ABSTRACT

We used 2.5D simulations to analyze the magnetohydrodynamic instabilities arising from an initial equilibrium configuration consisting of a plasma jet or wake in the presence of a magnetic field with strong transverse gradients, such as those arising in the solar wind. Our analysis extends previous results by considering both a force-free equilibrium and a pressure-balance condition for a jet in a plasma sheet, along with arbitrary angles between the magnetic field and velocity field. In the force-free case, the jet/wake does not contain a neutral sheet but the field rotates through the flow to invert its polarity. The presence of a magnetic field component aligned with the jet/wake destroys the symmetric nature of the fastest growing modes, leading to asymmetrical wake acceleration (or, equivalently, jet deceleration). In the case of a jet, the instability properties depend both on the magnetic field and flow gradients, as well as on the length of the jet. The results are applied to the post-termination shock jet recently found in 3D global heliospheric simulations, where our analysis confirms and explains the stability properties found in such simulations.

Key words. instabilities – magnetohydrodynamics (MHD) – plasmas – methods: numerical – Sun: solar wind

1. Introduction

The evolution of systems consisting of sheared flows in the presence of strong magnetic field gradients is relevant to magnetohydrodynamic (MHD) structures in several solar and astrophysical environments, such as the interaction of the solar wind with a magnetospheric boundary (Ubroi 1984), a model for Earth's magnetotail (Sato & Walker 1982), extragalactic jets (Ferrari 1998), cometary tails (Cravens 1997), galactic center nonthermal filaments (Shore & Larosa 1999) the heliospheric current sheet (hereafter HCS) (Wang et al. 1988; Opher et al. 2004), solar streamers (Einaudi et al. 1999), X-ray jets from the solar corona (Shibata et al. 1992), solar flares (Tsuneta 1996), and more generally, astrophysical jets and wakes (Parhi et al. 1999; Baty & Keppens 2002).

From the first studies of an incompressible plane current-vortex sheet (Dahlburg et al. 1997) and a magnetized jet (Dahlburg et al. 1998), a magnetohydrodynamic model for the formation of the slow solar wind has been developed in which the basic magnetic field is aligned to a fluid wake contained in a neutral sheet (Einaudi et al. 1999). This model accounts for the plasmoid puffs observed in helmet streamers and attributes them to reconnection of the magnetic field at the current sheet, their subsequent acceleration being due to a Kelvin-Helmholtz (hereafter KH) instability triggered once the equilibrium magnetic field is modified by reconnection. In the presence of a magnetic field, the KH instability of a flow parallel to the field lines in an otherwise homogeneous medium sets in, when the velocity jump exceeds the Alfvén speed (Chandrasekhar 1961). The instability criteria are modified in the case of a finite transition (shear) layer and of a compressible medium. This model has been recently improved via the inclusion of compressibility

effects (Einaudi et al. 2001), as well as those due to the curvature in a spherical geometry (Rappazzo et al. 2003), while the effect of converging flows has been analyzed by Lapenta & Knoll (2005).

Here we use a 2.5D MHD code to analyze the stability properties and successive evolution of an initially perturbed equilibrium configuration, consisting in a jet flow (or, equivalently, a wake flow) across which there is a change in the initial magnetic field polarity. The angle σ between the asymptotic magnetic field (AMF) direction and the jet/wake flow is a free parameter. In our simulations, we scan different values of σ to explore how it affects the instability properties, properties which also depend on the relative gradients of magnetic field and velocity through the jet/wake. For example, a one-dimensional field orthogonal to the jet/wake has no influence on the linear stability properties, since perturbations in the plane of the jet/wake do not introduce any magnetic tension. On the other hand, a force-free field configuration (hereafter FFC), where the field “rotates” across the current sheet, may stabilize the jet/wake if the magnitude is sufficiently strong.

The primary application of this study is the question of solar wind acceleration above helmet streamers (Woo 1995; Gosling et al. 1981), leading to the slow solar wind streams where one typically observes a global magnetic field polarity inversion, which may or may not coincide with a “neutral sheet”. In a reference frame co-moving with the slow solar wind, we therefore have a bimodal flow profile where the velocity is zero at the HCS, and across it the interplanetary magnetic field (IMF) changes sign from the Southern to the Northern solar hemispheres, regions of fast wind. The magnetic field geometry is shown in Fig. 1, where it reverses direction crossing the wake and has an arbitrary angle σ to the flow in the $Y-Z$ plane.

