Received 29 January 2005 / Accepted 29 March 2005

Abstract. We report on ground-based and HST(+STIS) imaging of the afterglow and host galaxy of the Gamma-Ray Burst (GRB) of March 5, 2002. The GRB occurred in a \( R = 25.17 \pm 0.14 \) galaxy, which apparently is part of an interacting system. The lightcurve of the optical afterglow shows a rebrightening, or at least a plateau, 12–16 days after the gamma-ray event. \( UBVRIK \) multi-band imaging of the afterglow ~12 days after the GRB reveals a blue spectral energy distribution (SED). The SED is consistent with a power-law with a spectral index of \( \beta = -0.63 \pm 0.16 \), but there is tentative evidence for deviations away from a power-law. Unfortunately, a spectroscopic redshift has not been secured for GRB 020305. From the SED we impose a redshift upper limit of \( z \leq 2.8 \), hence excluding the pseudo redshift of 4.6 reported for this burst. We discuss the possibilities for explaining the lightcurve, SED and host galaxy properties for GRB 020305. The most natural interpretation of the lightcurve and the SED is an associated supernova (SN). Our data can not precisely determine the redshift of the GRB. The most favoured explanation is a low redshift (\( z \approx 0.2 \)) SN, but a higher redshift (\( z \approx 0.5 \)) SN can not be excluded. We also discuss less likely scenarios not based on SNe, like a burst occurring in a \( z = 2.5 \) galaxy with an extinction curve similar to that of the Milky Way.

Key words. gamma rays: bursts – techniques: photometric

1. Introduction

For long duration GRBs the relation with supernovae (SNe) became firmly established with the discovery of the type Ic supernova SN 2003dh associated with GRB 030329 (Stanek et al. 2003; Hjorth et al. 2003). This result lends strong support to the collapsar model (Woosley 1993), but a SN is also an ingredient in other models (e.g. Dado et al. 2003; Fryer & Heger 2004). However, the associated SNe follow a broad distribution of optical luminosities (Zeh et al. 2004). Furthermore the connection of GRBs with SNe of other types than Ic can not be excluded, motivated by the two possible associations of GRBs and II type SNe (SN 1997cy, Germany et al. 2000; SN 1999E, Rigon et al. 2003). Therefore, the afterglow lightcurves and SEDs around the SN peak are far from being described by an universal SN template. In this study we present ground and space-based optical observations of GRB 020305 carried out from 11.5 to 321.2 days after the burst.

GRB 020305 was localised by the HETE-II satellite on March 5.4968 UT (Ricker et al. 2002). The high-energy emission as seen by the Interplanetary network (IPN) consisted in two broad pulses, with a total GRB duration of \( \sim 280 \) s (Hurley et al. 2002), placing it in the long-soft burst category. Price et al. (2002) reported the presence of a transient optical source in the HETE-II/IPN error box in images taken ~20 h after the GRB. Further imaging confirmed the fading behaviour of the candidate (Lee et al. 2002; Ohyama et al. 2002).

The paper is structured as follows: Sect. 2 details the observations and the data reduction, Sect. 3 reports the results on the SED, lightcurve and host galaxy, Sect. 4 discusses several interpretations of the results, and finally Sect. 5 draws the conclusions of this study.

2. Observations and data reduction

2.1. NOT observations

We observed the field of GRB 020305 from the ground with the 2.56-m Nordic Optical Telescope (NOT) on 2002 March 16.95–22.18 UT, i.e. 11.45–16.68 days after the GRB. The instrument used was the Andalucía Faint Object Spectrograph (ALFOSC) equipped with a 2048\(^2\) pixel Loral CCD having a pixel scale of 0\('\)189. The data were reduced using standard methods. The \( UBVRI \)-band calibration was carried out using standard stars.
Table 1. Calibrated magnitudes of the secondary standard stars displayed in Fig. 1. For the faintest standards (C, F and I) the $U$-band magnitudes show large errors (>0.08 mag) so the corresponding field is empty.

Fig. 1. The co-added NOT $R$-band image taken on 2002 Mar. 16.993–17.039 UT. The tickmarks indicate the position of the OA, and the labels the standard stars listed in Table 1. The scale of the image is indicated with a vertical bar at the lower right corner. North is upwards and East is leftwards.

out observing the Landolt field PG1047+003 (Landolt 1992) with the 3.58-m New Technology Telescope (NTT) on 2002 February 28.

