ABSTRACT

We present evidence that the mid infrared (MIR, rest frame 5–30 μm) is a good tracer of the total infrared luminosity, $L(\text{IR}) (=L[8\text{--}1000 \mu\text{m}])$, and star formation rate (SFR), of galaxies up to $z \sim 1.3$. We use deep MIR images from the Infrared Space Observatory (ISO) and the Spitzer Space Telescope in the Northern field of the Great Observatories Origins Deep Survey (GOODS-N) together with VLA radio data to compute three independent estimates of $L(\text{IR})$. The $L(\text{IR}, \text{MIR})$ derived from the observed 15 and/or 24 μm flux densities using a library of template SEDs, and $L(\text{IR}, \text{radio})$, derived from the radio (1.4 and/or 8.5 GHz) using the radio-far infrared correlation, agree with a $1\text{-}\sigma$ dispersion of 40%. We use the k-correction as a tool to probe different parts of the MIR spectral energy distribution (SED) of galaxies as a function of their redshift and find that on average distant galaxies present MIR SEDs very similar to local ones. However, in the redshift range $z = 0.4\text{--}1.2$, $L(\text{IR}, 24 \mu\text{m})$ is in better agreement with $L(\text{IR}, \text{radio})$ than $L(\text{IR}, 15 \mu\text{m})$ by 20%, suggesting that the warm dust continuum is a better tracer of the SFR than the broad emission features due to polycyclic aromatic hydrocarbons (PAHs). We find marginal evidence for an evolution with redshift of the MIR SEDs: two thirds of the distant galaxies exhibit rest-frame MIR colors ($L(12 \mu\text{m})/L(7 \mu\text{m})$ and $L(10 \mu\text{m})/L(15 \mu\text{m})$ luminosity ratios) below the median value measured for local galaxies. Possible explanations are examined but these results are not sufficient to constrain the physics of the emitting regions. If confirmed through direct spectroscopy and if it gets amplified at higher redshifts, such an effect should be considered when deriving cosmic star formation histories of dust-obscured galaxies. We compare three commonly used SED libraries which reproduce the color-luminosity correlations of local galaxies with our data and discuss possible refinements to the relative intensities of PAHs, warm dust continuum and silicate absorption.

Key words. galaxies: evolution – infrared: galaxies – galaxies: starburst

1. Introduction

Luminous infrared phases, during which galaxies radiate the bulk of their light in the infrared (IR) and are producing stars at rates larger than $20 M_{\odot} \text{ yr}^{-1}$, play a dominant role in the cosmic star formation history (CSFH) and in the production of the cosmic infrared background (CIRB) (Chary & Elbaz 2001; Elbaz et al. 2002, 1999; Xu et al. 2003; Franceschini et al. 2001, 2003; Lagache et al. 2004; Chary et al. 2004; Papovich et al. 2004). Those studies suggest that at least half of present-day stars were formed in “infrared luminous galaxies”,

which we define here as the combination of luminous (LIRGs, $10^{11} L_{\odot} \leq L(\text{IR}) < 10^{12} L_{\odot}$) and ultra-luminous (ULIRGs, $L(\text{IR}) \geq 10^{12} L_{\odot}$) infrared galaxies. Indeed, the comoving density of mid (15 and 24 μm) and total IR luminosities ($L(\text{IR}) = L[8\text{--}1000 \mu\text{m}]$) due to infrared luminous galaxies was about 70 times larger at $z \sim 1$ than it is today (LeFloc'h et al. 2005; Chary & Elbaz 2001). However, existing instruments do not allow direct measurement of $L(\text{IR})$ and one must rely on correlations between other wavelength ranges and $L(\text{IR})$ to derive its value as well as the obscured star formation rate (SFR) that it quantifies (Kennicutt 1998).

$L(\text{IR})$ can be derived from a single measurement in the mid IR (MIR, rest frame 5–30 μm) for local galaxies with a 68% uncertainty of 30–40% depending on the MIR wavelength (see Figs. 1 and 2 from Chary & Elbaz 2001). Similarly, the radio continuum exhibits an impressive correlation with $L(\text{IR})$ over four orders of magnitude with an uncertainty of only 5% over

^{*} Based on observations collected with the Spitzer Space Telescope (which is operated by the Jet Propulsion Laboratory, California Institute of Technology under NASA contract 1407) and on observations with ISO (an ESA project with instruments funded by ESA Member States (especially the PI countries: France, Germany, The Netherlands and the UK) with the participation of ISAS and NASA).

nearly 2000 galaxies (Yun et al. 2001). However, it must be noted that when limited to the 162 infrared luminous galaxies of the sample of Yun et al. (2001), this dispersion rises to 46% which is comparable to the one observed between the mid-infrared and total IR luminosities. The origin of both correlations, linking the radio and MIR to $L(\text{IR})$, is not yet completely understood since several physical processes are generally advocated to explain the emission in both domains.

It is generally acknowledged that the radio emission is produced by synchrotron radiation from relativistic electrons and free-free emission from HII regions. Most of the energy required for the acceleration of electrons is produced by the supernova remnants of stars more massive than $8 M_{\odot}$, which also dominate the ionization in HII regions. However, whether this is enough to explain the extent of the correlation remains a matter of debate.

The correlation between mid and far IR luminosities of galaxies is more direct since both are produced by the re-emission of UV photons by dust, but the physics of the emitting sources is quite complex. Above $60 \mu\text{m}$, the radiation of a galaxy is dominated by the grey body emission of “big dust grains” reaching an equilibrium temperature of 20–50 K. At shorter wavelengths, the spectrum of a galaxy results from the combination of:

- the continuum emission due to stochastically heated, warm dust grains, fluctuating around temperatures of a few hundred degrees. The carriers associated with this emission are commonly considered to be Very Small Grains (Desert et al. 1990, VSG);
- the PAH (polycyclic aromatic hydrocarbon) bands due to stochastically heated molecules producing broad features in emission at 3.3, 6.2, 7.7, 8.6, 11.3 and $12.7 \mu\text{m}$;
- the absorption features due to silicates which are centered at 9.7 and $18 \mu\text{m}$.

Extragalactic surveys in the MIR, FIR, sub-millimeter and radio have all been used to trace star formation without being affected by dust extinction. However, with existing datasets and instrument sensitivities, the MIR is the most efficient wavelength to detect galaxies in the LIRG regime up to $z \sim 2$. Sub-millimeter surveys are limited to the mJy level where LIRGs are only detected up to $z \sim 0.5$ and with a bias towards objects with cooler dust temperatures for a fixed IR luminosity (Chapman et al. 2005). Deep radio surveys provided a picture consistent with the one derived from the MIR but to a shallower depth (Haarsma et al. 2000; Elbaz et al. 2002; Elbaz & Cesarsky 2003). As a result, it is crucial to determine whether MIR properties of distant infrared luminous galaxies are similar to local ones and assess if the MIR can be used as a tracer of star formation in the distant universe. This is the goal of the present paper.

We will first compare the $L(\text{IR})$ derived independently from three tracers, namely the radio continuum at 1.4 and/or 8.5 GHz, the $15 \mu\text{m}$ flux density from ISOCAM (Cesarsky et al. 1996) onboard the Infrared Space Observatory (Kessler et al. 1996, ISO) and the $24 \mu\text{m}$ flux density from MIPS (Multiband Imaging Photometer for Spitzer Rieke et al. 2004) onboard the Spitzer Space Telescope (Werner et al. 2004). The flux density

and variation of the k-correction at the two MIR wavelengths are used to constrain the relative contributions of the three components of MIR light: VSGs, PAHs and silicate absorption. Using a similar strategy, Elbaz et al. (2005) and Teplitz et al. (2005) showed evidence that the MIR SED distant LIRGs did exhibit PAH features in emission. We will extend this work statistically by producing a direct comparison of the positions of local and distant galaxies in luminosity-luminosity diagrams at the same rest-frame wavelengths. This will allow us to test a possible variation of the relative roles played by the previous three ingredients of MIR SEDs which would have strong implications on the derivation of the CSFH.

