursion (Fig. 7) is to spread the highly-covered fields (avg x 4) over a larger area, but the size of the really deep fields is not much affected.

Additional issues (Leahy, priv. comm.) to be considered with respect to deep fields are:

- the extent to which deep fields overlap for different frequency channels. This is adequate at least for the central (CMB) channels;
- the connectivity within the deep fields. In this respect, 6-month period strategies are better than shorter-period strategies where the symmetries imply that the fields break up into several patches.

3.4. Sharp gradients in the observing-time map

The presence of sharp angular gradients in the noise characteristics creates severe difficulties for the recovery of the wanted signals (map-making). Detailed simulations are required to determine what levels are acceptable, furthermore currently the exact map-making algorithms that will be used by Planck have not been selected. Therefore we define a conservative threshold of acceptability as being that where the ratio between the integration-time gradient (per pixel) and the time quantity is below 2. Table 1 presents the fractional sky area which exhibits unacceptably sharp gradients, according to the above definition, and calculated using the Roberts edge-detection technique.

This analysis indicates that the fast scanning strategies exhibit a non-negligible amount of areas with sharp gradients. In contrast, the nominal and slow strategies do not exhibit a significant amount of such areas.

3.5. Scanning directions per pixel

The measurement of polarisation presents specific challenges for the scanning strategy. As outlined previously, to measure Stokes I, Q and U, Planck makes use of four detectors which are aligned along the scan direction. Together, the four detectors probe four directions of linear polarisation and constitute a minimum necessary set. However, probing more directions would help considerably to pin down more accurately the recovery errors. To be effective, the directions probed by each of the detectors thanks to the scanning redundancy should be homogeneously spread between 0$^\circ$ and 45$^\circ$ (Couchot et al. 1999), e.g. if only two measurements are taken, they should ideally be 22.5$^\circ$ apart. The focal plane design of Planck is such (see Fig. 2) that it is enough to use one detector (out of
Fig. 9. Close-up of the North Ecliptic polar regions for the slow (top) and fast (bottom) cycloidal strategies. The South Ecliptic regions are similar to these.

Fig. 10. The distribution of the number of scanning direction bins probed by one detector in each pixel, in the case of the slow (top) and fast (bottom) cycloidal strategies. The sampled directions are collected in 11 bins evenly spread around $2\pi$. Mollweide projections of the whole sky in Galactic coordinates (the Galactic plane is horizontal, the Galactic north pole is at the top).

each co-aligned group of four) to gauge the number of directions probed, and to use as a reference the direction of the scan across the sky (rather than the actual polarization direction of the detector). Therefore, we calculate the scan angle of each observation, i.e. the angle the scan direction makes with respect to isolatitude lines, and we count the number of visits per pixel per scan direction, collecting them into 4 bins spread over $45^\circ$ (each scanning angle $\alpha$ is equivalent to $\alpha$ modulo $45^\circ$). Table 1 presents the percentage of the sky which is well covered in terms of scanning directions within $45^\circ$ (3 or 4 directions). These numbers make it possible to have an idea of how good the redundancy is for the determination of the Stokes parameters, with respect to the different scanning strategies.

A different issue is the detection and removal of systematic effects which depend on the polarization direction. In this respect, it is important to have as many crossings as possible for each detector (e.g. Revenu et al. 2000), at least in some parts of the sky where it would be possible to understand very well the behaviour of the detectors. To be effective, the directions probed should be widely spread around $2\pi$. It should also be pointed out that some direction-dependent systematic effects may average out in areas with widely spread directions. The last line of Table 1 presents the percentage of the sky which is well covered in terms of scanning directions around $2\pi$, i.e. at least 5 bins out of 11 have been visited by a given detector. This percentage of the sky is not distributed over the sky as homogeneously as the total integration time, as is shown in Fig. 10.

Figures 3 and 5 also indicate the range of different crossing angles for each strategy. It is clear that none of the nominal and slow-precession strategies fulfil the desirable requirements in terms of range of directions probed. Indeed, a negligible part of the sky is covered with at least 5 scanning directions over $11$, and the angles between directions are small in most areas. The fast strategies are clearly much better in this respect. The same trend is observed for $45^\circ$-spread bins, which shows that fast-precession strategies are superior both for measuring the polarization and for removing the systematics.

4. Comparison with continuous-precession strategies

The choice of an optimal scanning strategy for WMAP has followed a rather different rationale than for Planck. Indeed, WMAP (Bennett et al. 2003a) uses a very fast (1 h$^{-1}$) and
continuous precession of the spin axis, and therefore scans a large part of the sky in a short time. Planck uses a slow step-wise motion which emphasizes revisits on short timescales and makes it possible to achieve very high sensitivity over a much smaller area per day. These different strategies can be traced to the choice of a differential (WMAP) versus “total-power” detector design, which was in turn driven by the original expectations of detector stability in each case, and the design philosophy. The WMAP approach requires a very complex optical design (dual telescope, matched detectors), whereas in the case of Planck the optics are simpler and make it possible to focus the design complexity in other areas (e.g. large focal plane arrays, maximising sensitivity; pointing accuracy and knowledge; but also cryogenics, which allows the use of extremely sensitive detectors – bolometers). In addition, the single-telescope design of Planck allowed more flexibility in designing the baffle which shields the optics from the Galactic straylight and provides sharp edges in the detector responsivity at large angles, a feature which can be efficiently used to detect systematics (e.g. Delabrouille 1998).

