Abstract. In an analysis of XMM-Newton archival observations of the bright Local Group spiral galaxy M 31 we study the population of X-ray sources (X-ray binaries, supernova remnants) down to a 0.2–4.5 keV luminosity of 4.4×10^{34} erg s⁻¹. EPIC hardness ratios and optical and radio information are used to distinguish between different source classes. The survey detects 856 sources in an area of 1.24 square degrees. We correlate our sources with earlier M 31 X-ray catalogues and use information from optical, infra-red and radio wavelengths. As sources within M 31 we detect 21 supernova remnants (SNR) and 23 SNR candidates, 18 supersoft source (SSS) candidates, 7 X-ray binaries (XRBs) and 9 XRB candidates, as well as 27 globular cluster sources (GIC) and 10 GIC candidates, which most likely are low mass XRBs within the GIC. Comparison to earlier X-ray surveys reveal transients not detected with XMM-Newton, which add to the number of M 31 XRBs. There are 567 sources classified as hard, which may either be XRBs or Crab-like SNRs in M 31 or background AGN. The number of 44 SNRs and candidates more than doubles the X-ray-detected SNRs. 22 sources are new SNR candidates in M 31 based on X-ray selection criteria. Another SNR candidate may be the first plerion detected outside the Galaxy and the Magellanic Clouds. On the other hand, six sources are foreground stars and 90 foreground star candidates, one is a BL Lac-type active galactic nucleus (AGN) and 36 are AGN candidates, one source coincides with the Local Group galaxy M 32, one with a background galaxy cluster (GCI) and another is a GCI candidate, all sources not connected to M 31.

Key words. galaxies: individual: M 31 – X-rays: galaxies

1. Introduction

In the XMM-Newton survey of the Local Group Sc galaxy M 33, Pietsch et al. (2004, hereafter Paper I) detected 408 sources in a 0.8 square degree field combining the counts of all EPIC instruments. The use of X-ray colours and optical and radio information allowed them to identify and classify the X-ray sources and proved to be efficient in separating super-soft X-ray sources (SSSs) and thermal supernova remnants (SNRs) in M 33 from Galactic stars in the foreground and “hard” sources. These hard sources may be either X-ray binaries (XRBs) or Crab-like SNRs in M 33 or active galactic nuclei (AGN) in the background of the galaxy.

The Andromeda galaxy M 31 is located at a distance similar to the one of M 33 (780 kpc, Holland 1998; Stanek & Garnavich 1998, i.e. 1'' corresponds to 3.8 pc and the flux to luminosity conversion factor is 7.3×10^{49} cm²) and – compared to the near face-on view of M 33 – is seen under a higher inclination (78°). The optical extent of the massive SA(s)b galaxy can

be approximated by an inclination-corrected D_{25} ellipse with a large diameter of 153.3 and axis ratio of 3.09 (de Vaucouleurs et al. 1991; Tully 1988). With its moderate Galactic foreground absorption ($N_H = 7 \times 10^{20}$ cm⁻², Stark et al. 1992) M 31 is well suited to study the X-ray source population and diffuse emission in a nearby spiral similar to the Milky Way. As M 31 is seen through a Galactic absorbing column comparable to that of M 33, one can use the same methods and similar source selection criteria that proved to be successful in the M 33 analysis. On the other hand, there is a large number of low mass XRBs (LMXBs) identified as bright X-ray sources in M 31 from earlier observations (see below). The properties of these sources may help to better classify some of the “hard” sources in M 33.

M 31 was a target of many previous imaging X-ray missions. The *Einstein* X-ray observatory detected 108 individual X-ray sources brighter than $\sim 5 \times 10^{36}$ erg s⁻¹, 16 of which were found to vary between *Einstein* observations (van Speybroeck et al. 1979; Collura et al. 1990; Trinchieri & Fabbiano 1991). The sources were identified with young stellar associations, globular clusters (i.e. LMXBs) and SNRs (see e.g. Blair et al. 1981; Crampton et al. 1984). With the ROSAT HRI, Primini et al. (1993) reported 86 sources brighter than $\sim 10^{36}$ erg s⁻¹ in the central area of M 31, nearly half of which were found to vary when compared to previous *Einstein*

* Based on observations obtained with XMM-Newton, an ESA science mission with instruments and contributions directly funded by ESA Member States and NASA.

** Table 2 is only available in electronic form at the CDS via anonymous ftp to cdsarc.u-strasbg.fr (130.79.128.5) or via <http://cdsweb.u-strasbg.fr/cgi-bin/qcat?J/A+A/434/483>

observations. With a separation of about one year between the M 31 surveys, the ROSAT PSPC covered the entire galaxy twice and detected 560 X-ray sources down to a limit of $\sim 5 \times 10^{35} \text{ erg s}^{-1}$ (Supper et al. 1997, 2001, hereafter SHP97, SHL2001). The intensity of 34 of the sources varied significantly between the observations, and SSSs were established as a new class of M 31 X-ray sources (see also Kahabka 1999).

With the new generation of X-ray observatories, *Chandra* and XMM-Newton, only parts of M 31 were surveyed. Deep *Chandra* ACIS-I and HRC observations of the central region (covering areas of 0.08 and 0.27 square degree) resolved 204 and 142 X-ray sources, respectively (Garcia et al. 2000; Kong et al. 2002b; Kaaret 2002). Three M 31 disk fields, spanning a range of stellar populations, were covered with short *Chandra* ACIS-S observations to compare their point source luminosity functions to that of the galaxy's bulge (Kong et al. 2003a). A synoptic study of M 31 with the *Chandra* HRC covered "most" of the disk (0.9 square degree) in 17 epochs using short observations, and resulted in mean fluxes and long-term light curves for the 166 objects detected (Williams et al. 2004a). In these observations, several M 31 SNRs were spatially resolved (Kong et al. 2002a, 2003b) and bright XRBs in globular clusters and SSSs and quasisoft sources (QSSs) could be characterized (Di Stefano et al. 2002, 2004; Greiner et al. 2004). During the XMM-Newton guaranteed time program there were four observations of the central area of M 31 and three aimed at the northern and two at the southern disk. These observations were used to investigate the bright and variable sources and diffuse emission (Shirey et al. 2001; Osborne et al. 2001; Trudolyubov et al. 2001, 2004), and to derive source luminosity distributions (Trudolyubov et al. 2002a). In addition, the time variability and spectra of several individual XRBs have been studied in detail (e.g. Trudolyubov et al. 2002b; Barnard et al. 2003a,b; Mangano et al. 2004).