While the derivation of $L(\text{IR})$ from a radio measurement depends only on the radio-far infrared (FIR) correlation and radio spectral index, which is well constrained for star forming galaxies, it is strongly dependant on the library of template SEDs that is chosen when using the MIR. Hence we will compare three commonly used SED libraries – CE (Chary & Elbaz 2001), DH (Dale & Helou 2002) and LDP (Lagache et al. 2004) – which present some noticeable differences in terms of the relative contributions of the three major components of MIR light.

We adopted a $H_0 = 75 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M = 0.3$, $\Omega_{\Lambda} = 0.7$ cosmology throughout this paper.

2. Sample

The sample consists of 49 IR luminous galaxies detected with ISOCAM and MIPS, including a subsample of 17 radio-detected galaxies, located in the Great Observatories Origins Deep Survey in the Northern hemisphere (GOODS-N) centered on the Hubble Deep Field North (HDFN). GOODS is a NASA Legacy Survey with Spitzer (Dickinson et al., in prep.) and with the Hubble Space Telescope (HST) Advanced Camera for Surveys (ACS) (Giavalisco et al. 2004).

The size of the sample is limited by the depth of the ISOCAM catalog at $15 \mu\text{m}$ (Aussel et al. 1999). This catalog is complete at the 90% level down to $100 \mu\text{Jy}$ but a total of 95 sources are detected down to $\sim 10 \mu\text{Jy}$ among which 81% have a spectroscopic redshift (Cohen et al. 2000; Wirth et al. 2004). We used a revised version of the Aussel et al. (1999) catalog (H. Aussel, private communication): $15 \mu\text{m}$ sources were attributed an optical counterparts from HST images and when two or more ISOCAM galaxies were closer than $12''$, the optical position of the HST sources was used to deblend the MIR sources. We rejected ISOCAM sources for which two potential optical counterparts were closer than the FWHM of the ISOCAM PSF ($4.6''$, Okumura 1998) and kept only the sources with negligible residuals after deconvolution using the optical centers in the final catalog. After extracting those, the catalog consists of 54 galaxies, all of which turned out to possess a MIPS counterpart. We checked all individual sources by eye in the MIPS- $24 \mu\text{m}$ image and found that blending was not an issue for any of this sub-sample of galaxies. Finally, we removed the five active galactic nuclei (AGN) that were identified from their X-ray emission (Fadda et al. 2002; Alexander et al. 2002) and the final sample consists of 49 galaxies.

The radio data used in this study came from VLA A-array observations done by Richards (2000) and new additional 26 h of B-array data acquired by Morrison et al. (2006). The combined data sets and new reductions used here yielded an improved rms of 5.3 uJy at the phase center of the reduced map and provided a significant fraction of new faint radio detections (Morrison et al. 2006). The final sample is described in Tables 3 and 4.

The astrometry of the MIPS 24 μm images is good to 0.2'' based on a cross correlation with the IRAC images. Fewer than 10 sources, none of which are relevant for this paper, are extended in the MIPS images which have a spatial resolution of 5.7'' (PSF FWHM). Furthermore, almost all 24 μm sources (down to $\sim 20 \mu\text{Jy}$, 5- σ) are found to have an IRAC 3.6 μm counterpart. 24 μm fluxes were determined by fitting a 24 μm PSF at the position of the IRAC sources, using a technique similar to DAOPHOT. The technique will be described in greater detail in the GOODS MIPS catalog paper (Chary et al. 2005, in prep.). This technique alleviates the effect of confusion noise and provides a direct association between the 24 μm source and its shorter wavelength counterpart.

The sample of local galaxies which will be compared to the distant luminous infrared galaxies consist of 154 galaxies ($z \leq 0.1$) with flux densities measured at 12, 25, 60 and 100 μm with IRAS and at 7 and 15 μm with ISOCAM as described in Chary & Elbaz (2001) and Elbaz et al. (2002). Only a subsample of these objects have 1.4 GHz radio flux densities.

3. Total IR luminosity and SED libraries

3.1. SED libraries and decomposition between VSGs and PAHs

We briefly summarize in the following the origin of the three libraries of template SEDs – CE, DH, LDP – (see Fig. 1) and we refer the reader to the associated papers for more details. While the CE templates were built to reproduce the observed local luminosity–luminosity correlations from 7 to 850 μm , the DH ones were designed to fit the observed color–color relationships between local galaxies. The DH library consists of 64 templates sorted as a function of the f_v^{60}/f_v^{100} ratio in the IRAS FIR bands. In order to compare this library to the CE and LDP ones, we attributed a total IR luminosity, $L(\text{IR})$, to each SED using Eq. (1) that we derived from the fit of the $\log_{10} [f_v^{60}/f_v^{100}]$ versus $\log_{10} [L(\text{IR})]$ relationship (see Fig. 6a from Soifer et al. 1987) for objects in the Bright Galaxy Sample. The coefficients and dispersion that we used are given in Eq. (1). The resulting SEDs exhibit total IR luminosities in the range $L(\text{IR}) = 2.1 \times 10^8 - 2.2 \times 10^{14} L_\odot$ (see Fig. 1) and fit the local luminosity–luminosity correlations used by CE with a comparable quality.

$$\log_{10} \left[f_v^{60}/f_v^{100} \right] = 0.128 \times \log_{10} [L(\text{IR})] - 1.611_{-0.119}^{+0.112} \quad (1)$$

The shape of the 46 LDP starburst templates ($L(\text{IR}) = 3 \times 10^9 - 6 \times 10^{12} L_\odot$) in the MIR present the smallest evolution with $L(\text{IR})$. They result from a revision by LDP of the Lagache et al. (2003) templates where the continuum in the 12–30 μm has been modified to allow a better fit of the MIPS-24 μm number counts. Another 46 normal templates were also built

Fig. 1. Evolution of the SED templates with infrared luminosity in the 3–30 μm range *top*: Chary & Elbaz SED templates (2001) *center*: Dale & Helou SED templates (Dale & Helou 2002) *bottom*: Lagache et al. (2004).

by Lagache et al. (2003) to reproduce the population of spiral galaxies which radiate more than half of their energy in the optical. Since infrared luminous galaxies do not fall in this category, we did not use these SEDs for the estimation of $L(\text{LIR}, \text{MIR})$. However, we will present their location in the MIR color–color diagrams of Sect. 5.

We have used the method of Verstraete et al. (2001) and Galliano et al. (2005) to decompose each SED from all three libraries into the sum of broad emission lines at 5.3, 5.7, 6.2, 7.7, 8.6, 11.3, 12.0, 12.7, 13.6 and 14.3 μm due to PAHs and warm dust continuum due to VSGs, hereafter called the PAH and VSG contributions. Lorentzian profiles were adopted for the emission features (as proposed by Boulanger et al. 1998; Verstraete et al. 2001), with line widths and intensities as free parameters. The VSG continuum was modeled with a modified black body, $\propto B_\nu(T) \times \nu^\beta$, $\beta = 1$ being the emissivity; the temperature, T , and the intensity of this component are free to vary, in order to minimise the χ^2 of the fit. The decomposition of the DH SED with $L(\text{IR}) = 9 \times 10^{11} L_\odot$ is presented in Fig. 2.

Fig. 2. Demonstration of the decomposition method on the template galaxy with $L(\text{IR}) = 9 \times 10^{11} L_{\odot}$, in the DH library. The spectrum (thin line) is fitted with the linear combination of a hot grain continuum (bold line), PAH bands (dashed lines) and ionic lines (dotted lines).