Fig. 1. Wind case: reference frame (for v_0 and B_0 see Eqs. (7)–(9) or (11)–(13)).

Because there are indications (Smith 2001) that the IMF may not vanish through the sheet, but rotates across something like a force-free configuration (FFC) with a finite, though large, plasma β in the HCS, the instabilities of the combined configuration are non-trivial. Depending on the value of σ there may also be a stabilizing component of the magnetic field along the shear flow.

We will consider both an FFC and a simpler model in which the heliospheric current sheet coincides with a neutral sheet and the equilibrium is maintained by a pressure balance condition (PBC). This case also corresponds better to the post-termination shock (hereafter TS) jet that has been recently discovered at the current sheet with 3D numerical simulations by Opher et al. (2003). This structure was observed to form beyond the solar wind TS on the solar equatorial plane and to extend through the Heliopause (hereafter HP). In the Heliosheath (HS), the region between the TS and the HP, the β parameter decreases by a factor of 10^3 , so the role of the magnetic field is fundamental in that zone. Approaching the TS on the equatorial plane, as schematically shown in Fig. 2, the azimuthal component of the magnetic field downstream the shock is amplified, forming magnetic pressure ridges on either side of the HCS (Suess 1990). Previous numerical studies (Linde et al. 1998; Washimi & Tanaka 2001) have indicated that the HCS also remains in the equatorial plane beyond the TS, so the solar wind can flow freely only in the HCS region, where there is no azimuthal magnetic field that can slow it down. Moreover, the flow undergoes an acceleration due to a de Laval Nozzle process (Opher et al. 2003). This structure is unstable, probably due to the velocity difference between the flow in the current sheet and the surrounding medium.

In the following sections we are going to describe the numerical setup for our analysis, the basic conditions, and the chosen initial perturbations, (Sect. 2). In Sect. 3 we summarize the results of the numerical simulations for the FFC and PBC case applied to the wake model of the solar wind, showing that in both cases the evolution depends on whether the basic flow and the AMF are orthogonal or whether there is a generic inclination between them. In Sect. 4 we analyze the numerical results for the heliospheric jet evolution and study its linear instability, comparing several basic configurations. Based on preliminary results concerning the effect of a dipole tilt (Opher 2005, private communication), we consider how this might affect the stability

Fig. 2. Jet case: schematic reconstruction of the heliospheric environment at the TS on the equatorial plane. The magnetic field azimuthal component is amplified across the shock.

of the jet. In the conclusions Sect. 5, we summarize the results and point to open questions.

2. Governing equations, parameters, initial conditions

We solve the set of dissipative MHD equations in a Cartesian geometry (see Fig. 1). Analogous with hydrodynamic problems, we define a *stream-wise*, or *Fourier*, direction (Y) along which we impose periodic boundary conditions and use spectral methods to calculate derivatives, a *cross-stream* direction (X) along which the mean flow varies and we impose nonreflecting boundary conditions using the method of the projected characteristics (Jeffrey 1969; Roe & Balsara 1996; Vanajakshi et al. 1989), adopting a compact finite-difference scheme (Lele 1992) coupled with a hyperbolic tangent mesh stretching around the current sheet, and a *span-wise* direction (Z), corresponding to an invariance direction for the quantities describing our system. Our basic set of equations, written in non-dimensional form, is:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0 \quad (1)$$

$$\rho \frac{\partial \mathbf{v}}{\partial t} + \rho \mathbf{v} \cdot \nabla \mathbf{v} = -\nabla P - \left[\nabla \left(\frac{|\mathbf{B}|^2}{2} \right) - (\mathbf{B} \cdot \nabla) \mathbf{B} \right] + \frac{1}{\mathcal{R}} \nabla \cdot \boldsymbol{\zeta} \quad (2)$$