Here we present X-ray images and a source catalogue for the archival observations of M 31 combining the three XMM-Newton EPIC instruments and using only times of low background. For the source catalogue and source population study of these observations we analyzed the individual pointings and the merged data of the central area simultaneously in five energy bands in a similar way as described in our M 33 analysis in Paper I. The covered area of 1.24 square degree and limiting sensitivity is a significant improvement compared to the *Chandra* surveys, but only covers about 2/3 of the optical M 31 extent (D_{25} ellipse) with a rather inhomogeneous exposure.

2. Observations and data analysis

Table 1 summarizes the archival XMM-Newton (Jansen et al. 2001) EPIC (Strüder et al. 2001; Turner et al. 2001) observations which at least partly overlap with the inclination-corrected optical M 31 D_{25} ellipse. For each observation we give the field name and the abbreviation used in the text for the M 31 observation (Col. 1), the observation identification (2), date (3), pointing direction (4, 5) and systematic offset (6), as well as filter and exposure time after screening for high background for EPIC PN (7, 8), MOS1 (9, 10), and MOS2 (11, 12).

To create the full field colour image we had to apply an even more stringent background screening which resulted in the shorter exposure times given in brackets.

In the XMM-Newton observations the EPIC PN and MOS instruments were operated in the full frame mode providing a time resolution of 73.4 ms and 2.6 s, respectively. The medium filter was in front of the EPIC cameras in all but the observations c4, s1 and s2 which were performed with the thin filter. To create the merged images and for source detection we used medium and thin filter observations together. This procedure can be justified as the difference in absorption between the medium and soft filters corresponds to an $N_H = 1.1 \times 10^{20} \text{ cm}^{-2}$, significantly lower than the Galactic foreground absorption.

We carefully screened the event files for bad CCD pixels remaining after standard processing. To create a homogeneous combined colour image with a similar background level for all fields we had to carefully screen the data for times of high background using the high energy (7–15 keV) background light curves provided by the SAS tasks *epchain* and *emchain*. For the images that were used for the source detection procedures in the individual fields we adopted a less stringent background screening which due to the then longer exposures allowed us to detect fainter sources. The good time intervals (GTI) were determined from the higher statistic PN light curves and also used for the MOS cameras. Outside the PN time coverage, GTIs were determined from the combined MOS light curves. The corresponding low background times for the individual observations are listed for the PN and MOS cameras in Table 1.

The archive contains four observations of the centre area of M 31 separated by half a year adding up to low background exposures for source detection of 124.6, 133.1 and 133.2 ks for EPIC PN, MOS1 and MOS2 cameras, respectively. In addition there are two pointings in the southern and three in the northern disk of M 31 that aimed at a 60 ks exposure. Due to high background, for two of the observations the time usable for detection is significantly shorter (s2, n2). In addition the archive contains four shorter pointings into the halo of M 31 (h1–h4, PI Di Stefano). These observations mainly contain foreground and background objects as they were pointed far off the disk of the galaxy. Only observation h4 (11 ks low background) partly covers the disk and therefore is included in our analysis. In total, the observations in our analysis cover an area of 1.24 square degrees.

The data are treated in a similar way to the M 33 data described in Paper I. We used five energy bands: (0.2–0.5) keV, (0.5–1.0) keV, (1.0–2.0) keV, (2.0–4.5) keV and (4.5–12) keV as band 1 to 5. We intentionally split the (0.5–2.0) keV band used in the 1XMM XMM-Newton Serendipitous Source Catalogue¹ to get on average a more homogeneous distribution of the source counts to the energy bands which leads to a better spread of the hardness ratio values and allows effective source classification (see Paper I; and Sect. 5).

For PN we selected only "singles" (PATTERN = 0) in band 1, for the other bands "singles and doubles"

(PATTERN ≤ 4). For MOS we used “singles” to “quadruples” (PATTERN ≤ 12). To avoid background variability over the PN images we omitted the energy range (7.2–9.2) keV in band 5 where strong fluorescence lines cause higher background in the outer detector area (Freyberg et al. 2004). To convert source count rates in the individual bands to fluxes we used count rate to energy conversion factors (ECF) for PN and MOS observations calculated for the epoch of observation and filters used, assuming the same spectrum as for the first XMM-Newton source catalogue, i.e. a power law spectrum with photon index 1.7 absorbed by the Galactic foreground column of $7 \times 10^{20} \text{ cm}^{-2}$. As has been demonstrated in Table 2 of Paper I, ECF values only vary by about 20% for PN in energy bands 1 to 4 for different spectra, like an absorbed 1 keV thin thermal model typical of SNRs or a 30 eV black body model typical of SSSs. The same is true for EPIC MOS, with the exception of the black body ECF in the 0.2–0.5 keV band where the MOS sensitivity is much lower. For the detection in the merged centre images (combining observations with thin and medium filter) we used averaged ECFs which may lead to wrong flux estimates of at most 5%.

For most sources band 5 just adds noise to the total count rate. If converted to fluxes due to the high ECF this noise often dominates the total flux. To avoid this problem we calculated count rates and fluxes for detected sources in the “XID” (0.2–4.5) keV band (bands 1 to 4 combined). While for most sources this is a good solution, for extremely hard or soft sources there may still be bands just adding noise. This then leads to rate and flux errors that wrongly indicate a lower source significance. A similar effect occurs for the all instrument rates and fluxes if a source is mainly detected in one instrument (e.g. soft sources in PN).

To classify the source spectra we computed four hardness ratios from the source count rates. These hardness ratios and errors are defined as

$$H Ri = \frac{B_{i+1} - B_i}{B_{i+1} + B_i} \text{ and } E H Ri = 2 \frac{\sqrt{(B_{i+1} E B_i)^2 + (B_i E B_{i+1})^2}}{(B_{i+1} + B_i)^2},$$

for $i = 1$ to 4, where B_i and $E B_i$ denotes count rates and corresponding errors in band i as defined above. In the standard source detection products, hardness ratios and count rates in individual energy bands are not combined for all instruments. To improve the statistics we calculated for all energy bands “all EPIC” count rates, fluxes and hardness ratios. We are aware that these products have some jitter in their meaning, as the relative integration times for individual sources in the EPIC instruments differ. Due to the better signal in the combined products they are still very valuable for source classification. For investigations needing accurate calibration, the products for the individual instruments that are also given should be used.

We created for PN, MOS1 and MOS2 in each of the 5 energy bands mentioned above images, background images, exposure maps (without and with vignetting correction), masked for an acceptable detector area. For PN the background maps contain the contribution from the “out of time (OOT)” events (parameter `withootset=true` in task `espinemap`). In contrast to our M 33 raster, the M 31 images (with the exception of the four observations towards the M 31 centre, c1, c2, c3, c4) only overlap at the edge of the field of view (FOV). We therefore searched for sources in each of these fields individually and only merged the centre fields for source detection. For visualization purposes we created images of all observations individually, for the centre and for the full area merging all EPIC instruments (see Sect. 4). To allow an easy merging of the galaxy centre images, we re-calculated for the events of all contributing observations the projected sky coordinates with respect to reference position RA = 00^h42^m45^s.0, Dec = +41°15′00″ (J2000) and for the full field images with respect to reference position RA = 00^h43^m24^s.0, Dec = +41°24′00″ (J2000), respectively.