A differential approach à la WMAP implies a time-stream with very reduced long-time-scale correlations (e.g. Tegmark 1997), and in this situation the best map-making algorithms require to estimate the low-frequency noise components from both time- and spatial-domain constraints (Stompor & White 2003). At the same time, a manageable amount of data implies that it is possible to apply optimal methods to the map-making problem. These characteristics imply that the best strategy for WMAP is indeed to uninterruptedly cover a large amount of area in a short time, maximizing the number of scan crossings (spatial constraints) at all time-scales.

In the case of Planck, the very large amount of data to be converted into maps would complicate the use of optimal map-making algorithms in the case of a continuous-precession strategy; rather, two-step methods have to be used which require the pre-estimation of noise characteristics. Among the simplest of such methods are the de-striping algorithms (e.g. Delabrouille 1998) which estimate the low-frequency noise components based on the pre-processing of multiply-observed (high-sensitivity) scan paths. Such algorithms have been shown to be very effective when applied to Planck. The “total-power” detector design of Planck (which does produce time-streams with significant levels of low-frequency noise), and its map-making requirements, are therefore fully consistent with the current approach based on repeated circles which almost achieve the final sensitivity in the observed pixels each hour. Nonetheless, the level of scan cross-linking is clearly not as widely spread on the sky as could be wished, even when making use of the flexibility allowed by the spin-axis excursion strategies explored in Sect. 2. This is particularly true if unexpected systematic signals arise with time-scales of order one day (the time scales where scan cross-linking is most deficient for Planck). To overcome some of these difficulties, K. Górski & C. Lawrence (2000, priv. comm.), advocated the implementation for Planck of a continuous precession of the spin axis with a period of around one day. Wright (2004) also suggested that the Planck scanning strategy would be much better if its excursion period was of the order of 10 h. While continuous precession has proved impossible to implement due to the inertial behavior of the Planck spacecraft, it could in principle be approximated by the satellite in a step-wise fashion, though it would most probably not be compatible with a two-step map-making approach and may also lead to sampling problems for the highest-frequency detectors; in addition the observing efficiency would drop dramatically and the fuel consumption rise to unacceptable levels. In spite of these difficulties which make it impossible to implement this approach, we have simulated the coverage that such a hypothetical scenario would lead to. In this thought experiment, we keep the nominal feature of having one 85°-wide ring per minute, shifted successively by 2.5° per minute in a 7° radius circle around the spin axis, leading to a full excursion period of 17.6 h. This period would be the absolute minimal value possible given the sky-sampling requirements of the highest-frequency detectors. Figure 11 presents the scan pattern obtained from this “very fast precession strategy”, in the case of a cycloidal path. Figure 12 shows the integration-time map resulting from this strategy, and its characteristics are presented in Table 1.

This very fast precession would allow a very good uniformity of the integration time on the sky, as can be seen from Table 1, in this sense it is not too different from the nominal

![Fig. 11. Scan pattern of the main optical axis for a one-year survey (very fast cycloidal scanning strategy). For clarity, only one ring in 20000 is plotted.](image1)

![Fig. 12. Integration-time map for one detector and a one-year survey for the very fast cycloidal-precession strategy. The precession angle is 7 degrees. Mollweide projection of the whole sky in Galactic coordinates (the Galactic plane is horizontal, the Galactic north pole is at the top).](image2)
strategy studied in Sect. 2.1. Its main drawback is that no deep fields are present.

The number of crossings is not dissimilar to that of the other strategies, but they are much more evenly spread across the sky, in particular to lower Ecliptic latitudes. The crossings are also present at short time scales, which is clearly advantageous from the point of view of map-making. This strategy is moreover much better than any of the others in terms of the coverage of scanning directions per pixel.

5. Conclusion

We have presented simulations of the observing-time distribution on the sky for a variety of scanning strategies for the Planck surveyor. The slow-precession strategies are better in general than the fast-precession ones, because they allow a good uniformity of the coverage, while providing two deep fields. On the other hand, they do not allow a wide spread of the scan-crossing directions. This drawback will become a serious problem for the mission requirements only if the systematic effects are much worse than expected. This characteristic can be improved by reducing the precession period to 2 months, which would also favor the dipole-based calibration. However, the 2 month-period strategy suffers from bad coverage in a large part of the sky and many sharp gradients. A 4-month period does not induce such drawbacks, but the gain in scanning directions with respect to 6 months is negligible. It would however be better in terms of dipole-based calibration.

No very significant differences are found between cycloidal and sinusoidal simulations, or indeed with any other smooth precession for a given amplitude and period. The sinusoidal strategies offer a slight advantage in terms of north/south uniformity, and the cycloidal one in terms of decreased response to thermal fluctuations.

A continuous precession of the spin axis would allow a good uniformity of the coverage and a good redundancy in the scanning directions. However, this last option is not technically feasible given the Planck mission design.

In this context, a reasonable choice for a baseline strategy for Planck will be driven by tests of thermal response to be performed in the early part of the mission. If the response is very low, the choice will be for a sinusoidal strategy, probably with a precession period of four months. In the opposite case, a cycloidal strategy will be preferred. This preliminary selection will be confirmed in the coming years by on-going simulations which will examine the impact of various scanning strategies on the noise covariance matrix of recovered CMB maps.

Acknowledgements. We would like to thank K. M. Górski and his collaborators for their so useful HEALPix package. We also thank very much J.-P. Bernard for having provided us with seed software, J.-L. Puget for very useful comments and many other members of the Planck collaboration for fruitful discussions.