$$\frac{\partial T}{\partial t} + \mathbf{v} \cdot \nabla T = 0 \quad (3)$$

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{v} \times \mathbf{B}) + \frac{1}{\mathcal{R}_M} \Delta \mathbf{B}, \quad (4)$$

supplemented by the equation of state $P = \rho T$. In the above equations $\rho(\mathbf{x}, t)$ is the mass density, $\mathbf{v}(\mathbf{x}, t)$ the flow velocity, $P(\mathbf{x}, t)$ the thermal pressure, $\mathbf{B}(\mathbf{x}, t)$ the magnetic induction field, $T(\mathbf{x}, t)$ the plasma temperature, and $\boldsymbol{\zeta}_{ij} = \xi_{ij} - \frac{2}{3} \delta_{ij} \nabla \cdot \mathbf{v}$ is the viscous tensor, where $\xi_{ij} = \partial_i v_j + \partial_j v_i$. In order to obtain dimensionless equations, we use the characteristic quantities L^* , v^* , ρ^* , and the related quantities t^* , T^* , B^*

$$t^* = \frac{L^*}{v^*} \quad k_B T^* = \frac{1}{2} m_p (v^*)^2 \quad B^* = v^* \sqrt{4\pi \rho^*}$$

where m_p is the proton mass, and k_B the Boltzmann constant. We assume a very simplified diffusion model in which the characteristic high temperature of our system allows us to consider that the thermal conductivity is set to zero and both the magnetic

resistivity, η , and the shear viscosity, ν , are constant and uniform. The kinetic and magnetic Reynolds numbers are given by

$$\mathcal{R} = \frac{\rho_* v_* L^*}{\nu} \quad \mathcal{R}_M = \frac{v_* L^*}{\eta}.$$

To ensure the solenoidality of the magnetic field, we introduce the magnetic potential ϕ defined by

$$\mathbf{B} = \nabla \times (\phi \hat{\mathbf{e}}_z) + B_z \hat{\mathbf{e}}_z.$$

Thus we decompose Eq. (4) into two equations, one for B_z and one for ϕ :

$$\begin{aligned} \frac{\partial B_z}{\partial t} = & -v_x \frac{\partial B_z}{\partial x} - v_y \frac{\partial B_z}{\partial y} - B_z \left(\frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} \right) \\ & + \frac{\partial \phi}{\partial y} \frac{\partial v_z}{\partial x} - \frac{\partial \phi}{\partial x} \frac{\partial v_z}{\partial y} + \frac{1}{\mathcal{R}_M} \left(\frac{\partial^2 B_z}{\partial x^2} + \frac{\partial^2 B_z}{\partial y^2} \right) \end{aligned} \quad (5)$$

$$\frac{\partial \phi}{\partial t} = -v_x \frac{\partial \phi}{\partial x} - v_y \frac{\partial \phi}{\partial y} + \frac{1}{\mathcal{R}_M} \left(\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} \right). \quad (6)$$

Time is discretized by an explicit third-order Runge-Kutta scheme.

As stated in the introduction, we adopt two different equilibrium configurations. The FFC case is described by the following choice of functions:

$$v_{0y}(x) = \text{sech}(x) \quad (7)$$

$$B_{0y}(x) = \mathcal{A} [\cos \sigma \text{sech}(\delta x) + \sin \sigma \tanh(\delta x)] \quad (8)$$

$$B_{0z}(x) = \mathcal{A} [-\sin \sigma \text{sech}(\delta x) + \cos \sigma \tanh(\delta x)] \quad (9)$$

$$T = \frac{1}{\mathcal{M}_s^2}. \quad (10)$$

Here we introduce another characteristic parameter, $\delta = a_V/a_B$, which is the ratio between the fluid jet width and the current sheet width. We assume a uniform density $\rho = 1$. $\mathcal{A}$ is the Alfvén number, that is the ratio between the Alfvén speed and the flow speed, and $\mathcal{M}_s$ is the sonic Mach number, that is the ratio between the flow speed and the sound speed. The angle σ , as already pointed out, defines the initial direction of the AMF relative to the basic flow. Thus, if

$\sigma = 0$, then AMF is orthogonal to the velocity field. We have a “rotation” magnetic field component in the stream-wise direction near $x = 0$, where it inverts its polarity, and its intensity depends on the value of $\mathcal{A}$.