To create event lists and images we used the latest calibration products for the linearisation of the EPIC MOS CCDs (MOS*_LINCOORD_0017.CCF) and EPIC bore-sight (XMM_BORESIGHT_0018.CCF). We verified with the source-rich M 31 centre pointings that PN and MOS source positions coincide to better than 0.5″. On the other hand

there were still significant offsets between the observations that had to be corrected for before merging. For the centre observations these offsets were determined from source lists of the individual observations. We used the USNO-B1, 2MASS, and *Chandra* catalogues to define an absolute reference frame. The offsets applied are listed in Col. 6 of Table 1. This finally resulted in a residual systematic position error of less than $0.5''$.

The images for PN, MOS1 and MOS2 do not fully overlap at the borders due to the different FOV of the EPIC instruments. Nevertheless, we used the full area for source detection.

The data analysis was performed using tools in the SAS v6.0 and some later versions from the development area as specially mentioned, EXSAS/MIDAS 03OCT_EXP, and FTOOLS v5.2 software packages, the imaging application DS9 v3.0b6 and spectral analysis software XSPEC v11.2.

3. Source catalogue

We searched for sources using simultaneously 5×3 images (5 energy bands and PN, MOS1 and MOS2 camera). For the pointings into the disk and halo of M 31 this procedure was applied to the individual observations. The centre pointings strongly overlap and we therefore merged the images to reach higher detection sensitivity. A preliminary source list created with the task `boxdetect` with a low likelihood threshold was used as starting point for the task `emldetect` v. 4.40. To resolve sources that overlap due to the PSF, we used parameters `fitextent=false` and `multisourcefit=4`. We selected sources equivalent to a single camera likelihood of 10 by accepting sources in the combined fit which have a likelihood above 7. This procedure produced acceptable results when checked against the smoothed images (see Sect. 4). Two emission peaks were resolved into several sources with no sign of multiplicity from the smoothed images. In a specific detection run with parameters `fitextent=true` and `multisourcefit=1` these peaks were – with a high likelihood – found as extended sources (747 and 832) that can be characterized by a King beta model with a core radius of $30'.1 \pm 0'.3$ and $28'.3 \pm 1'.2$, respectively. We rejected spurious detections in extended emission around the centre. Finally we merged the source lists of the centre and individual pointings to the disk and ordered the sources according to increasing right ascension. For sources detected in more than one observation we included the parameters of that source in the catalogue that was found with the highest detection likelihood. A recurrent transient source was reported from *Chandra* and XMM-Newton observations (Garcia et al. 2000; Osborne et al. 2001; Williams et al. 2004a). It is only visible during the short observation c2 and was not significantly detected above the central diffuse emission by the detection procedure in the merged centre observation. We therefore derived the source parameters of this source from just observation c2, and added them at the end of the catalogue. In total we detect 856 sources in the field.

The source parameters are summarized in Table 2 (EPIC combined products and products for EPIC PN, MOS1 and MOS2, separately) which is available in electronic form at the CDS.

Table 2 gives the source number (Col. 1), detection field from which the source was entered into the catalogue (2), source position (3 to 9) with 1σ uncertainty radius (10), likelihood of existence (11), integrated PN, MOS1 and MOS2 count rate and error (12, 13) and flux and error (14, 15) in the (0.2–4.5) keV XID band, and hardness ratios and errors (16–23). Hardness ratios are calculated only for sources for which at least one of the two band count rates has a significance greater than 2σ . Errors are the properly combined statistical errors in each band and can extend beyond the range of allowed values of hardness ratios as defined previously (–1.0 to 1.0). The EPIC instruments contributing to the source detection are indicated in the “Val” parameter (Col. 24, first character for PN, second MOS1, third MOS2) as “T”, if inside the field of view (FOV), or “F”, if outside of FOV. There are 52 sources at the periphery of the FOV where only part of the EPIC instruments contribute. The positional error (10) does not include intrinsic systematic errors which amount to $0''.5$ (see above) and should be quadratically added to the statistical errors.

Table 2 then gives for the EPIC PN instrument the exposure (25), source existence likelihood (26), count rate and error (27, 28) and flux and error (29, 30) in the (0.2–4.5) keV XID band, and hardness ratios and error (31–38). Columns 39 to 52 and 53 to 66 give the same information corresponding to Cols. 25 to 38, but for the EPIC MOS1 and MOS2 instruments. Hardness ratios for the individual instruments were again screened as described above. From the comparison of the hardness ratios derived from integrated PN, MOS1 and MOS2 count rates (Cols. 16–23) and the hardness ratios of the individual instruments (Cols. 31–38, 45–52 and 59–66) it is clear that combining the instrument count rate information yielded significantly more hardness ratios above the chosen significance threshold.

Column 67 shows cross correlations with M 31 X-ray catalogues in the literature (see detailed discussion in Sect. 5). Only 364 sources in our catalogue correlate with previously reported M 31 X-ray sources, i.e. our catalogue doubles the number of known X-ray sources in M 31.

In the remaining columns of Table 2, we give cross correlation information with sources in other wavelength ranges, which is further described in Sect. 6. We used the foreground stars, globular cluster sources and candidates to verify the assumed source position errors. All but six of the 33 identifications and 100 candidates are located within the 3σ statistical plus systematic positional error given above.

The faintest sources detected have an XID band flux of 6.0×10^{-16} erg cm $^{-2}$ s $^{-1}$. The brightest source (50, XID band flux of 4.5×10^{-12} erg cm $^{-2}$ s $^{-1}$) is identified as AGN in the M 31 field. The brightest M 31 source (291, an XRB) has an XID band flux of 3.9×10^{-12} erg cm $^{-2}$ s $^{-1}$. The XMM-Newton detected sources in M 31 therefore cover an absorbed luminosity range of 4.4×10^{34} erg s $^{-1}$ to 2.8×10^{38} erg s $^{-1}$ in the XID band.

4. Images

For Figs. 1, 3 and 4, we smoothed the images and exposure maps used for detection with a Gaussian (*FWHM* of $5''$, $10''$ and $20''$, respectively). For PN we subtracted OOT images, that

Fig. 1. Logarithmically-scaled XMM-Newton EPIC low background image with a pixel size of 1 arcsec^2 of the M 31 centre observations combining PN and MOS1 and MOS2 cameras in the (0.2–4.5) keV XID band. The data are smoothed with a Gaussian of $FWHM 5''$ which corresponds to the point spread function in the centre area of the combined observations. The image is corrected for un-vignetted exposure and masked for exposures above 5 ks for the individual cameras. Contours are at $(1, 2, 4, 8, 16, 32) \times 10^{-6} \text{ ct s}^{-1} \text{ pix}^{-1}$ including a factor of two smoothing. Sources from the catalogue are marked in the outer area. The inner area is shown in detail in Fig. 2.

were masked and smoothed in the same way as the images. For the EPIC combined images we added the images of the individual cameras scaled according to the background in the individual energy bands. For the colour image Fig. 4, we added images for the individual bands as needed, masked them to a total un-vignetted exposure of 5 ks and indicated the optical extent of M 31 by the D_{25} ellipse.