This technique provides excellent fits for all SEDs regardless of luminosity and without introducing a silicate feature in absorption at $9.7 \mu\text{m}$. The presence of a trough around $10 \mu\text{m}$ that is visible mostly in the CE SEDs below $5 \times 10^{11} L_{\odot}$ (Fig. 1) is perfectly reproduced by the depression between the right wing of the $8.6 \mu\text{m}$ feature and the left wing of the $11.3 \mu\text{m}$ one. It has been shown by various authors that the MIR SED of local star forming galaxies can be reproduced in the absence of silicate absorption at $9.7 \mu\text{m}$ which is difficult to separate from PAH bands when the latter are intense (e.g. Sturm et al. 2000). PAHs are always strong in the three SED libraries both around $7 \mu\text{m}$ and $12 \mu\text{m}$, except for the most luminous galaxies in the CE library, but this is also where no trough is noticeable (see Fig. 3).

This decomposition allows to follow the relative contribution of each component of the SEDs, i.e. PAHs and VSGs, as a function of wavelength for all SEDs and to study its evolution with $L(\text{IR})$. We computed this evolution with $L(\text{IR})$ in two passbands centered on the two strongest PAH features at 7 and $12 \mu\text{m}$. These two passbands correspond to the rest-frame central wavelenths probed by the ISOCAM- $15 \mu\text{m}$ and MIPS- $24 \mu\text{m}$ filters at $z = 1$. The two components for each passband are hereafter called L_7^{PAH} , L_7^{VSG} and L_{12}^{PAH} , L_{12}^{VSG} . The DH and LDP libraries present a similar behavior (see Fig. 3), i.e. very little variation of the contribution of PAHs to these bands over the whole range of total IR luminosities: PAHs are responsible for $\sim 90\%$ ($\sim 50\%$) of the light in the $7 \mu\text{m}$ ($12 \mu\text{m}$) band.

On the contrary, while the contribution of PAHs remains larger than 80% in the $7 \mu\text{m}$ band for the CE library, it becomes smaller than that of the VSGs in the $12 \mu\text{m}$ band $L(\text{IR}) = 5 \times 10^{11} L_{\odot}$, and reaches 20% for the highest luminosities. A direct comparison with a sample of local galaxies for which both ISOCAM spectroscopy and IRAS broadband fluxes are available suggests that the behavior of the DH and LDP templates is more representative of the 7 – $12 \mu\text{m}$ color for local galaxies although we do see a trend for the contribution of PAHs to decrease in the ULIRG regime (see galaxies 18 and 19 in Fig. 3). These local galaxies are comprised of local spirals

(Roussel et al. 2001), starbursts (Laurent et al. 2000) and dwarf galaxies (Madden et al. 2005b) observed with the Circular Variable Filter of ISOCAM. Note that the LDP templates provide a ratio of the 12 over $7 \mu\text{m}$ flux densities which does not vary with luminosity, contrary to what is observed for local galaxies, and is twice smaller than the observed average ratio (see Sect. 5).

In Fig. 3, galaxies number 4 to 19 have metallicities between 0.6 and $2 Z_{\odot}$, typical of relatively massive galaxies at $0 < z < 1$. Four galaxies (numbers 0 to 3 in Fig. 3), have metallicity lower than $0.4 Z_{\odot}$. Their properties may be reflective of primeval galaxies, for which local SED libraries might not be valid in the derivation of total IR luminosities (see Galliano et al. 2003, 2005; Engelbracht et al. 2005a).

3.2. Derivation of the total infrared luminosity (8–1000 μm)

The correlations between the FIR (40 – $120 \mu\text{m}$, L_{FIR}) or total IR (8 – $1000 \mu\text{m}$, $L(\text{IR})$) luminosity with the radio and MIR can be used to derive independent estimates of $L(\text{IR})$. We use $L(\text{IR}, \text{radio})$, $L(\text{IR}, 15)$ and $L(\text{IR}, 24)$ for the infrared luminosity derived from the radio, ISOCAM-15 and MIPS-24 passbands respectively. L_{FIR} and $L(\text{IR})$ are related by Eq. (2) computed from the Bright Galaxy Sample (Soifer et al. 1987) where we use the definitions of Helou et al. (1988) for L_{FIR} and Sanders & Mirabel (1996) for $L(\text{IR})$.

$$L_{\text{IR}} = 1.91(\pm 0.17) \times L(\text{FIR}). \quad (2)$$

For the radio-FIR correlation, we used a q -parameter of 2.34 as defined in Eq. (3) (Condon 1992; Yun et al. 2001):

$$q = \log_{10} \left(\frac{L(\text{FIR})(\text{W})}{3.75 \times 10^{12} (\text{Hz})} \frac{1}{L_{1.4 \text{ GHz}} (\text{WHz}^{-1})} \right). \quad (3)$$

The rest-frame 1.4 GHz monochromatic luminosity was derived from the observed 1.4 or 8.5 GHz flux densities assuming a radio spectral slope for star forming galaxies of $\alpha = 0.8 \pm 0.15$ (Yun et al. 2001, $S_{\nu} \propto \nu^{-\alpha}$).

To derive $L(\text{IR})$ from the MIR (15 and/or $24 \mu\text{m}$), we used the strategy advocated in Chary & Elbaz (2001). Each one of the template SEDs is redshifted to the distance of the observed source. Then, the SED whose MIR flux density is the closest to the observed one is used to derive $L(\text{IR})$ after it is normalized to the exact observed flux density.

4. Global consistency of the $15 \mu\text{m}$, $24 \mu\text{m}$ and radio star formation indicators

The 15 and $24 \mu\text{m}$ passbands probe different sources of MIR emission at the median redshift ($z \sim 0.85$) of the sample considered here. At this distance, the $15 \mu\text{m}$ band samples the PAH emission centered around $7.7 \mu\text{m}$ while the $24 \mu\text{m}$ band measures the combined emission from VSGs and the 11.3 and $12.7 \mu\text{m}$ bands. However, both bandpasses provide consistent values for $L(\text{IR})$ (see Fig. 4) with a median ratio of 1 and an rms of 40% when using the DH library (LIRGs/ULIRGs only, i.e. third line of Table 1). This dispersion is the same as

Fig. 3. Evolution of the $L_{\text{PAH}}/(L_{\text{PAH}} + L_{\text{VSG}})$ with $L(\text{IR})$ at $7 \mu\text{m}$ (up) and $12 \mu\text{m}$ (down). Sample of galaxies: 0: SBS 0335 ($0.03 Z_{\odot}$) 1: IIZw 40 ($0.2 Z_{\odot}$), 2: NGC 5253 ($0.2 Z_{\odot}$), 3: NGC 1140 ($0.4 Z_{\odot}$), 4: NGC 520, 5: M 51, 6: NGC 3256, 7: Cen A, 8: M 82, 9: IC 342 (central starforming region), 10: NGC 6946, 11: NGC 253, 12: Circinus, 13: NGC 1365, 14: NGC 6240, 15: M 83, 16: NGC 4038/39 (Mirabel et al. 1998, overlapping region of the Antennae galaxies), 17: nucleus of NGC 4038 (Mirabel et al. 1998), 18: Arp 220 (Charmandaris et al. 1999), 19: IRAS 23128–5919 (Charmandaris et al. 2002). Galaxies number 4 to 19 have metallicities between 0.6 and $2 Z_{\odot}$ while galaxies number 0 to 3 have metallicity $\leq 0.4 Z_{\odot}$ as indicated within parenthesis.

the MIR versus $L(\text{IR})$ one for local galaxies which suggests that the MIR SED of galaxies did not strongly evolve with redshift up to $z \sim 1$.