Figure 1 shows an image of the optical afterglow (OA) and the positions of the secondary standard stars listed in Table 1. The mean celestial coordinates obtained from 6 NOT images are: RA(J2000) = 12°42′27.963′′ ± 0.020′, Dec(J2000) = −14°18′11.45″ ± 0′.20. The astrometry is based on ~30 USNO A2.0 stars per image. The errors do not include the systematic uncertainty of the USNO A2.0 catalogue (~0′.25; Assafin et al. 2001).

Table 2. Upper subtable: Log of the ground-based NOT observations. The magnitudes are given in the Vega system and are not corrected for Galactic extinction. The contribution of the host has not been subtracted. Lower subtable: Log of the HST observations. The HST magnitudes are in the AB system, are not corrected for Galactic extinction and only consider the OA flux.

2.2. HST observations

From space the OA was observed using the Space Telescope Imaging Spectrograph (STIS) on the Hubble Space Telescope (HST). The HST observations were carried out clustered around three mean epochs: ~39, ~103 and ~300 days after the GRB. In each of the three epochs two broad filters were used: the long-pass (LP) and the 50CCD clear (CL) filter. The journal of observations is displayed in Table 2.
The CCD gain was set to 1 $e^{-}$/ADU and the read-out noise was 4.46 $e^{-}$. The STIS images were preprocessed through the standard STIS pipeline and combined using the DITHER (v1.2) software (Fruchter & Hook 2002) as implemented in IRAF (v2.11.3)/STSDAS (v2.1.1). The “pixfrac” parameter was set to 0.7 and the output scale to $0''0.0254$ pixel$^{-1}$ (“scale” parameter 0.5).

For both STIS filters the third epoch images were subtracted from the first and second epoch frames, allowing us to perform photometry of the OA with no contamination from the host galaxy. Aperture photometry was carried out with a small aperture radius of 4 drizzled pixels ($\sim 0.1''$), which gave the optimal signal-to-noise ratio. Then an aperture correction was applied for both filters based on the growth curve of the star CPD $-$ 60 7585$^1$, which has a similar $m_{CL}^{AB} - m_{LP}^{AB}$ colour to the OA. The use of other apertures yielded consistent aperture corrected magnitudes, implying that the assumed growth curve is suitable for the OA. Figure 2 shows the OA fading as imaged by HST.

3. Results

3.1. The afterglow SED $\sim$11.5 days after the burst

The optical multicolour imaging carried out during the first NOT observing night (March 16.950–17.226 UT, see Table 2) allowed us to construct the optical SED of the afterglow. Furthermore, including the $K'$-band detection of March 14.39 UT reported by Burud et al. (2002) the SED was extended to the near-infrared (NIR). We have re-reduced and analysed the original $K'$-band data taken by Burud et al. (2002). In order to enhance the signal-to-noise ratio we convolved the final image with the Point Spread Function (PSF) constructed using field stars. We obtained a value of $K' = 20.10 \pm 0.31$ consistent with the value of Burud et al. (2002; $K' = 19.8 \pm 0.2$).

The extended underlying flux distribution imposed a seeing-dependent host galaxy subtraction. Thus, for the images acquired in seeing conditions above $1''1$, the flux of the host plus the companion galaxy (see Fig. 2) was subtracted. We note that the seeing values of the observations by Burud et al. (2002), Ohyama et al. (2002) and Lee et al. (2002) were; $\sim 1''6$, $\sim 0''9$ and $\sim 3''0$, respectively (Priv. Comm.). The determination of the $UBVRI'$-band magnitudes for the host and the companion galaxy was based on the $R$-band magnitudes and the power-law spectral indexes reported in Sect. 3.4.