The (0.2–4.5) keV XID band images (Figs. 1 and 3) give an overview on the sources detected in the XMM-Newton analysis. To better visualize faint structures we added contours. By comparing images in the different energy bands it is clear that many sources only show up in some of the images, a fact that indicates spectral diversity and is further quantified in the different hardness ratios of the sources. This fact can be

visualized even more clearly in the combined EPIC colour image where we coded the (0.2–1.0) keV band in red, the (1.0–2.0) keV band in green and the (2.0–12) keV band in blue (see Fig. 4). The image is a demonstration of the colourful X-ray sky. SSSs, thermal SNRs and foreground stars appear red or yellow, XRBs, Crab-like SNRs and AGN green to blue. Bright diffuse emission fills the bulge and fainter emission the area of the disk (yellow and red, see also Fig. 1). A detailed analysis of this emission is outside the scope of this paper. XMM-Newton analysis of the diffuse emission of the M 31 bulge region was reported by Shirey et al. (2001) and Takahashi et al. (2004) and of the northern disk by Trudolyubov et al. (2004).

Fig. 2. Inner area of Fig. 1. Contours are at $(1, 2, 4, 8, 16, 32, 64, 128, 256) \times 10^{-6} \text{ ct s}^{-1} \text{ pix}^{-1}$. *Left:* sources from the XMM-Newton catalogue are marked as $30'' \times 30''$ squares. *Right:* sources from the *Chandra* analysis of Kong et al. (2002b) and Williams et al. (2004a) are marked.

5. Cross-correlation with other M 31 X-ray catalogues

In this section we discuss the cross-correlation of the XMM-Newton detected sources with sources reported in earlier X-ray catalogues. All correlations (together with other X-ray information like variability (v) or transient nature (t), reported in these catalogues as well as extent (ext) detected in this work) are indicated in the XID column of Table 2 (Col. 67).

From the 108 *Einstein* sources reported in Trinchieri & Fabbiano (1991, hereafter TF91), 14 are outside the field covered by the XMM-Newton observations ([TF91] 6, 9, 11, 13, 15, 38, 81, 86, 95, 97, 98, 102, 106, 108). From the remaining 94 sources 22 are not detected in our analysis while they were clear *Einstein* detections ([TF91] 29, 30, 31, 35, 37, 39, 40, 43, 46, 47, 53, 65, 66, 72, 75, 78, 88, 93, 96, 99, 100, 107) and have to be classified as transient. Three *Einstein* sources ([TF91] 10, 70, 103) are resolved by XMM-Newton into two sources. Several of the transient candidates ([TF91] 31, 39, 40, 46, 47, 53, 75, 78, 96) were already classified as transients or variable ([TF91] 37, 88) after the ROSAT HRI and PSPC observations (Primini et al. 1993, hereafter PFJ93; and SHL2001). On the other hand, the *Einstein* source [TF91] 84, classified as transient by SHL2001, was detected with XMM-Newton at an absorbed XID band luminosity of $1.5 \times 10^{36} \text{ erg s}^{-1}$, about a factor of 8 below the luminosity reported by TF91 and a factor of two below the SHL2001 upper limit. This source therefore either is a recurrent transient or just highly variable.

In the correlation with ROSAT detected sources we concentrate on the catalogue of the central HRI pointing (PFJ93) performed in July 1990, and the first (July 1991) and second (August 1992) PSPC survey of the full galaxy (SHP97, SHL2001). With the HRI 86 sources are detected within the central $\sim 34'$ of M 31. The XMM-Newton observations cover the full field and detect all but 7 of the sources.

The missing sources ([PFJ93] 1, 2, 31, 33, 51, 63, 85) are not in confused regions and covered the luminosity range $(0.2\text{--}2.4) \times 10^{37} \text{ erg s}^{-1}$. While [PFJ93] 1, 2, 85 were still detected in the first and/or second ROSAT PSPC survey, sources [PFJ93] 31, 33, 51, 63 were no longer active. All ROSAT HRI sources should have clearly been detected as bright sources in the XMM-Newton survey and the missing sources therefore have to be classified as transients.

The ROSAT PSPC surveys of M 31 contain 396 sources each, covering 6.3 and 10.7 deg^2 , an area much larger than the 1.24 deg^2 of the XMM-Newton survey. In Table 3 we list sources of SHP97 and SHL2001 that are not detected by XMM-Newton. From the ROSAT PSPC survey I and II, 156 and 191 sources are outside the field covered by the XMM-Newton observations, 43 and 23 are not detected by XMM-Newton, respectively. For M 33 we found in Paper I that many of the sources with the lowest detection likelihoods LH were spurious detections. To search for similar effects in the M 31 ROSAT catalogues we arranged the ROSAT sources in the field that are not detected by XMM-Newton according to LH. From the first ROSAT survey, we do not detect 12 out of 18 sources with LH below 12 and 9 out of 29 sources with LH below 15. These sources should have been detected by the deeper XMM-Newton observations if still at the ROSAT brightness. While in principle they all could have dimmed by such an amount that we do not detect them, this seems rather unlikely and probably most of these sources were spurious detections. They may have originated if a too low background had been used for the long observations (exposures up to 50 ks) taken during the “reduced pointing phase” of the ROSAT mission. As Table 3 shows, this problem does not affect the sources of the second ROSAT survey. There are many ROSAT PSPC sources detected with high LH that are missing in our XMM-Newton catalogue. Many of these sources have already been classified as transient compared with the M 31 *Einstein* catalogue or just

Fig. 3. XMM-Newton EPIC M 31 images in the (0.2–4.5) keV band: North 3 (upper left), North 2 (upper right), North 1 (lower left), and Halo 4 (lower right).

ROSAT survey I and II by SHP97 and SHL2001. At the position of one of these possible transients ([SHL2001] 240) we detect a source with a luminosity of $\sim 1.5 \times 10^{35}$ erg s $^{-1}$ (if located in M 31), which is about a factor of 100 fainter than during the outburst detected by ROSAT.