The 18 galaxies of the sample for which both MIR and radio data are available are located at redshifts between $0.3 < z < 1.3$. The total IR luminosity derived from $24 \mu\text{m}$ and the radio are consistent within 40% (rms defined as the 68% confidence level, see Fig. 5), in agreement with previous studies (Elbaz et al. 2002; Garrett 2002; Gruppioni et al. 2003; Appleton et al. 2004). The median ratio of $L(\text{IR}, \text{MIR})$ over $L(\text{IR}, \text{radio})$ is ~ 1 (see Table 2) but the dispersion around this value depends on the MIR wavelength that is used and on the library of template SEDs. Note that the 40% dispersion of $L(\text{IR}, \text{MIR})/L(\text{IR}, \text{radio})$ is comparable to the 46% dispersion for $L(\text{FIR})/L(\text{IR}, \text{radio})$ found for the 162 local IR luminous galaxies of Yun et al. (2001) and Reddy & Yun (2004). Hence, the agreement between MIR and radio derived total IR luminosities at $z \sim 1$ is at least as good as in the local universe, which suggests that the SED of galaxies in the IR were not strongly different at $z \sim 1$ from what it is today.

The $24 \mu\text{m}$ passband gives the lowest dispersion, with an rms of ~ 30 and 40% for the CE and DH libraries respectively. At $15 \mu\text{m}$, the dispersion becomes as large as 100%

for the CE library and 60% for DH. The very good agreement of $L(\text{IR}, 24)$ with $L(\text{IR}, \text{radio})$ supports the idea that the radio remains a robust SFR indicator up to $z \sim 1.3$. This in turns implies that the $15 \mu\text{m}$ passband is a less robust tracer of $L(\text{IR})$ than $24 \mu\text{m}$. Since the median redshift of those galaxies is $z \sim 0.85$, this suggests that the warm dust continuum is a better tracer of $L(\text{IR})$ than PAHs.

A comparison between the results obtained with the CE and DH libraries shows that systematic effects are observed for $L(\text{IR}, 24) \geq 10^{11} L_{\odot}$. We find that the $L(\text{IR}, 15)$ derived from the CE library is 30% larger than $L(\text{IR}, 24)$ and that the ratio of both luminosities presents a dispersion between 60 and 90% (see Table 1). The major difference between the CE and DH libraries is the progressive dilution of PAHs by the VSG continuum as a function of increasing $L(\text{IR})$ for the CE SEDs (see Fig. 1) If this dilution were to be excessive or if PAHs were to be stronger than predicted by this library then one would expect the CE SEDs to overestimate the $L(\text{IR})$ derived from a flux density measured around the peak of PAHs emission around $8 \mu\text{m}$. This would explain the excess ratio of $L(\text{IR}, 15)$ over $L(\text{IR}, 24)$. And indeed, when compared to an independent tracer of $L(\text{IR})$, the radio, we find that $L(\text{IR}, 15)/L(\text{IR}, \text{radio})$ is 20% larger than one, with a dispersion larger than with

all galaxies	$0.84^{+0.17}_{-0.38}$	$1.2^{+0.8}_{-0.7}$	$1.0^{+0.8}_{-0.4}$	$0.5^{+0.4}_{-0.2}$
$L(\text{IR}, 24) < 10^{11} L_{\odot}$	$0.47^{+0.09}_{-0.22}$	$0.8^{+0.8}_{-0.4}$	$0.8^{+1.0}_{-0.4}$	$0.8^{+0.9}_{-0.5}$
$L(\text{IR}, 24) \geq 10^{11} L_{\odot}$	$0.85^{+0.19}_{-0.10}$	$1.3^{+1.0}_{-0.6}$	$1.0^{+0.4}_{-0.4}$	$0.5^{+0.2}_{-0.2}$

the DH library (see Table 2). When computed using the LDP library, $L(\text{IR}, 24)$ is twice larger than $L(\text{IR}, 15)$ (see Table 1). The origin of this discrepancy is opposite to the one with CE, i.e. the strength of PAHs around $\lambda \sim 8 \mu\text{m}$ (in the rest-frame of the $z \sim 0.85$ galaxies) is too strong for these luminosities. Indeed the $L(\text{IR}, \text{MIR})$ predicted with the LDP library exhibit a systematic offset with respect to $L(\text{IR}, \text{radio})$ (see Table 2). To avoid confusion, we did not plot those points in Fig. 5. This discrepancy results from the $7.7 \mu\text{m}$ PAH feature being too strong and the continuum plus PAH emission around $12 \mu\text{m}$ being too faint in their SED library.

Finally, we note that the three galaxies with redshifts close to $z \sim 0.5$ – for which $L(\text{IR}, \text{radio}) \leq 3 \times 10^{11} L_{\odot}$ – exhibit a $L(\text{IR}, 15)/L(\text{IR}, \text{radio})$ ratio lower than 1 both for CE and DH (Fig. 5). At $z \sim 0.5$, the $15 \mu\text{m}$ passband probes the $10 \mu\text{m}$

trough in the rest-frame which might be underestimated by those templates. The number of galaxies at this redshift for which both MIR and radio data are available is too small in the present sample to derive any strong conclusion. However, we will address this point by comparing the MIR sample to local galaxies in the next section.

5. Testing the redshift dependence of mid-infrared SEDs

In order to check whether distant and local luminous IR galaxies exhibit consistent MIR properties, we have compared the evolution of the observed $24 \mu\text{m}$ over $15 \mu\text{m}$ luminosity ratio with redshift to prototypical starbursts and active galactic nuclei (Fig. 6a) and to SEDs such as CE and DH (Fig. 6b). We have also selected two redshift bins ($z \sim 0.6$ and 1) such that the 15 and $24 \mu\text{m}$ passbands probe rest-frame wavelengths for which data on local galaxies are already available. Local and distant galaxies are represented with filled triangles and circles respectively in the Figs. 8, 9. We distinguish three domains in luminosity for “normal” galaxies, “LIRGs” and “ULIRGs”, corresponding to $[10^{10}-10^{11}]$, $[10^{11}-10^{12}]$ and greater than $10^{12} L_{\odot}$ range. In both figures, the median ratio of the luminosities for local and distant galaxies are marked with dark solid triangles and circles respectively. The 1σ error bars