$\sigma = \pi/2$, then magnetic field is parallel to the velocity field, except for a rotation component in the negative span-wise direction near $x = 0$, where the magnetic field inverts its direction.

$0 < \sigma < \pi/2$, then AMF is in the $Z - Y$ plane and makes an angle σ with respect to the positive span-wise direction.

In the PBC configuration we choose the following set of functions as the basic state of the wake:

$$v_{0y}(x) = \text{sech}(x) \quad (11)$$

$$B_{0y}(x) = \mathcal{A} \tanh(\delta x) \sin(\sigma) \quad (12)$$

$$B_{0z}(x) = \mathcal{A} \tanh(\delta x) \cos(\sigma) \quad (13)$$

where the equilibrium is set by a pressure gradient that is in turn

assured by a temperature gradient and a constant density. Thus from Eqs. (12) and (13) we find that

$$T = T_0 + \frac{\mathcal{A}^2}{2} \text{sech}^2(\delta x), \quad (14)$$

where $T_0 = 1$.

In several astrophysical environments the thickness of the neutral sheet is much less than for the shear, such as in the case of the interaction between a galactic magnetized wind and a molecular cloud (Shore & Larosa 1999), as well as in the case of cometary tails (Slavin et al. 1986). At 1 AU from the Sun the HCS has a width of about $a_B \sim 10^4$ km ($\sim 6.7 \times 10^{-5}$ AU), while the surrounding plasma sheet is thicker by a factor of 30 (Smith 2001): the parameter δ is much greater than one and it is reasonable to assume that this value remains high near the cusp of the helmet streamers that extend to about $3-4 R_\odot$ from the Sun. In particular we assume that $a_V = L^* = 0.1 R_\odot$. Beyond the cusp on the equatorial plane, $r \sim 3-4 R_\odot$, the simple assumption of mass conservation in a spherically symmetric isothermal atmosphere with radial magnetic field leads to an Alfvén speed that varies between 750 km s^{-1} and 1500 km s^{-1} depending on the assumed values of the density and magnetic field at the base of the coronal region (An et al. 1990; Mann et al. 2003). Fast streams have a velocity of approximately $v_0 = v_* \sim 600 \text{ km s}^{-1}$, so the Alfvénic number, $\mathcal{A}$, varies between 1.25 and 2.5. In the simulations shown here we adopt $\delta = 5$ and $\mathcal{A} = 1.5$.

Due to numerical constraints we use a value of δ smaller than was supposed for the HCS at a few solar radii, however linear and nonlinear theory in the limit of $\sigma = \pi/2$ for an incompressible flow (Dahlburg et al. 1998) has shown that the dynamics of the jet/wake configuration is magnetically dominated for $\delta > 4$ and $\mathcal{A} > 0.5$. Although the differential velocity between fast and slow streams is supersonic, $\mathcal{M}_s \sim 4$, our numerical scheme does not allow us to use such high values. Numerical simulations with different values of the sound Mach number in the range 0.5–1.5 have not shown significant changes in the evolution of the system, so we chose to show here only simulations using the critical value $\mathcal{M}_s = 1$.

For the stability analysis of the heliospheric jet, we use a set of initial parameters obtained from the data reported in Opher et al. (2003):

$$\delta \sim 0.45 \quad (a_V \sim 2.1 \text{ AU}; a_B \sim 4.7 \text{ AU}) \quad (15)$$

$$v_0 \sim 210 \text{ km s}^{-1} \quad (16)$$

$$B_0 \sim 0.36 \text{ nT}, \quad (17)$$

where the temperature profile ensures pressure equilibrium and is also chosen according to the interstellar medium features at the TS cited above:

$$T = 0.39 + \frac{\mathcal{A}^2}{2} \text{sech}^2(\delta x). \quad (18)$$

Moreover, considering a particle density $n \sim 1.4 \times 10^{-3} \text{ particle cm}^{-3}$, it is possible to estimate the Alfvén number $\mathcal{A} \sim 1$. Due to the topology of the magnetic field close to the TS on the solar equatorial plane (Suess 1990), we consider the case $\sigma = 0$. We have also performed a few simulations with different values of the δ parameter (see Table 2), which may be relevant to other heliospheric magnetic field configurations. For example, the effective width of the current sheet or velocity jet may depend on the original tilt of the dipole field with respect to the rotation axis.