There are *Chandra* catalogues of M 31 X-ray sources based on observations of the centre area with the ACIS-I (204 sources, 43 not detected by XMM-Newton, Kong et al. 2002b) and HRC (142 sources, 18 not detected by XMM-Newton, Kaaret 2002) detectors, and of shorter observations rastering part of the disk with the HRC (166 sources,

4 outside XMM-Newton field, 23 not detected by XMM-Newton, Williams et al. 2004a). While the *Chandra* centre area surveys are fully covered by the XMM-Newton survey, the *Chandra* disk raster partly exceeds the field covered by the XMM-Newton observations. In addition to these larger *Chandra* survey papers, there are shorter lists of e.g. GIC sources and SSSs and reports of transients detected by *Chandra*. Correlations are given in the XID column of Table 2 and further references in the footnotes. While most of the *Chandra* detected sources can be resolved with XMM-Newton EPIC, there are sources close to the M 31

Fig. 3. continued. XMM-Newton EPIC M 31 images in the (0.2–4.5) keV XID band: South 1 (*left*) and South 2 (*right*). The images are integrated in $2''$ pixels and smoothed with a Gaussian of $FWHM\ 10''$, corrected for un-vignetted exposure and masked for exposures above 5 ks for the individual cameras. Contour levels are $(4, 8, 16, 32, 64, 128) \times 10^{-6}$ ct s^{-1} pix^{-1} including a factor of two smoothing. Sources from the catalogue are indicated.

Fig. 4. Logarithmically-scaled, three-colour XMM-Newton EPIC low background image of the M 31 medium and thin filter observations combining PN and MOS1 and MOS2 cameras. Red, green and blue show respectively the (0.2–1.0) keV, (1.0–2.0) keV and (2.0–12.0) keV bands. The data in each energy band have been smoothed with a Gaussian of $FWHM\ 20''$ to use an average point spread function for the different off-axis angles. The camera images have been corrected for un-vignetted exposure and masked for exposure above 5 ks. The image scale and the optical D_{25} ellipse of M 31 are marked. Shown in detail to the upper right is a factor three zoom-in to the bulge area using images binned to $1''$ and smoothed with a Gaussian $FWHM\ 5''$ corresponding to the point-spread-function (PSF) in the center of the field-of-view.

Table 3. Summary of cross-correlation with the M 31 catalogue of the first (July 1991) and second (August 1992) ROSAT PSPC survey (SSHP97, SHL2001). ROSAT sources, not detected in our XMM-Newton analysis, are arranged according to detection likelihood (LH) levels.

Not detected, $12 \leq LH < 15$:	(9 of 29 sources) 49, 82, 93, 109, 128, 196, 283, 334, 372	(2 of 17 sources) 76, 79
Not detected, $LH \geq 15$:	(22 of 193 sources) 68(LH = 14294), 77(25), 80(16), 126(217), 133(40), 160(26), 166(17), 190(113), 191(55), 192(54), 203(103), 214(400), 215(251), 232(104), 263(38), 270(40), 277(16), 284(20), 309(82), 325(21), 331(20), 340(28)	(18 of 167 sources) 104(LH = 901), 121(94), 171(43), 173(317), 190(216), 207(98), 208(299), 230(76), 232(1166), 246(40), 256(60), 267(22), 322(2703), 324(148), 344(41), 356(15), 380(17), 384(16)

nucleus (319, 321, 325) or with arcsecond separation (360, 366) that remain unresolved. Many of the *Chandra* sources not detected by XMM-Newton are rather faint (luminosities of a few 10^{36} erg s $^{-1}$ in the centre area and down to 10^{35} erg s $^{-1}$ further out in the bulge) and therefore not resolved from the surrounding diffuse emission. The remaining undetected *Chandra* sources are rather bright and all but one of them (source n1–77 from Williams et al. (2004a)) are already classified as transient (s1–79, s1–80, r3–46, s1–82, r1–34, r3–43, r2–28, r1–34, s1–85, r1–23, r1–19, n1–85).

Chandra spatially resolved several SNRs in M 31. Only some of them are detected by XMM-Newton (see Sect. 6.4).

Only lists of bright XMM-Newton sources have been published up to now (see e.g. Osborne et al. 2001; Trudolyubov et al. 2004). All of these sources are contained in our catalogue. For bright sources in M 31, many photons were collected by the XMM-Newton EPIC cameras resulting in detailed light curves and spectra that could be analyzed in detail and allowed us to define the source class (see references in Table 2 and the discussion of source classes in the following section).

6. Classes of point-like X-ray sources detected in the direction of M 31

To identify the X-ray sources in the M 31 field we searched for correlations around the X-ray source positions within a radius of $3 \times (\sigma_{\text{stat}} + \sigma_{\text{syst}})$ in the SIMBAD and NED archives and within several catalogues. In Cols. 68 to 73 of Table 2, we give extraction information from the USNO-B1 catalogue (name, number of objects within search area, distance, B2, R2 and *I* magnitude of the brightest object). To improve the

reliability of identifications we have used the *B* and *R* magnitudes to calculate $\log(\frac{f_x}{f_{\text{opt}}}) = \log(f_x) + (m_{B2} + m_{R2})/(2 \times 2.5) + 5.37$, following Maccacaro et al. (1988, see Col. 74).

The X-ray sources in the catalogue are identified or classified based on properties in the X-ray (HRs, variability, extent) and of correlated objects in other wavelength regimes (Table 2, Cols. 75 and 76). The criteria are summarized in Table 4 and are similar to the ones used in Paper I for M 33. However, M 31 is more massive than M 33 with more interstellar matter in the disk which in addition is more inclined. Therefore sources in or behind M 31 may suffer higher absorption than similar sources in the M 33 field. To take this into account, we compare our HRs to model HRs determined assuming Galactic foreground absorption and additional absorption within M 31 of 9×10^{21} cm $^{-2}$, a factor of 2 higher than in Paper I. We count a source as *identified* if at least two criteria secure the identification. Otherwise, we only count a source as *classified* (indicated by pointed brackets).

We plot X-ray colour/colour diagrams based on the HRs (see Fig. 5). Sources are plotted as dots if the error in both contributing HRs is below 0.2. Classified and identified sources are plotted as symbols even if the error in the contributing HRs is greater than 0.2. Symbols including a dot therefore mark the well-defined HRs of a class. To identify areas of specific source classes in the plots, we over-plot colours of sources, derived from measured XMM-Newton spectra and model simulations.

Identification and classification criteria and results are discussed in detail in the subsections on individual source classes below. Many foreground stars, SSSs and SNRs can be classified or identified. However, besides a few clearly identified XRBs and AGN, and SNR candidates from positions in other

Table 4. Summary of identifications and classifications.