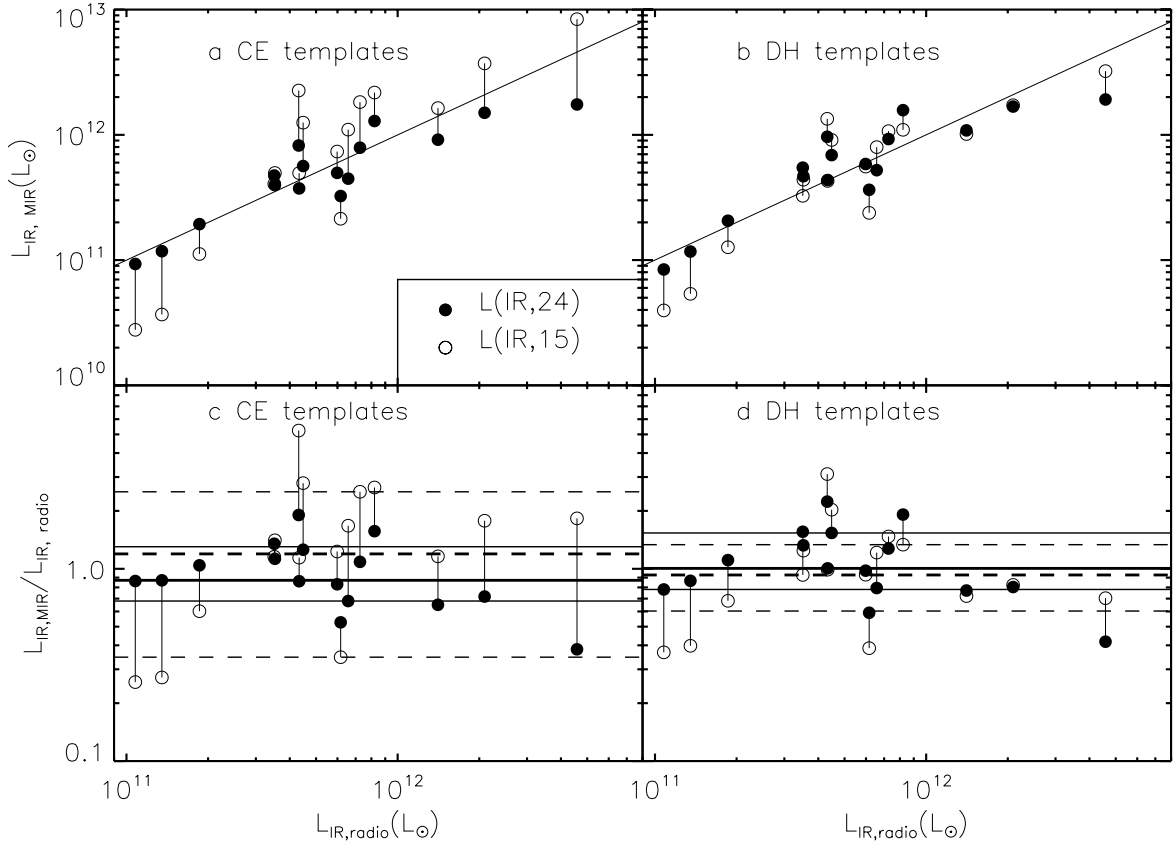

Fig. 5. Comparison of the total IR luminosity (8–1000 μm) derived from the radio (from the 1.4 and/or 8.5 GHz bands) and the MIR at 15 μm (open circles) and 24 μm (filled circles). **a)**, **c)** and **b)**, **d)** were produced using the CE and DH libraries of template SEDs respectively, to derive $L_{\text{IR, MIR}}$. The solid line in **a)**, **b)** is the one-to-one correlation between the two $L(\text{IR})$. The solid and dashed lines in **c)**, **d)** represent the median (thick lines) and 1- σ (68%) dispersion (thin line) around this median for the 24 (solid) and 15 μm (dashed) data respectively.

Table 2. Median and 68% dispersion around the median of the ratio $L(\text{IR, MIR})/L(\text{IR, radio})$ estimated with the template SEDs of CE, DH and LDP.

z	$L(\text{IR, MIR})/L(\text{IR, radio})$						
	15 μm			24 μm			
	CE	DH	LDP	CE	DH	LDP	
$10^{11} \leq L(\text{IR}) \leq 10^{12} L_{\odot}$	$0.85^{+0.4}_{-0.4}$	$1.2^{+1.4}_{-0.8}$	$1.0^{+0.6}_{-0.5}$	$0.6^{+0.3}_{-0.3}$	$1.0^{+0.3}_{-0.2}$	$1.1^{+0.4}_{-0.3}$	$1.3^{+0.8}_{-0.5}$

were computed by the quadratic sum of a poissonian error and an error computed to include 68% of the galaxies in each bin. We will center the discussion on the normal and LIRG populations due to a lack of objects outside of these domains. We will start by presenting the redshift evolution of the observed 15 over 24 μm color as a test for the presence of PAHs in distant galaxies.

5.1. Testing the presence of PAHs in distant galaxies using the 15 over 24 μm ratio

In Fig. 6a, we compare the location of the GOODS-N galaxies (circles) in the 24 over 15 μm luminosity ratio versus redshift space to several prototypical local SEDs. This figure reproduces Fig. 3 of Elbaz et al. (2005) from which the square points

are taken. The closest starburst M 82 ($L(\text{IR}) = 4 \times 10^{10} L_{\odot}$), the merging system of the Antennae (NGC 4038-39; LIRG, $L(\text{IR}) = 1.4 \times 10^{11} L_{\odot}$, Mirabel et al. 1998), the highly obscured LIRGs NGC 4418 (Spoon et al. 2001), the classic, but atypical, ULIRG, Arp 220 (Charmandaris et al. 1999) and the Compton thick Seyfert II NGC 1068 (Le Floc'h et al. 2001) are compared to our distant LIRGs.

The templates can be divided into three families:

1. *Starbursts.* M 82 and the overlapping region of the Antennae galaxies Mirabel et al. (1998); Vigroux et al. (1996); the SEDs of M 82 and of the overlapping region of the Antennae galaxies (Mirabel et al. 1998; Vigroux et al. 1996) globally reproduce the behavior of the observed data but tend to respectively over- and under-estimate the L_{15}/L_{24} ratio above $z = 0.5$. This could be explained either

Table 3. Description of the sample. The ISOCAM^r ($f_{15\ \mu\text{m}}$) and MIPS ($f_{24\ \mu\text{m}}$) flux densities are given with their 68% error bars. $f_{1.4}$ and $f_{8.5}$ are the 1.4 and 8.5 GHz flux densities respectively from Morrison et al. (in prep.) and Richards (2000). The logarithm of the total IR luminosities were derived using the recipe described in the paper.

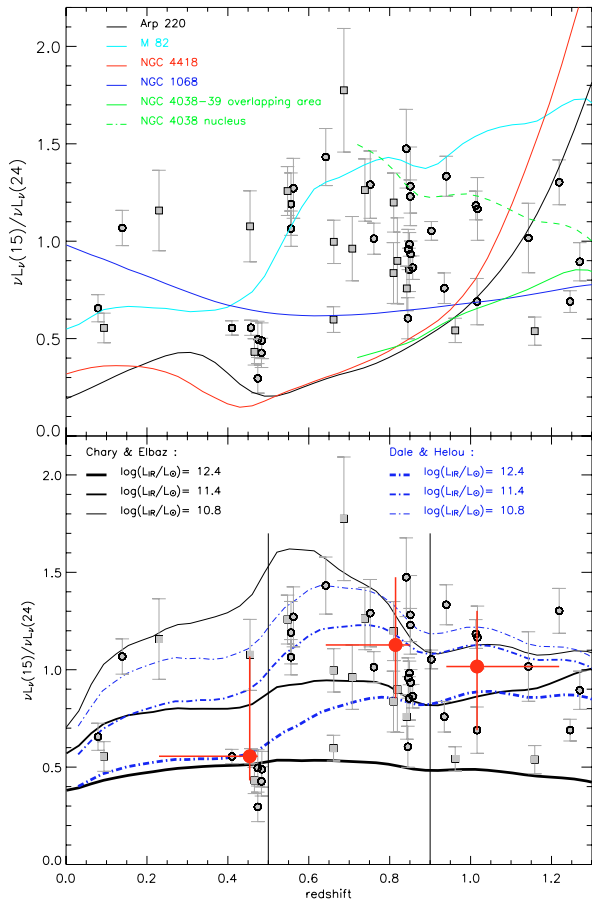

Fig. 6. $\nu L_{\nu}^{15 \mu\text{m}} / \nu L_{\nu}^{24 \mu\text{m}}$ as a function of the redshift. *Black and grey circles*: our distant sample of galaxies. *Black and grey squares*: data presented in Elbaz et al. (2005). *Red circles* median $\nu L_{\nu}^{15 \mu\text{m}} / \nu L_{\nu}^{24 \mu\text{m}}$ in each redshift bin with 1σ error bars.

by the warm dust continuum being too faint or the silicate absorption feature being too weak.

2. *Heavily obscured starbursts*: Arp 220, NGC 4418 and the nucleus of NGC 4038.