Two different initial perturbations are chosen to trigger the instabilities, depending on the equilibrium. For the solar wind

Table 1. Tables of parameters for the solar wind simulations. The last two rows of each table report the maximum linear growth rate for each run and the associated perturbation wave number.

SOLAR WIND: FFC case					
$\delta = 5, \mathcal{A} = 1.5, \mathcal{M}_S = 1$					
RUN	F0	F1	F2	F3	F4
σ	0	$\pi/8$	$\pi/4$	$3\pi/8$	$\pi/2$
κ_1	0.05		0.15		
Γ	0.093	0.157	0.243	0.282	0.296
κ^{fast}	0.3-0.35	0.6	1.05	1.05	1.2
SOLAR WIND: PBC case					
$\delta = 5, \mathcal{A} = 1.5, T_0 = 1$					
RUN	P0	P1	P2	P3	P4

κ_1	0.05		0.15		
Γ	0.090	0.141	0.217	0.265	0.280
κ^{fast}	0.55	1.2	1.2	1.2	1.2

case, there are no indications of which instability dominates the linear and nonlinear dynamic of the system and, in particular, which modes drive its evolution according to the direction of the asymptotic magnetic field to the jet/wake flow. We therefore consider a white noise in velocity and in the magnetic potential in order to observe the growth of all the possible unstable modes:

$$v_{1x}(x, y) = \epsilon \mathcal{N}_{\text{random}}^{vx}(x, y) \quad (19)$$

$$v_{1y}(x, y) = \epsilon \mathcal{N}_{\text{random}}^{vy}(x, y) \quad (20)$$

$$\phi_1(x, y) = \epsilon \mathcal{N}_{\text{random}}^{\phi}(x, y) \quad (21)$$

where $\mathcal{N}$ is a random number in the range 0–1 and ϵ represents the initial perturbation amplitude, $\epsilon \simeq 10^{-7}$, which allows us to have a sufficiently long time interval for the development of the linear dynamics. The smallest perturbation wave number is given by the size of the numerical box in the stream-wise direction, $\kappa_1 = 2\pi/\mathcal{L}_y$, while the largest one, $\kappa_{\text{max}} = 2/3n_y$, as determined by the de-aliasing (Jerri 1977).

For $\sigma = \pi/2$, the maximum growth rate of the KH instability and the tearing mode is known to be about 0.35 and 1.35, respectively (Rappazzo et al. 2005). After a few simulations the fundamental wave number, κ_1 , has been chosen in order to resolve the instability region for each value of σ (see Table 1).

For the heliospheric jet we make use of monochromatic incompressible fluctuations as perturbations. From a dynamical point of view, these fluctuations enable the fastest growing instability by neglecting the initial ignition of compressible modes that deprive instability of energy and slow it down. We choose a functional form that rapidly goes to zero at the boundary of the numerical domain in the cross-stream direction. In order not to force the system to evolve according to an instability path that doesn't correspond to the maximum growth rate allowed by the system, the chosen functions must not have a defined parity. One of the possible sets of perturbations that satisfy all the previous constraints is the following:

$$v_{1x} = \epsilon \mathcal{H}(x) \sin(\kappa y) \quad (22)$$

$$v_{1y} = \frac{\epsilon}{\kappa} \partial_x \mathcal{H}(x) \cos(\kappa y) \quad (23)$$

$$\mathcal{H}(x) = \frac{4}{3\sqrt{3}} (\text{sech } x + \tanh x \text{ sech } x) \quad (24)$$

where κ is the wave number of the perturbation and we choose $\epsilon = 10^{-3}$.