The mentioned optical/NIR data where extrapolated in time to a common epoch of March 17.0 UT, assuming a power-law lightcurve ($F_{\nu} \sim \nu^{-\alpha}$). Two different values of the decay index ($\alpha$) were used for the $K'$ and for the optical bands. Given that the $K'$-band measurement was carried out before the rebrightening, the $\alpha_{K'}$ value was obtained assuming a power-law stretch connecting the $R$-band point by Ohyama et al. (2002) with our $R$-band magnitude of March 16.993–17.039 UT, yielding $\alpha_{K'} = 0.36$. For the rest of bands ($UBVRI$) the adopted value of $\alpha_{\lambda_{UBVRI}}$ was obtained based on our $R$-band measurements of March 16.993–17.039 UT and March 18.960–19.040 UT, implying $\alpha_{\lambda_{UBVRI}} = -1.05$. Thus, the $K'$-band flux extrapolation was performed assuming a slow fading, whereas the $UBVRI$-band fluxes were shifted in time

---

1 STIS handbook
http://www.stsci.edu/hst/stis-/documents/handbooks/
The low redshift SN scenario. The filled squares show the $UBVRIK$-band data points measured around March 17.0 UT. The straight long dashed line shows a pure power-law fit ($\beta = -0.63 \pm 0.16$, $\chi^2$/d.o.f. = 0.8), whereas the solid bumpy curve shows the fitted solution when a SN 1998bw-like component is added. The best SED solution is obtained with a low redshift ($z \sim 0.1$) faint SN (the amplitude is only $\sim 2\%$ of SN 1998bw), which improves the fit ($\chi^2$/d.o.f. = 0.3). Larger redshifts make the SN 1998bw template unable to fit the high $UB$-band flux, so are not plotted here. The dotted thin smooth curve shows the fit obtained at $z \sim 0.1$ when the contribution of a thermal spectrum and a pure power-law ($\beta = -1$) are added. The rest-frame temperature of the black body is $T \sim 9200 \pm 1300$ K. All the fits assume no intrinsic extinction, since the introduction of it provides worse fits.

Fig. 3. The low redshift SN scenario. As in Fig. 3 the filled squares display the $UBVRIK$-band SED around March 17.0 UT. The solid curve displays the satisfactory ($\chi^2$/d.o.f. = 0.1) result obtained with the SN 1998S template when a $F_\nu = \text{const.} \times \nu^\alpha$ function is fitted if $z = 1.73$ and $k = 12.5$. The long dashed straight line shows the underlying power-law spectrum ($\beta = -1.38 \pm 0.28$) whereas the dashed curve shows the SN component.

Fig. 4. The high redshift SN scenario. The combination of the NOT and HST observations (see Sect. 3.3) presented here and data points from other authors (Lee et al. 2002; Ohyama et al. 2002) allowed us to construct the $R$-band lightcurve of the OA. The $R$-band magnitudes reported by Ohyama et al. (2002) have been shifted to our photometric zero point (Kosugi 2003). The data point by Price et al. (2002) has not been included due to lack of information on the photometric system (their detection is based on unfiltered images) and the unreported error-bar.

The resulting OA lightcurve (see Fig. 5) can not be described using only a power-law ($F_\nu \sim \nu^\alpha$; $\alpha = 1.02 \pm 0.04$, $\chi^2$/d.o.f. = 34.9). The poor fit is due to the fast decay between the first two HST epochs and especially because of the lightcurve bump present 12–16 days after the GRB.

3. The late time decay

The first two HST epochs imply a fast decay. A power-law fit leads to decay slopes of $\alpha_{CL} = 2.85 \pm 0.19$ and $\alpha_{LP} = 2.45 \pm 0.22$. Extrapolating this decay to the third epoch, afterglow magnitudes of $m_{CL}^{AB} = 31.38 \pm 0.43$ and $m_{LP}^{AB} = 29.66 \pm 0.46$ (AB system) are predicted. This is consistent with the fact that no obvious point source emission is seen at the position of the afterglow in the third epoch images. For the third epoch images the peak flux of the mean azimuthal host galaxy profiles at the afterglow position are equivalent to $m_{CL}^{AB} = 28.20$ and $m_{LP}^{AB} = 28.07$. These magnitudes can be considered as conservative upper limits of the OA contribution in the third HST epoch and have been included in Table 2.

The broad STIS CL and LP filters only allow a rough determination of the OA colour. In order to estimate the colours of the two first HST observations, the CL and LP magnitudes have been rescaled to April 13.5 UT and June 16.5 UT using the above calculated decay indexes ($\alpha_{CL} = 2.85 \pm 0.19$, $\alpha_{LP} = 2.45 \pm 0.22$).
α_{LP} = 2.45 \pm 0.22). In any case, the first four HST visits are well clustered around the two mentioned epochs, so the magnitude shifts are <0.06 mag. The m_{CL}^{AB} - m_{LP}^{AB} colours are 0.46 \pm 0.04 and 0.88 \pm 0.30, on April 13.5 UT and June 16.5 UT, respectively (uncorrected for Galactic extinction). This is consistent (1.39σ) with an achromatic decay between 39 and 103 days after the GRB.