NGC 4418 is either a strongly embedded AGN or a compact starburst (Evans et al. 2003). The MIR spectrum shows strong silicate absorption without strong evidence for PAH features (Spoon et al. 2001).

The MIR spectrum of Arp 220 shows characteristics of a highly obscured continuum with silicate absorption (like NGC 4418) and a starburst component characterized by PAH emission (like M 82) (Spoon et al. 2004).

All three cases predict a low value for L_{15}/L_{24} at $z \leq 0.9$ and a high value at $z \geq 1.1$. This is probably due to a combination of strong silicate absorption and continuum emission from warm dust.

3. *Active galactic nucleus (AGN)*. NGC 1068 harbors a central black hole with a circumnuclear starburst. 75% of the MIR emission is dominated by the AGN emission (Le Floc’h et al. 2001). The MIR spectrum is dominated by a strong continuum, without PAH. Its L_{15}/L_{24} ratio is too weak for 68% of the sample due to its flat SED and the absence of PAH features in emission.

In Fig. 6b, we have indicated three bins of redshift (0–0.5, 0.5–0.9, 0.9–1.3) which correspond approximately to three bins in luminosity because of selection effects: $[3 \times 10^8 - 3 \times 10^{11}]$, $[3 \times 10^9 - 7 \times 10^{11}]$ and $[10^{10} - 3 \times 10^{12}] L_{\odot}$. In each bin, the red dot is associated to the median value of the data with an error bar including 68% of the sample. The position of the red dots confirms the conclusion of Elbaz et al. (2005) that the L_{15}/L_{24} ratio increases from $z \sim 0.2$ to 0.7 due to the entrance of the $7 \mu\text{m}$ PAH emission feature into the ISOCAM- $15 \mu\text{m}$ band.

The template SEDs from CE and DH are represented for three luminosities, $L(\text{IR}) = 10^{10.8}$ (thin line), $10^{11.4}$ (thick line) and $10^{12.4}$ (very thick line) L_{\odot} . The global behaviour of the data is well represented by both families of synthetic templates. However, for the CE templates, the $z = 0.5-0.9$ bin is better represented by SEDs less luminous than LIRGs while the observed galaxies are predominantly LIRGs. This confirms the previous statement that in the CE templates, the PAHs emission in IR luminous galaxies is underestimated by about 15–20%, while this is not the case of the DH templates.

5.2. L_{12} versus L_7

At $z \sim 1$, the 15 and $24 \mu\text{m}$ observations measure rest-frame wavelengths of approximately 7.5 and $12 \mu\text{m}$, respectively. We will designate the rest-frame luminosities at these wavelengths as L_7 and L_{12} . L_7 measures the “PAH bump” centered on the $7.7 \mu\text{m}$ dominant PAH feature, while L_{12} measures a combination of the 11.3 and $12.7 \mu\text{m}$ PAH bands with the warm dust continuum due to VSGs, as well as some contribution from the silicate feature in absorption, if any. We may compare L_7 and L_{12} for the high-redshift galaxies to data for local ($z \sim 0$) galaxies observed with ISOCAM-LW2, centered at $6.75 \mu\text{m}$, and IRAS $12 \mu\text{m}$ respectively. Figure 7a shows the rest-frame wavelengths observed by the 15 and $24 \mu\text{m}$ bands at $z \sim 1$ as grey shaded regions, and compares them to the ISOCAM-LW2 and IRAS $12 \mu\text{m}$ bandpasses for local galaxies. The comparison between local and distant galaxies at these wavelengths is presented in Fig. 8. Since the redshifted ISOCAM and MIPS filters do not exactly match the observed ISOCAM and IRAS filters used for local galaxies, we computed a color correction for each individual galaxy, taking into account its proper redshift, using the SED libraries. This color correction factor is always smaller than 20% and the choice of the CE or DH library makes less than a 5% difference.

We extracted a subsample of 116 galaxies from the local sample, all of which have flux measurements at both 7 and $12 \mu\text{m}$. The distant sample was made of 26 distant galaxies with a flux at 15 and $24 \mu\text{m}$ and located in the $0.8-1.25$ redshift range in the redshift range $0.8 < z < 1.25$, with median redshift $z = 0.90$.

Distant galaxies follow the same trend as local galaxies in their L_7 versus L_{12} correlation (Fig. 8a). This shows that at least in the MIR domain, the SED of galaxies have not evolved strongly between $z \sim 0$ and $z \sim 1$. We do find an indication of marginal evolution: nearly all $z \sim 1$ galaxies lie above the polynomial fit of degree 2 to the local sample (solid line

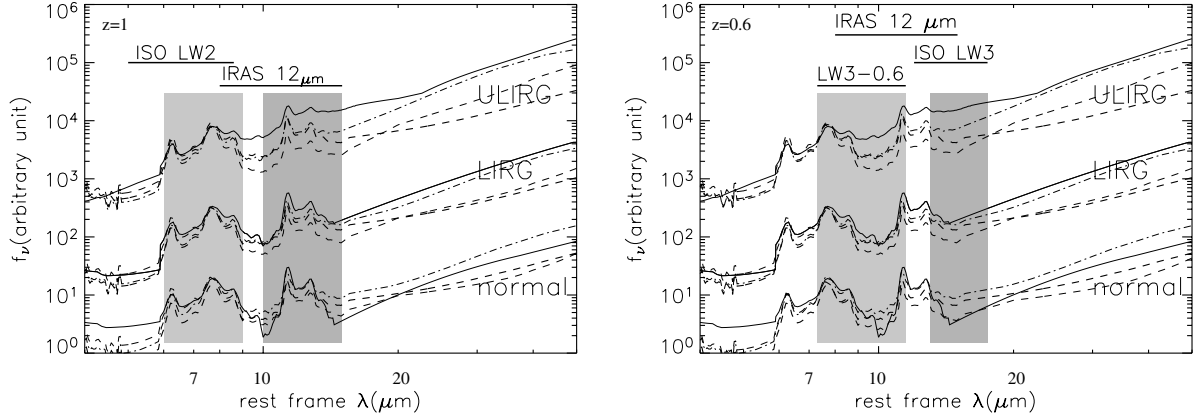

Fig. 7. Relative positions of the ISOCAM-15 μm and MIPS-24 μm bands for galaxies located at $z \sim 1$ **a)** and 0.6 **b)** with respect to the observed ISOCAM-LW2, LW3 and IRAS-12 μm bands. represented in the plots is f_ν in arbitrary units as a function of λ . Origin of the template SEDs at 3 different luminosities ($L(\text{IR}) = 10^{10} L_\odot$, “normal”, $10^{11} L_\odot$, “LIRG” and $10^{12} L_\odot$, “ULIRG”): CE (solid line), DH (dash-dotted line), LDP (dashed line: starburst template, thick dashed line “cold” template).