Source type	Selection criteria	identified	classified
fg Star	$\log(\frac{f_x}{f_{\text{opt}}}) < -1.0$ and $HR2 - EHR2 < 0.3$ and $HR3 - EHR3 < -0.4$ or not defined	6	90
AGN	Radio source and not classification as SNR from $HR2$ or optical/radio	1	36
Gal	optical id with galaxy	1	
GCl	X-ray extent and/or spectrum	1	1
SSS	$HR1 < 0.0$, $HR2 - EHR2 < -0.99$ or $HR2$ not defined, $HR3$, $HR4$ not defined		18
SNR	$HR1 > -0.1$ and $HR2 < -0.2$ and not a fg Star, or id with optical/radio SNR	21	23
GIC	optical id	27	10
XRB	optical id or X-ray variability	7	9
hard	$HR2 - EHR2 > -0.2$ or only $HR3$ and/or $HR4$ defined, and no other classification		567

wavelengths, we have no clear hardness ratio criteria (see below) to select XRBs, Crab-like SNR or AGN. They are all “hard” sources and we therefore introduced a class ⟨hard⟩ for sources with $HR2$ minus $HR2$ error greater than -0.2 . In the following subsections we first discuss foreground and background sources in the catalogue and then sources within M 31. Thirty-eight sources remain unidentified or without classification.

6.1. Foreground stars (fg Star)

Foreground stars are a class of X-ray sources homogeneously distributed over the FOV of M 31. The good positioning of XMM-Newton and the available catalogues USNO-B1 and 2MASS allow us to effectively select this type of source. All our foreground stars and candidates are 2MASS sources. We identified two sources (139 and 709) with stars of known type in the SIMBAD data base. Two sources (552 and 565) are W UMa type variables identified in the DIRECT program (Kaluzny et al. 1998; Stanek et al. 1999). Two sources (284 and 385) are identified as foreground stars in the Revised Bologna Catalogue of candidate globular clusters in M 31 (Galleti et al. 2004). Their X-ray fluxes are in the range expected for these sources. In addition, we classify 90 sources as foreground stars ($\log(\frac{f_x}{f_{\text{opt}}}) < -1$, see Maccacaro et al. (1988) and in addition $HR2 - EHR2 < 0.3$ and $HR3 - EHR3 < -0.4$). For several of the star candidates we estimate the type from the optical colours in the USNO-B1 catalogue using the stellar spectral flux library from Pickles (1998). For many candidates we cannot determine the type from the optical colours. This may indicate that these sources are not isolated stars but more complicated systems or even in some cases galaxies. This expectation can for instance be confirmed for source 766, which is resolved into two sources in DSS2 images.

Several of the foreground star candidates close to the centre of M 31 (219, 231, 304, 378, 423, 434) have no entry in the USNO-B1 catalogue, however, they are clearly visible on Digital Sky Survey images, they are 2MASS sources and fulfill the X-ray hardness ratio selection criteria. Therefore, we also classify them as foreground stars.

For three sources (2,802,835) the HRs indicate a foreground star, however, $\log(\frac{f_x}{f_{\text{opt}}})$ are $(-0.98, -0.87, -0.81)$ slightly bigger than the assumed limit for classification. Comparing

USNO-B1 and 2MASS optical magnitudes for these sources clearly indicates variability. Therefore, we still include them as foreground star candidates.

Searching for correlations in the SIMBAD database, we found that source 136 correlates with the recurrent nova Rosino 61. Rosino (1973) reports: “maxima of 16.4 pg and 17.7 pg have been respectively observed on August 12, 1966 and Oct. 25, 1968. In both cases, the star was near maximum for only one or two days, rapidly declining below the limit of visibility. Although the apparent magnitude at maximum may be consistent with that of a nova at the distance of M 31, the light curve is abnormal, even for a recurrent nova. An alternative hypothesis is that the star may be not a nova, but a foreground U Gem variable, projected by chance over M 31”. The X-ray hardness ratios of the source and its 2MASS classification support the latter explanation and we therefore add the source as a foreground star candidate.

For seven sources (40, 78, 114, 206, 495, 562, 686), $\log(\frac{f_x}{f_{\text{opt}}})$ suggests a stellar identification. However, the HRs including errors are outside the assumed limits for foreground stars. Source 686 in addition correlates with a radio source making it a good candidate for an AGN behind M 31.

Optical spectroscopy of all foreground star candidates is needed to prove the suggested identification.

6.2. Galaxies (Gal), galaxy clusters (GCl) and AGN

After the *Einstein* observations the X-ray bright source [TF91] 51 (315) was identified with the local group galaxy M 32. Mainly based on ASCA and ROSAT HRI observations, Loewenstein et al. (1998) argued that the X-ray emission is dominated by a LMXB, slightly offset from the black hole nucleus of M 32. *Chandra* observations allowed one to resolve this central emission of M 32 into three sources, one coincident with the nucleus and the by far brightest source at an offset from the galaxy nucleus of $8''.3$ coincident with the position of the proposed LMXB (Ho et al. 2003). In addition to these sources, Williams et al. (2004a) detected a bright X-ray transient in M 32 (s1–85). The XMM-Newton source 315 is positioned far off-axis in observation s1 and does not allow us to resolve the three *Chandra* sources close to the nucleus. The luminosity of $5 \times 10^{37} \text{ erg s}^{-1}$ and HRs of the source are certainly dominated by the LMXB and typical for this source class

Fig. 5. Hardness ratios of sources detected by XMM-Newton EPIC. Shown as dots are only sources with HR errors smaller than 0.20 on both $HR(i)$ and $HR(i+1)$. Foreground stars and candidate are marked as big and small stars, AGN and candidates as big and small crosses, SSS candidates as triangles, SNR and candidates as big and small hexagons, GICs and XRBs and candidates as big and small squares. In addition, we mark positions derived from measured XMM-Newton EPIC spectra and models for SSSs (S1 to S4) as filled triangles, low mass XRBs (L1 and L2) as filled squares, SNRs (N132D as N1, 1E 0102.2–7219 as N2, N157B as N3, Crab spectra as C1 and C2) as filled hexagons, AGN (A1 and A2) as asterisk.

($HR1 = 0.31, HR2 = 0.07, HR3 = -0.28, HR4 = -0.33$). The M 32 transient detected by *Chandra* was not active during the XMM-Newton observation.

The brighter of the two extended sources in our survey (747) has been identified as a cluster of galaxies (GCl) at a redshift of $z = 0.293$ based on the X-ray spectrum (Kotov et al. 2003). The second extended source (832) is detected in the northeast part of the n3 field outside the optical D_{25} ellipse of M 31. We therefore classify this source as a GCl candidate.

There are no correlations with AGN with known redshift. However, the brightest X-ray source in the M 31 field (50) which was always active since the first *Einstein* observations correlates with a radio source and an unresolved optical object with a magnitude in the R band of 18.2. It has been identified as a BL Lac type AGN (NED).