The HST magnitudes on April 13.5 UT and June 16.5 UT can be transformed to the Vega system using the LP and CL filter throughputs implemented in the SYNPHOT package of IRAF yielding R = 24.38 \pm 0.05 (April 13.5 UT) and R = 28.31^{+2.4}_{-1.07} (June 16.5 UT).

3.4. The host galaxy

The HST observations revealed an extended galaxy (~1.3'' \times 0.6'') coincident with the OA position (see Fig. 2). The integrated CL and LP magnitudes (measured in the third epoch observations) of the host are m_{CL}^{AB} = 25.38 \pm 0.05 and m_{LP}^{AB} = 25.18 \pm 0.12, corresponding to a Vega R-band magnitude of R = 25.17 \pm 0.14. The photometry was performed with SExtractor using the automatic aperture magnitude (MAG_AUTO), which is suitable to measure the total flux of extended objects (Bertin & Arnouts 1996). The STIS host magnitudes correspond to a spectral index \beta = -0.45^{+0.12}_{-0.13} (dereddened for Galactic extinction).

The HST imaging also revealed another extended source located l'1 northeastwards from the host (see Fig. 2). The magnitudes of this galaxy are m_{CL}^{AB} = 25.14 \pm 0.03 and m_{LP}^{AB} = 24.92 \pm 0.06, corresponding to R = 24.95 \pm 0.08 in the Vega system. The inferred spectral index, \beta = -0.53^{+0.26}_{-0.24}, is similar to that of the host galaxy.

4. Discussion

A natural interpretation of the lightcurve and the SED would be the existence of a SN component present ~2 weeks after the GRB. Given the limited number of measurements in the lightcurve/SED, and the unknown redshift, the space of SN-like lightcurve/SED solutions (determined by \alpha_V, the SN amplitude, the stretching factor, and the temporal offset between the SN and GRB) is highly degenerate. Hence, we will only attempt to demonstrate existence and not uniqueness of possible SN fits to our data. For simplicity we decided to fix the stretching factor to 1 and to assume that the GRB event was simultaneous to the SN. Moreover, the blue colour of the OA suggests that the host galaxy extinction can not be high, so we considered no host galaxy extinction (\alpha_V = 0).

4.1. Possible SN interpretations

4.1.1. The SED

The SED around 17.0 March UT shows a blue optical afterglow (U - B = -0.56 \pm 0.18, B - V = 0.31 \pm 0.13, V - R = 0.09 \pm 0.09, R - I = 0.29 \pm 0.12, corrected for Galactic extinction), in comparison to the mean colours measured for other optical afterglows ((B - V) = 0.47 \pm 0.17, (V - R) = 0.40 \pm 0.13, (R - I) = 0.46 \pm 0.18; Simon et al. 2001).

In order to fit our optical/NIR SED, we considered two spectroscopic templates; SN 1998bw (moderately blue, Patat et al. 2001) and SN 1998S (very blue, Fassia et al. 2001). The fitted expression is given by; F_\nu = \text{const.} \times \nu^\alpha \times \mathcal{F}_{\nu}^{SN}, where \mathcal{F}_{\nu}^{SN} is the SN template at the GRB redshift and k an amplitude. As shown in Fig. 3, a dimmed SN 1998bw template at z \sim 0.1 improves the quality of the fit with respect to the pure power-law (\chi^2/d.o.f. = 0.3 vs. \chi^2/d.o.f. = 0.8), yielding a spectral index \beta = -0.59 \pm 0.21. However, at z \sim 0.1 the SN 1998bw amplitude has to be dimmed by a factor of ~50 to reach the observed optical flux level, implying a B-band absolute peak magnitude of: M_B \sim -15. This would imply a very subluminous type Ic SN (e.g., Richardson et al. 2002). The moderately blue SN 1998bw template is unable to reproduce the observed blue SED beyond z \sim 0.2. We note that the SN 1998bw spectrum was extended in the \lambda < 3600 \AA rest-frame UV domain adopting a power-law \mathcal{F}_{\nu}^{SN} \sim \nu^{-2.8} spectrum as previously assumed by other authors (Bloom et al. 1999; Lazzati et al. 2001).