Fig. 8. Comparison between the rest-frame 7 and 12 μm luminosities of local (filled triangles) and $z \sim 1$ ($0.8 \leq z \leq 1.25$, big filled circles: $f_{15} \geq 150 \mu\text{Jy}$, little filled circles: $f_{15} \leq 150 \mu\text{Jy}$) galaxies. L_7 and L_{12} correspond to νL_ν at these central wavelengths for the local-ISOCAM-6.75 μm and IRAS-12 μm passbands – and $z \sim 1$ – rest-frame bands corresponding to the observed ISOCAM-6.75 μm and MIPS-24 μm – galaxies. Two domains of luminosities are defined by vertical lines (see text) where the local and distant galaxies are compared. **a)** L_7 as a function of L_{12} . The plain line is a polynomial of degree 2 fit to the local sample alone. **b)** L_{12}/L_7 ratio as a function of L_{12} . The median ratio for local and distant galaxies are indicated with dark triangles and circles respectively, in each luminosity bin. The lines indicate the prediction for the CE (plain line), DH (dash dot line), LDP cold (thick dashed line) and starburst (dashed line) templates.

in Fig. 8a). We computed in Fig. 8b the median L_{12}/L_7 ratio for local (filled black triangle) and distant (filled black circle) LIRGs. Distant galaxies exhibit a lower L_{12}/L_7 ratio than local

ones in both luminosity bins (LIRGs- normal galaxies), with an apparently stronger difference in the lower luminosity bin. However, this bin consists of only six galaxies, four of which are fainter than 75 μJy and therefore lie below the 60% completeness regime of the ISOCAM image (Aussel et al. 1999). The risk that the galaxies detected at this flux density level might not be representative of the average galaxy properties (Malmquist bias in the sense of favoring objects with strong 15 μm flux densities and low L_{12}/L_7) is therefore not negligible. Hence we consider that our sample is not robust against biases outside of the LIRG regime.

In the LIRG luminosity bin, all but two of the galaxies fall above the 90% completeness limit of 100 μJy . The median L_{12}/L_7 ratio for local galaxies lies above the 1- σ dispersion (including error bars) around the median ratio for distant galaxies, i.e. two thirds of the distant galaxies present a L_{12}/L_7 ratio lower than the median value for local galaxies. Although, this effect needs to be consolidated by a larger sample, we believe that it is important to consider the possibility that we are already seeing some indication of evolution that will become stronger at larger redshifts. Possible explanations for this evolution are discussed in Sect. 6.

The L_{12}/L_7 versus L_{12} trend is globally fitted by the CE and DH libraries but not the LDP one, which systematically underestimates L_{12}/L_7 over all luminosities. This observation confirms the excess PAH emission, already discussed in Sect. 4, for this library. Finally, we note that the CE library presents a rapid increase of L_{12}/L_7 with increasing luminosity in the IR luminous regime and that the $L(\text{IR})$ derived using this library might be overestimated by up to 50% for distant ULIRGs. This can be explained by the same reasons discussed in the previous section, i.e. the weak emission from PAHs around 8 μm in this library.

5.3. L_{10} versus L_{15}

At $z \sim 0.6$, the 15 and 24 μm observations measure rest-frame wavelengths of approximately 9.4 and 15 μm , respectively. We will designate these rest-frame luminosities as L_{10} and L_{15} .

While both L_{10} and L_{15} contain emission from the VSG warm dust continuum, only L_{10} is affected by the silicate absorption feature. Hence, the flux ratio of these two bands helps to quantify the strength of the silicate absorption. We may compare L_{15} for high-redshift galaxies to data for local ($z \sim 0$) galaxies observed with ISOCAM-LW3, centered at $15 \mu\text{m}$. There is no direct observation of L_{10} for local galaxies, but we may derive it from a combination of observations with ISOCAM-LW2 and IRAS- $12 \mu\text{m}$ as described below. We will designate this synthetic bandpass as “LW3-0.6”. We illustrate the local and redshifted bandpasses for the $z \sim 0.6$ sample in Fig. 7b. The comparison between local and distant galaxies at these wavelengths is presented in Fig. 9.

We have compared 115 local galaxies that have measured 12 and $15 \mu\text{m}$ flux densities to 35 distant galaxies at $z \sim 0.6$ ($0.4 \leq z \leq 0.8$). In order to probe the wavelength range associated with the $10 \mu\text{m}$ feature, we constructed a synthetic passband centered at $10 \mu\text{m}$ using a combination of the ISOCAM-LW3 ($12\text{--}18 \mu\text{m}$) and IRAS- $12 \mu\text{m}$ ($8\text{--}15 \mu\text{m}$) filters. The passband of the synthetic filter was chosen to reproduce the rest-frame wavelength range probed by the ISOCAM-LW3 filter for a galaxy located at $z \sim 0.6$, i.e. centered at $9.4 \mu\text{m}$ and therefore close to the $10 \mu\text{m}$ feature. We found that a combination of the ISOCAM-LW3 and IRAS- $12 \mu\text{m}$ filters could provide an estimate of the synthetic passband (hereafter called LW3-0.6) flux density with an accuracy of 20%. We optimized this combination for CE and DH templates independently but found that the difference between both computations is only 10% (see Eq. (4) computed for galaxies which $L(\text{IR}) \geq 4.7 \times 10^{10} L_{\odot}$). The LW3-0.6 filter is represented with a line in Fig. 7. At $z = 0.6$, the MIPS- $24 \mu\text{m}$ passband is roughly equivalent to the rest-frame ISOCAM-LW3 filter; however, we calculated a filter correction to take into account the k-correction and the difference of filter shapes. The correction is estimated at 10% when using the DH templates and 30% for CE.

$$\begin{aligned} L_{\text{LW3-0.6}}^{\text{CE}} &= 1.64_{-0.42}^{+0.14} \times L_{12} - 0.74_{-0.13}^{+0.70} \times L_{15} \\ L_{\text{LW3-0.6}}^{\text{DH}} &= 1.72_{-0.06}^{+0.02} \times L_{12} - 0.71_{-0.02}^{+0.04} \times L_{15}. \end{aligned} \quad (4)$$

Here again, as in Sect. 5.2, distant galaxies (light grey circles) follow the trend traced by local galaxies (filled triangles), hence confirming that no strong evidence is found for an evolution of the MIR SED of galaxies with redshift (see Fig. 9). Again, distant galaxies exhibit a systematically lower L_{10}/L_{15} ratio with two thirds of the distant LIRGs showing a lower ratio than local LIRGs. This cannot be explained by a selection effect since in this luminosity range, all galaxies exhibit ISOCAM flux densities above the 90% completeness limit. Possible explanations are discussed in Sect. 6.

6. Discussion and conclusions

We have presented a comparison of the mid infrared (MIR) and radio properties of local and distant galaxies (up to $z \sim 1.3$) with particular emphasis on IR luminous galaxies, i.e. LIRGs and ULIRGs. Our goal was to assess the possibility of deriving a total IR luminosity, $L(\text{IR})$, corresponding to a