In addition, we classify 36 sources as AGN based on SIMBAD, NED, and other radio source correlations (NVSS, Braun 1990; Gelfand et al. 2004) with the additional condition of being not a SNR or SNR candidate from the X-ray HR. A final decision will only be possible from optical spectra as some of the sources may still be plerion-type SNRs. In Fig. 5 we include typical HRs for an AGN spectrum (power law with photon index of 1.7 assuming Galactic foreground absorption (A1) and absorption of $9 \times 10^{21} \text{ cm}^{-2}$ through M 31 (A2)). The AGN candidates populate the area in the HR diagrams expected from the model spectra. Many of the other sources in that HR diagram area – now just classified as hard – may turn out to be AGN.

6.3. Super-Soft Sources (SSSs)

SSSs show black body spectra with temperatures below 50 eV, radiate close to the Eddington luminosity of a $1 M_{\odot}$ object and are believed to be white dwarf systems steadily burning hydrogen at the surface. They were identified as a class of X-ray sources by ROSAT and are often observed as transient X-ray sources (see Greiner 2000, and references therein). In the catalogue, SSSs are only classified using their HRs. To guide the classification we calculated SSS HRs assuming a 25 and 50 eV black body spectrum assuming Galactic foreground absorption (S1 and S3) and absorption of $9 \times 10^{21} \text{ cm}^{-2}$ within M 31 (S2 and S4). At the high absorption, the sources would no longer be detectable with XMM-Newton as the intrinsic flux (expected to be around $10^{38} \text{ erg s}^{-1}$) would be reduced by 5 and 4 orders of magnitude for the two model spectra, respectively. This led to the selection criteria in Table 4 and the classification of 18 M 31 SSSs. They are detected with absorbed XID band luminosities of $6 \times 10^{34} \text{ erg s}^{-1}$ to $9 \times 10^{36} \text{ erg s}^{-1}$. Only eight of the sources and the model values can be plotted in Fig. 5. For the other 10, $HR2$ is not determined.

One of the SSS candidates (430) was already detected by *Einstein* and ROSAT. It was found to be variable, however not classified as a SSS in the ROSAT survey which may be caused by nearby sources unresolved by the ROSAT PSPC. This source as well as another six (313, 320, 336, 359, 369, 431) were also detected by *Chandra*. Sources 320, 336, 367, 431 were classified as supersoft transients (Williams et al. 2004a; Di Stefano et al. 2004). Source 431 shows a 865 s

period in the XMM-Newton data reminiscent of a rotation period of a magnetized white dwarf (Osborne et al. 2001). Four of the sources correlate with optical novae (313, 347, 359, 456) and two correlate with 2MASS sources, indicating a dusty surrounding (191, 401).

A special case is source 352, where *HR1* indicates a SSS, however, *HR2* is 0.94 and within the error not compatible with -1.0 and *HR3* and *HR4* are not undefined. Therefore we do not classify the source as a SSS. On the other hand, this source was classified as a variable SSS from *Chandra* observations (Di Stefano et al. 2004). It is detected by *Einstein* and ROSAT. There are several possibilities: Due to the position close to the centre of M 31 and the high source density in this region, XMM-Newton may not be able to resolve this source from nearby sources, the source detection may be fooled by the surrounding diffuse emission, or it is not a source with typical SSS properties.

Another source (395), classified as a transient SSS from *Chandra* observations (Williams et al. 2004a; Di Stefano et al. 2004), has (hard) HRs in XMM-Newton and is classified here as XRB candidate.

In the discussion above two sources (352, 395) were mentioned that are also covered by the *Chandra* survey for SSSs and QSSs. In this survey, Di Stefano et al. (2004) determined 33 SSSs and QSSs using rates and hardness ratio criteria based on the *Chandra* ACIS-S (0.1–1.1), (1.1–2) and (2–7) keV bands. As the authors discuss, this survey not only selects classical SSSs as defined above but also includes sources with effective temperatures as high as 350 eV. This expectation is confirmed by the 16 sources of the catalogue which coincide with sources from the XMM-Newton catalogue. Here, three of them are classified as SSS candidates (320, 336, 369), one as SNR (154), three as SNR candidates (295, 318, 704), four as foreground star candidates (128, 157, 231, 727), two as XRB candidates (321, 395), and one even as hard (169).

6.4. Supernova remnants (SNR)

SNRs can be separated into sources where thermal components dominate the X-ray spectrum below 2 keV (examples are N132D in the Large Magellanic Cloud and 1E 0102.2–7219 in the Small Magellanic Cloud) and so called “plerions” with power law spectra (examples are the Crab nebula and N157B in the Large Magellanic Cloud). To guide the classification we calculated HRs from archival XMM-Newton spectra of these SNRs. Spectra of N132D (N1), 1E 0102.2–7219 (N2), and N157B (N3) can directly be compared to M 31 SNRs as they are seen through comparable foreground absorption. For the Crab nebula spectrum, we assumed Galactic foreground absorption (C1) and absorption of $9 \times 10^{21} \text{ cm}^{-2}$ within of M 31 (C2). It is clear from Fig. 5 that “thermal” SNRs are located in areas of the X-ray colour/colour diagrams that only overlap with foreground stars. If we assume that we have identified all foreground star candidates from the optical correlation and inspection of the optical images, the remaining sources can be classified as SNRs with the criteria given in Table 4. Compared

to our M 33 analysis in Paper I, we relaxed our *HR2* selection slightly to adjust to the higher absorption in the M 31 disk.

Extensive searches for SNRs in M 31 were performed in the optical (Dodorico et al. 1980; Magnier et al. 1995, and references therein) and radio (Braun & Walterbos 1993). Before *Chandra* and XMM-Newton, M 31 X-ray sources were identified as SNR by positional coincidence with optical and radio catalogues. For our catalogue, many X-ray sources correlate with optical and/or radio SNRs or radio sources (see Table 2). With *Chandra* and XMM-Newton, we now have the possibility to identify M 31 SNRs by their X-ray properties (extent, HRs, or spectra). *Chandra* observations of sources 260, 342 and 454 (Kong et al. 2002a; Williams et al. 2004b) were analyzed in detail and the SNR nature determined by X-ray extent and optical/radio correlation. We count sources as SNR identifications (21) if they correlate with optical and/or radio SNRs or radio sources and fulfill the HR criteria (see above). We count sources as classified SNRs (23) if they either fulfill the HR criteria (22) or correlate with an optical/radio SNR (1). The SNRs and candidates cover an absorbed XID band luminosity range from $4 \times 10^{34} \text{ erg s}^{-1}$ to $5 \times 10^{36} \text{ erg s}^{-1}$. The 22 HR selected SNR candidates have been selected by their X-ray properties and significantly enlarge the number of M 31 SNR candidates. For three of these sources, the classification may be questionable: From *Chandra* observations (Kong et al. 2002a), source 316 is classified as variable, and 295 and 318 correlate with a star of the catalogue by Haiman et al. (1994).