The UV rest-frame flux of SN 1998S has been obtained combining HST(+STIS) observational spectra (Lentz et al. 2001) and black body extensions to the optical spectra.
(Fassia et al. 2001). The black body temperatures have been obtained interpolating in time the SN 1998S photospheric temperatures (Anupama et al. 2001; Fassia et al. 2000).

With the bluer SN 1998S template it is possible to fit the SED at larger redshifts. The best fit based on SN 1998S is reached at $z \sim 1.7$, where the fit quality is considerably improved in comparison to the pure power-law fit ($\chi^2$/d.o.f. = 0.1 vs. $\chi^2$/d.o.f. = 0.8, see Fig. 4). In this case the derived spectral index is $\beta = -1.38 \pm 0.28$. The amplitude of the best fit is $\sim 12.5$ times SN 1998S, which implies $M_B \sim -21.5$ (see Fig. 4). To our knowledge only the exceptionally bright Ic-type SN 1999as has reached such high luminosity ($M_B \sim -21.4$; Hatano et al. 2001).

Therefore, both a low redshift and a high redshift SN scenario are able to fit the blue and bumpy optical/NIR SED around March 17.0 UT. Note that we do not exclude SN solutions based on SNe at intermediate redshifts (i.e., $0.2 < z < 1.7$).

Two additional complementary arguments support a substantial SN flux contribution around 11.5 days after the burst: i) The colours of the afterglow roughly agree with the ones measured for several blue SNe close to their lightcurve peaks: SN 1993J (Richmond et al. 1994), SN 1998S (Fassia et al. 2001); ii) at low redshift the addition of a black body term to the power-law spectrum improves the fit ($\chi^2$/d.o.f. = 0.4 vs. $\chi^2$/d.o.f. = 0.8, see Fig. 3), yielding rest-frame temperatures of $T \sim 9200$ K, compatible with the high photospheric temperatures measured in SNe. This scenario resembles the SED of the low redshift GRB 011121 at $t-t_0 \sim 13.5$ days (being $t_0$ the epoch of the gamma-ray event), which was reproducible with a black body template having a temperature of $T \sim 6300$ K (Greiner et al. 2003).

4.1.2. The lightcurve

In Fig. 5 we have overplotted the lightcurves of these SNe on our R-band data points. The SN 1998bw and SN 1998S lightcurves have been dimmed by a similar factor to the one needed to fit the SEDs (Figs. 3 and 4, respectively). At low redshift SN 1998bw and SN 2002ap fit the peak reasonably well, but the fast decay SN 1994I provides the best match being the only one able to explain the first HST data point. We note that SN 1994I-like lightcurves also provide good fits for the lightcurves of GRB 021211 (Della Valle et al. 2003) and XRF 030723 (Fynbo et al. 2004).

The SN 1998S lightcurve redshifted to $z = 1.7$ peaks too late ($t-t_0 \sim 30$ days) and is therefore highly inconsistent with the R-band data points. Lower redshifts provide better fits for all templates, but the late time fast decay (given by the two HST points) is difficult to fit at any redshift. Even with a SN 1994I template at low redshift the second HST data point is not well fitted. However, a break in the afterglow lightcurve would yield a lower total (SN + afterglow) flux at the second HST epoch, hence leading to a better fit. From the lightcurve peak epoch we conclude that a high redshift SN scenario seems unlikely.

4.2. A SN-less interpretation

An alternative interpretation of the RI-band SED decrement is based on the redshifted 2175 Å broad absorption bump. In this framework the SED shape is not the result of a SN, but rather the result of features in the extinction law. The 2175 Å bump is prominent in the Milky Way (MW), moderate in the Large Magellanic Cloud (LMC) and almost undetectable in the Small Magellanic Cloud (SMC). In order to test this possibility, the flux densities corresponding to our data points were fitted with an expression in the form: $F_{\nu} \sim \nu^{\beta} \times 10^{-0.4A_{\nu} \log \nu}$, where $A_{\nu}$ is the extinction in magnitudes at rest-frame frequency $\nu$. We have considered the three extinction laws given by Pei (1992), i.e., for the MW, LMC and SMC. $A_{\nu}$ has been parametrised in terms of $A_V$, so the fit determines $A_V$ and $\beta$ simultaneously. Given that the OA distance is unknown, the redshift has been ranged from $z = 0$ to $z = 2.8$.