As in the previous case, the length of the numerical box in the stream-wise direction is adapted to the wave number, i.e. $\mathcal{L}_y = 2\pi/\kappa$. In the cross-stream direction the box length in dimensionless units is $L_x = 23.62$, and we use a numerical grid with $n_x \times n_y = 361 \times 128$. After several simulations, we decided to assume a value for the Reynolds number such that it is possible to obtain an effective dissipation of energy at the discretization scale, so we consider $\mathcal{R} = \mathcal{R}_M = 200$. Actually, their values are much less than their estimations in astrophysical environments, yet they are large enough to assure an ideal dynamic on large scales.

3. Results of numerical simulations: the wind case

In Table 1 all performed simulations and characteristic parameters are summarized. Different values of σ are considered to study how the relative configuration between the basic magnetic and the sheared velocity field affects the stability properties of the system. In both F0 and P0 (F and P refer to the FFC and PBC cases, respectively) a Kelvin-Helmholtz sinuous evolution develops, as seen in Fig. 3, where the contour of density at different instants is reproduced for run F0. By computing the average in the cross-stream direction of the Fourier transform (hereafter “1d” average) of the magnetic potential

$$\langle \phi^{\kappa} \rangle_{1d}(t) = \frac{1}{L_x \sqrt{L_y}} \int dx \int dy \phi(y, x, t) e^{-i\kappa y}, \quad (25)$$

it is possible to obtain the modal decomposition of ϕ and follow the time evolution accordingly. In Fig. 4 we show the unstable modes with the highest linear growth rate of function (25) for run F0. The modes with $\kappa = 0.2$ –0.45 drive the linear regime and also determine the nonlinear evolution of the system. In this case, the fastest mode in the linear regime is $\kappa^{\text{fast}} = 0.35$ with a growth rate of $\Gamma \sim 0.093$. All the modes with $\kappa > 0.7$ are stable during the linear regime, but show a fast growth due to the nonlinear couplings between the modes. We observe the saturation for $t \sim 200$ –250.

For the PBC case, we observe that the maximum growth rate is almost equal to the one in the other configuration, but the dispersion relation of the unstable modes is significantly shifted towards higher wavenumber values; in particular, the wave number corresponding to the highest growth rate is $\kappa^{\text{fast}} = 0.55$. In the FFC, the magnetic tension of the stream-wise component can inhibit the growth rate at higher wavenumbers. In fact, in the linear regime it is given by

$$\mathbf{B} \cdot \nabla \mathbf{B} \sim B_0 \kappa B_1, \quad (26)$$

so the stabilizing effect of the stream-wise component of the magnetic field is greater for large wavenumbers. This should produce the observed displacement of the dispersion relation.

Despite the value of $\sigma > 0$ for both FFC and PBC, the evolution of the system is driven by a tearing mode that produces a varicose-resistive instability. Although the precise features of the dynamic depend on the initial configuration of the wake flow and the magnetic field, the nonlinear regime is always characterized by a reconnection process that leads to the destruction of the neutral/current sheet by producing magnetic islands that coalesce afterwards. In Fig. 5 we show the magnetic potential at different instants for run F2: at the end of the linear regime, $t = 80$, the most unstable modes are well-developed. During the nonlinear regime, the coalescence mechanism leads the system to be structured on larger and larger scales until the maximum characteristic length allowed by the system is reached.

Fig. 3. Contour of density at different instants for run F0 (see Table 1).

Fig. 4. Average in the cross-stream direction of the Fourier transform of the magnetic potential, $\langle \phi^k \rangle_{1d}$, as given by Eq. (25) for run F0 (see Table 1), as a function of time. In particular, we show the modes with highest linear growth rate, $\kappa = 0.2\text{--}0.45$.

Rappazzo et al. (2005) have studied the evolution of the solar wind FFC wake model using a monochromatic perturbation and considering a magnetic field strictly parallel to the wake, and found a maximum growth rate $\Gamma \sim 0.3$ with an associated

wave number $\kappa^{\text{fast}} = 1.2$. In Fig. 6 we report the Γ as function of σ ; the growth rate increases with σ , but as seen in Table 1 the wave number associated with the maximum growth rate increases slightly with σ , from $\kappa^{\text{fast}} = 0.6$ in F1 to $\kappa^{\text{fast}} = 1.2$ in F4. Meanwhile, in the PBC it is not affected by the value of the angle between the basic flow and the AMF, $\kappa^{\text{fast}} = 1.2$, although we obtain a rather flat dispersion relation for the different initial configurations. Besides, the PBC linear growth rate is always slightly less than the FFC one. In the run F4 we recover both the same Γ and κ^{fast} as found by Rappazzo et al. 2005.