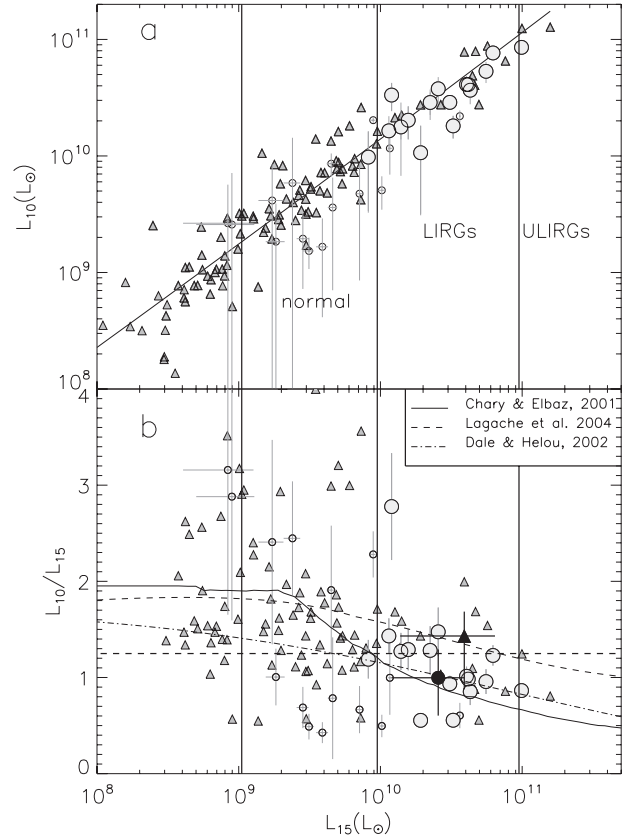

Fig. 9. Comparison of the rest-frame 10 and $15 \mu\text{m}$ luminosities of local (filled triangles) and $z \sim 0.6$ ($0.4 \leq z \leq 0.8$, *big filled circles*: $f_{15} \geq 150 \mu\text{Jy}$, *little filled circles*: $f_{15} \leq 150 \mu\text{Jy}$) galaxies. L_{15} corresponds to νL_{ν} at this central wavelength for the ISOCAM- $15 \mu\text{m}$ and MIPS- $24 \mu\text{m}$ passbands for local and $z \sim 0.6$ galaxies respectively. L_{10} corresponds to the rest-frame emission measured in the ISOCAM- $15 \mu\text{m}$ band at $z \sim 0.6$ and was derived from a combination of the IRAS- $12 \mu\text{m}$ and ISOCAM- $15 \mu\text{m}$ bands for local galaxies (see Eq. (4)). **a)** L_{10} as a function of L_{15} . The plain line is a polynomial of degree 2 fit to the local sample alone (here equivalent to a linear fit). **b)** L_{10}/L_{15} as a function of L_{15} . The median ratio for local and distant galaxies are respectively indicated with dark triangles and circles in both luminosity bins. The lines indicate the prediction for the CE (plain line), DH (dash dot line), LDP cold (thick dashed line) and starburst (dashed line) templates.

star formation rate (SFR), on the sole basis of a measured flux density in the MIR for those galaxies. We derived three $L(\text{IR})$ estimates using independently the measured ISOCAM- $15 \mu\text{m}$, MIPS- $24 \mu\text{m}$ and VLA- 1.4 GHz flux densities and found that all three luminosities were consistent at the 40% confidence level, i.e. an uncertainty similar to the one measured for the local MIR-FIR and radio-FIR correlations for IR luminous galaxies. This first result, obtained for a sample of 49 galaxies with redshifts up to $z \sim 1.3$, and a sub-sample of 18 galaxies detected in the radio, suggests that the MIR can be used as a tracer of the SFR of distant actively star forming galaxies. However, the $L(\text{IR})$ computed from $15 \mu\text{m}$ shows a 10–20% larger scatter than the one computed from $24 \mu\text{m}$ in comparison to the radio derived $L(\text{IR})$. This result suggests that the warm dust continuum and neutral PAH is a better tracer of the SFR than is the ionized PAH emission at rest-frame $7.7 \mu\text{m}$.

The redshift evolution of the 24 over 15 μm colors show a bump around $z \sim 0.7$ as one would expect from the entrance of PAH emission centered around 7.7 μm into the 15 μm passband. This behavior reinforces previous studies by Elbaz et al. (2005) and Teplitz et al. (2005) which were also interpreted as evidence for the presence of PAHs in distant IR luminous galaxies.

We attempted to probe the same rest-frame wavelength range in local galaxies and high redshift galaxies. We selected galaxies within two redshift bins centered at $z \sim 0.6$ and 1, where the observed 15 μm (24 μm) passband corresponds to the rest-frame 10 and 7 μm (15 and 12 μm) respectively. In both redshift bins, the distant galaxies fall in the same region as local galaxies of equivalent luminosities and provides an extension of local correlations to higher luminosities. We find marginal evidence of evolution with redshift of the MIR SEDs: two thirds of the distant galaxies exhibit rest-frame MIR colors ($L(12 \mu\text{m})/L(7 \mu\text{m})$ and $L(10 \mu\text{m})/L(15 \mu\text{m})$ luminosity ratios) below the median value measured for local galaxies. Possible explanations are examined below. It is indeed to be expected that an evolution should take place if not at the $z \sim 1$ level, then at higher redshifts. The first cause that one may consider is the role played by metallicity. It was recently showed by Engelbracht et al. (2005b) and Madden et al. (2005a) that the PAH over VSG continuum ratio was increasing as a function of metallicity, with a trend for galaxies with metallicities below $\log(Z) = 12 + \log(O/H) = 8.2$ to exhibit nearly no PAH contribution. Liang et al. (2004) found the gas metallicity of LIRGs ranging between half-solar to solar ($\log(Z) = 8.63\text{--}8.93$) at similar redshifts. Hence, the influence of metallicity is not expected to be strong in our sample. Furthermore, it would be responsible for a stronger L_{12}/L_7 for the distant galaxies instead of the lower values that we tend to find. We measure a L_{12}/L_7 ratio for the distant LIRGs which is similar to the one found for “normal” nearby galaxies. This may suggest that distant LIRGs, which are probably more gas rich than local ones, could also be triggered by less violent causes, i.e. minor mergers, gas infall or even spiral waves instead of the major mergers found in local galaxies, as suggested by their morphologies (see Bell et al. 2005). We note that the dust temperature measured in the far infrared also depends on the geometry of the regions of star formation (Chanial et al. 2005; Wang & Helou 1992). The lower L_{10}/L_{15} ratio may result from a deeper 9.7 μm silicate absorption. Another possibility would be that the level of ionization of PAHs in distant galaxies is higher: more ionised PAHs tend to present a lower L_{12}/L_7 (e.g. Dartois & D’Hendecourt 1997). Other causes might also play a role such as a different grain size distribution but it is not possible to disentangle between all those possibilities with existing data. Extended samples of objects at higher redshifts with Spitzer 16 μm and 24 μm imaging as well as mid-infrared spectroscopy will soon be available which might help discriminate between the various effects.

We tested three commonly used libraries of template SEDs – CE (Chary & Elbaz 2001), DH (Dale & Helou 2002) and LDP (Lagache et al. 2004) – in which the relative strengths of broad emission lines from PAHs with respect to warm dust continuum due to VSGs increases from CE to DH and to LDP.

The LDP library predicts values for $L(\text{IR})$ which are 40% too low from the measured 15 μm flux density and 30% too large from the 24 μm one, with respect to the radio ones. They also exhibit the largest dispersion and inconsistency between $L(\text{IR}, 15)$ and $L(\text{IR}, 24)$. This is mostly due to enhanced 8 μm and decreased the continuum between 11–32 μm and to a lesser extent, due to a lack of evolution of MIR SEDs as a function of $L(\text{IR})$.

The CE and DH libraries both provide robust fits to both local and distant galaxies but we find evidence for more PAH emission in IR luminous galaxies than predicted in the CE SEDs. As a result, the CE library would overestimate $L(\text{IR})$ for distant galaxies by 20–30%. If, as suggested above, distant galaxies do exhibit stronger PAH emission than local ones, then both libraries need to be revised and the CE library would overestimate $L(\text{IR})$ by up to 50% for ULIRGs at $z \sim 1$. Since LIRGs dominate the star formation rate density per unit comoving volume at least up to $z \sim 1.5$, this evolution of MIR SEDs does not significantly affect the derivation of the cosmic star formation history (CSFH). We have checked this by replacing the CE SEDs by the DH ones in the Chary & Elbaz (2001) model and found two CSFH which are consistent within 30%.

The true accuracy with which FIR luminosities can be determined at high redshift are being tested for the most luminous objects with Spitzer, and will be pushed to fainter luminosities with the Herschel satellite scheduled for launch 2007, and the Atacama Large Millimeter Array, ALMA. Direct MIR spectroscopy with the InfraRed Spectrograph onboard Spitzer will also provide very useful constraints if pushed to detect distant LIRGs.

Acknowledgements. We wish to thank the anonymous referee for his constructive remarks which helped improving the paper in particular on the discussion of possible biases and Guilaine Lagache for useful comments. We also wish to thank Hervé Aussel for giving us the possibility to use his latest version of his ISOCAM-15 μm catalog, including source deblending not included in the published version of the catalog.