Table 3 shows that the best fit solution ($\chi^2$/d.o.f. = 0.1) is reached with a MW extinction law at $z = 2.5$, consistent with a power-law spectrum with $\beta = -0.35 \pm 0.23$ and an extinction $A_V = 0.25 \pm 0.14$ (see Fig. 6). The MW is the only extinction law providing a spectral index fully consistent (within error bars) with $\beta < 0$, and therefore agrees with the $\beta$ values measured in OAs to date. For the MW any redshift in the range $2.2 < z < 2.8$ provides values of $\chi^2$/d.o.f. < 1.

However, this interpretation “per se” can not account for the simultaneous rebrightening of the lightcurve 12–16 days after the burst, being necessary an additional mechanism to explain it. One possible solution would be to describe the lightcurve bump in the context of the two-component jet model, invoked to interpret the rebrightenings measured in GRB 030329 (Berger et al. 2003) and XRF 030723 (Huang et al. 2004).

This scenario is opposite to the OA SEDs measured to date, where for all cases the metal-rich MW extinction law gives poor fits (Jensen et al. 2001; Fynbo et al. 2001; Holland et al. 2003; Jakobsson et al. 2004). Thus, we consider this interpretation less likely than the SN interpretation, however it can not be excluded.

Fig. 6. The UBVIK-band photometry measured around March 17.0 UT and the best-fitting SED solutions (not including any SN component). The three thin curves show the results of assuming different extinction laws (MW, LMC and SMC). The thick long dashed straight line displays a pure power-law. The best-fitted solution (χ²/d.o.f. = 0.1) corresponds to a MW extinction law at a redshift $z = 2.5$ (solid curve). The absorption between the $R$ and the $I$-band might be due to the redshifted graphite 2175 Å broad signature, prominent in the MW, faint in the LMC (dashed curve) and almost absent in the SMC extinction law (dotted curve).

5. Conclusions

In this paper optical ground-based and HST imaging have been reported for the GRB 020305 afterglow. The HST imaging revealed an extended host galaxy with $R = 25.17 \pm 0.14$, which might be part of an interacting system.

The lightcurve of the afterglow, constructed with our data and with data of other authors, shows a rebrightening 12–16 days after the GRB. On the other hand, the UBVIK-band SED constructed around the time of the expected SN peak shows a blue and bumpy SED which might deviate from the power-law fit with $\beta = -0.63 \pm 0.16$. The afterglow $U$-band detection imposes an upper limit to the GRB redshift of $z \lesssim 2.8$, inconsistent with previous redshift estimates (Atteia 2003).

We have considered several interpretations that may account simultaneously for the lightcurve rebrightening and the bumpy blue spectral energy distribution. The most natural scenario is based on an SN associated to the GRB.

Our UBVIK-band SED can not precisely constrain the redshift of the GRB. Both a low ($z \lesssim 0.2$) and a high redshift ($z \sim 1.7$) SN solutions can match the SED reasonably well. The high redshift scenario has the (only) advantage of being able to explain easily the low host galaxy luminosity, which seems unlikely for $z \sim 0.1$. However, the high redshift scenario requires an extraordinarily bright SN ($M_B \sim -21.5$). Contrary to this, the absolute peak magnitude derived in the low redshift SN solution is more realistic, especially given that the fraction of SNe that are subluminous ($M_B > -15$) appears to be higher than 1/5 (Richardson et al. 2002). Furthermore, the high redshift SN scenario is not able to fit the $R$-band lightcurve, and especially around the rebrightening. In conclusion, we consider the low redshift SN scenario the most likely interpretation of the data.

If the GRB 020305 SED/lightcurve bumps have a SN origin, then our data would support the diversity of the SNe related to GRBs, since the extensively used SN 1998bw template does not necessarily yield the best fits.

In an alternative SN-less interpretation the bumpy SED is the result of structure present in the extinction curve. A fit with a MW-like extinction law leads to an estimated redshift of $z \approx 2.5$. This interpretation can not naturally describe the simultaneous lightcurve rebrightening, requiring an extra explanation for the lightcurve bump (given for instance by the two-component jet model), and hence we consider it less likely than the SN interpretations.

The determination of the host galaxy redshift, either via a deep spectrum or based on a photometric redshift would drastically reduce the many free parameters of the present study.