A special case is source 642 with an XID band luminosity of $1.0 \times 10^{36} \text{ erg s}^{-1}$, which correlates with the optical SNR candidate [MPV95] 1–013 (Magnier et al. 1995). The XMM-Newton HRs clearly indicate a hard spectrum as expected for a plerion embedded in the M 31 disk. If the identification is correct this source would be the first plerion detected outside the Galaxy or the Magellanic Clouds. Final proof can only be achieved if the source turns out to be extended and shows no time variability.

Kong et al. (2003b) reported the *Chandra* detection of two additional resolved X-ray SNRs in the centre of M 31. The first of the sources lies about $40''$ northeast of the XMM-Newton source pair 338, 341, the second between these two sources. With X-ray luminosities of $(4 \text{ and } 8) \times 10^{35} \text{ erg s}^{-1}$ in the (0.3–7) keV band, they are too faint to be detected by XMM-Newton in the neighbourhood of the bright sources and surrounding diffuse emission.

6.5. Globular cluster sources (GIC)

A significant part of the luminous X-ray sources in the Galaxy and M 31 are found in globular clusters. Most of the GICs in the Galaxy show bursts and therefore are low mass neutron star X-ray binaries (see e.g. Verbunt & Lewin 2004). There have been extensive surveys for globular clusters in M 31 in the optical and infrared band (see Magnier 1993; Galleti et al. 2004). From the ROSAT survey sources, SHL2001 identify 33 sources as GICs. We correlated the XMM-Newton catalogue with the catalogues of Galleti et al. (2004) and Magnier (1993) and add one candidate, found in SIMBAD. We count sources as

identifications (27) when the correlating source is listed as confirmed GIC in Galleti et al. (2004). The remaining correlations are counted as classified. Two sources (91, 146), correlating with GIC candidates in Galleti et al. (2004) showed X-ray HRs typical of SNRs, source 91 correlates with an optical SNR candidate and both with radio sources. We therefore identify them as SNRs.

In Fig. 5, the GICs are plotted with the same symbols as the XRBs. All of our GIC identifications and candidates have been reported in earlier work and many of them have been classified as time variable in X-rays (see Table 2). They cover an absorbed XID band luminosity range from $4.5 \times 10^{35} \text{ erg s}^{-1}$ to $2.4 \times 10^{38} \text{ erg s}^{-1}$. Only the brightest source (351) has a luminosity that seems to be at the upper end, allowed for neutron star LMXBs.

For source 414, Trudolyubov et al. (2002b) report intensity dips with a period of 2.78 h reminiscent of a neutron star LMXB.

6.6. X-ray binaries (XRB)

As already mentioned in the introduction to this section, expected spectra of XRBs are similar to AGN and Crab-like SNRs. To guide the classification we calculated HRs as expected for low mass XRBs (5 keV thermal Bremsstrahlung spectrum assuming Galactic foreground absorption (L1) and absorption of $9 \times 10^{21} \text{ cm}^{-2}$ within M 31 (L2)). High mass XRB (HMXB) spectra are expected to be even harder. As can be seen in Fig. 5 the different source classes do not separate in the HR diagrams into distinct areas.

Detailed work on individual sources using XMM-Newton and/or *Chandra* data, has identified four black hole XRBs (sources 257, 287, 310, 384, Barnard et al. 2003b; Trudolyubov et al. 2001; Barnard et al. 2004), three neutron star LMXBs (297, 353, 403, Barnard et al. 2003b; Kaaret 2002; Mangano et al. 2004) and an XRB pulsar (544 Trudolyubov et al. 2004). In addition, we classify X-ray transients from XMM-Newton and/or *Chandra* data as XRB candidates. While in general transient behaviour of bright X-ray sources indicates an XRB nature, in this selection we may also pick up variable background sources. Such a source may be (405) which also correlates with a radio source. The XRBs selected in this way cover the same area in the X-ray colour/colour diagrams as the GICs (see Fig. 5). The absorbed XID band luminosities range from $8.4 \times 10^{35} \text{ erg s}^{-1}$ to $2.8 \times 10^{38} \text{ erg s}^{-1}$.

Besides the *Chandra* transients covered in the XMM-Newton catalogue, we identified many transients in earlier catalogues in Sect. 5 that are further XRB candidates. There certainly are more transient XRBs buried in the XMM-Newton catalogue which only may be discovered by a detailed comparison of fluxes of all the XMM-Newton sources with earlier missions. Such an analysis was outside the scope of this work and, due to the lower sensitivity of the catalogues before XMM-Newton and *Chandra*, transient sources detected on this basis may be less reliable. On the other hand, X-ray sources classified as variable may also turn out to be XRBs. However, this criterion is not unique as it would also cover

many variable background sources. Up to now no high mass XRBs have been identified in M 31. Several identifications with emission line objects (EmO) in SIMBAD may be good candidates for Be-type high mass XRB.

All the candidates mentioned above need further X-ray work to confirm an XRB nature.

7. Summary

We present a catalogue of 856 X-ray sources based on archival XMM-Newton observations covering an area of 1.24 square degrees. We correlate our sources with earlier M 31 X-ray catalogues and use information from optical, infra-red and radio wavelengths and in addition their X-ray properties for source classification. We applied a source classification scheme similar to the one successfully used in Paper I for M 33. As M 31 sources we detect 21 SNRs and 23 SNR candidates, 18 SSS candidates, 7 XRBs and 9 XRB candidates, as well as 27 GICs and 10 GIC candidates, which most likely are low mass XRBs within the GIC. Comparison to earlier X-ray surveys reveals transients not detected with XMM-Newton, which add to the number of M 31 XRBs. The number of 44 SNRs and candidates more than doubles the X-ray detected SNRs. 22 sources are new SNR candidates in M 31 based on X-ray selection criteria. Another SNR candidate may be the first plerion detected outside the Galaxy and the Magellanic Clouds. On the other hand, six sources are foreground stars and 90 foreground star candidates, one is a BL Lac type AGN and 36 are AGN candidates, one source coincides with the Local Group galaxy M 32, one with a background galaxy cluster and another is a GIC candidate, all sources not connected to M 31.

There are 567 sources classified as hard, which may either be XRBs or Crab-like SNRs in M 31 or background AGN. If source variability is detected, SNRs may be excluded from source identification. Thirty-eight sources remain unidentified or without classification.

The archival XMM-Newton M 31 observations allowed us to probe the point source population of the covered area significantly deeper than during the ROSAT PSPC surveys. However, the XMM-Newton EPIC coverage is rather inhomogeneous and a significant part of the M 31 disk has not been observed at all. To get a full census of the M 31 X-ray point sources it would be very important to fully cover this nearby galaxy with XMM-Newton observations.