Although FFC and PBC have a very similar linear regime, they show different behavior in the nonlinear regime, when the wake (jet) is accelerated (decelerated). In Fig. 7 we show the cross-stream average of the stream-wise velocity component for different simulations, both in the FFC and PBC case. The Profiles shown are at different instants starting from when the nonlinear regime sets in and the initial condition (solid line) has been plotted as a reference. While for the P-runs the profile is exactly symmetric with respect the stream-wise direction, an asymmetric deceleration of the jet in F-runs is observed. This effect is more relevant for $\sigma = 22.5^\circ$ (first column), and it subsides as its value increases (middle and right column). This reflects the initial parity property of the basic configuration: in the FFC we always have a stream-wise, magnetic field component that produces an anti-symmetric magnetic field with respect to the initial flow: the greater the value of σ , the lower this asymmetry, and it vanishes for $\sigma = 90^\circ$ as derived from Eqs. (8), (9). Both in the FFC and PBC, we have an enlargement of the velocity profile,

Fig. 5. Contour of the magnetic potential field at different instants for run F2 (see Table 1).

Fig. 6. Wind case: linear growth rate, Γ , for both the FFC and the PBC with $0^\circ < \sigma \leq 90^\circ$. The rate increases together with the angle.

together with a strong jet deceleration which is about $|\Delta v_y| \sim 0.8$. This means an acceleration of the solar wind wake such that we can estimate a velocity of about 480 km s^{-1} for the slow component of the solar wind.

Table 2. Table of the simulations and parameters for the heliospheric jet. With the label D0 we gather all the monochromatic simulations used to determine the dispersion relation and the linear dynamic features of the heliospheric jet.

HELIOSPHERIC JET		
$\sigma = 0, \mathcal{A} = 1, T_0 = 0.39$		
RUN	δ	MAIN FEATURES
D0	0.45	$\kappa = 0.15\text{--}0.95$
D1	10^{-3}	$\kappa = 0.55$
D2	5	$\kappa = 0.55$
D1WN	10^{-3}	white noise $\kappa_1 = 0.1$
D2WN	5	white noise $\kappa_1 = 0.1$
D3WN	0.5	white noise $\kappa_1 = \pi$

4. Results of numerical simulations: the heliospheric jet

Our first set of simulations was performed with the monochromatic incompressible fluctuations given by Eqs. (22), (23), whose wave number was varied in the range $0.15\text{--}0.95$ as summarized in Table 2. The resulting dispersion relation is shown in Fig. 8 (solid line). It is possible to observe a maximum in the linear growth rate $2\Gamma = 0.173$ corresponding to a perturbation wave number $\kappa^{\text{fast}} = 0.55$. Taking the characteristic time, $t^* = a_V/v_0 \sim 4.7 \times 10^{-2}$ year, into account, along with the length scale, $L^* = a_V = 2.1$ AU (see Sect. 2), we have a physical growth rate $\Gamma_{\text{phys}} \sim 1.84 \text{ year}^{-1}$ with a perturbation wave length $\lambda_{\text{phys}} \sim 24$ AU.

Fig. 7. Cross-stream average of the stream-wise velocity component, $\langle V_Y \rangle_{1d}$, for the runs F1, F2, F3 (top) and the runs P1, P2, P3 (bottom), see Table 1, taken at different instants (t_A is the computational time). Each column shows the comparison between FFC and PBC for a given value of σ .

Fig. 8. Dispersion relation given by the simulations summarized in Table 2. The maximum of the curve with the solid line corresponds to the coordinates (0.55, 0.173).

For comparison we calculate the linear KH growth rate for an infinitely thin layer in the presence of a uniform magnetic field (Chandrasekhar 1961) that is, in dimensionless units, $\Gamma^{\text{KH}} = 0.5 |\hat{k} \cdot \hat{v}_0| \times [1 - 2 \mathcal{A}^2 (\hat{k} \cdot \hat{B}_0)^2 / (\hat{k} \cdot \hat{v}_0)^2]^{1/2}$, where $\hat{k}$ is the direction of the wavevector (here $\hat{y}$), $\hat{B}_0$ the magnetic field direction, and $\hat{v}_0$ the direction of the velocity jump across the shear layer. If we consider the values used in our simulations, we find that

$\Gamma^{\text{KH}} \sim 0.275$, that is, $\Gamma_{\text{phys}}^{\text{KH}} \sim 5.85 \text{ year}^{-1}$. We have a discrepancy of a factor 3, so to observe how this growth rate is influenced by the jet structure and, above all, by the choice of the a_B parameter, we carried out simulations with a different ratio between the jet and the neutral sheet width: $\delta = 10^{-3}$ and 5. In order to determine the corresponding dispersion relations, we considered two simulations (D1WN and D2WN respectively) of the jet using a white noise perturbation, as in the solar wind case, but with $\kappa_1 = 0.1$ and an amplitude of $\epsilon = 10^{-4}$. Afterwards we performed two other simulations (D1 and D2) with a monochromatic perturbation corresponding to the maximum wave numbers previously obtained.

In Fig. 8 we show the dispersion relations obtained for these two configurations, D1 (dotted line) and D2 (dashed line), and observe that the linear behavior of the system is not affected by the variation of the δ parameter. Also in the nonlinear regime for both configurations, we have the same sinuous evolution typical of the KH instability as in the D0 case, which leads to the destruction of the neutral sheet, as shown in Fig. 9 where the contour of the density taken at different instants for run D2 is shown. On the other hand, the size of the neutral sheet can strongly affect the stability properties of the jet. Assuming that the width of the jet is the same order as its length, the maximum wavelength allowed is ~ 1 , in dimensionless units, and $\kappa_1 \sim 2\pi$. In practice, the minimum wavenumber we considered was $\kappa_1 = \pi$, meaning that the length of the jet is about two times larger than its width. We performed another simulation, D3WN (see Table 2), in which the Alfvénic number, the sonic number, and the asymptotic temperature (see Sect. 2) were the same as the previous simulations. Moreover, we used $\delta = 0.5$ to recover the value obtained by

Fig. 9. Density contour for run D2 (see Table 2) at different times. The evolution of the system leads inevitably to the destruction of the basic flow in the nonlinear regime.

Opher et al. (2004). In this case we used a white noise perturbation, whose amplitude is $\epsilon = 10^{-3}$. In Fig. 10, on the left, we report the first 6 modes of the “1d” average of the cross-stream velocity as a function of time, while on the right is shown the quadratic fluctuation of the same quantity, that is:

$$\langle v_x^2 \rangle(t) = \frac{1}{L_x L_y} \int dx \int dy \delta v_x^2. \quad (27)$$

One sees that the system is stable, and the jet does not undergo to a KH sinuous evolution as in the previous configurations.

5. Conclusions

By observing the evolution of a sheared flow in the presence of a strong magnetic field gradient, we are able to make a few considerations about the dynamic properties of a magnetically dominated fluid system. There it is possible to observe a generic inclination between the velocity and the magnetic field, measured by the angle σ , such as the wake configuration of the solar wind within the first 15–20 solar radii.

We consider two different configurations, a force-free and a pressure balance initial equilibrium, both characterized by the angle σ between the initial fluid jet direction and the asymptotic magnetic field. We observe a similar global evolution of the instability for the solar jet/wake for a fixed value of σ , but with quite different dynamical features. Both for FFC and PBC we have a typical Kelvin-Helmholtz sinuous evolution for $\sigma = 0$,

while for $\sigma \neq 0$ a linear tearing mode leads to a varicose-resistive instability that determines the start of a reconnection process that in turn leads to a successive coalescence mechanism that drives the final nonlinear evolution of the system on such large scales and destroys the basic system. The two configurations differ essentially due to presence of a stream-wise component of the magnetic field at the initial instant in the force-free case, which is absent for $\sigma = \pi/2$ and becomes more and more relevant as the angle decreases. This produces a displacement between the two dispersion relations because of the stabilizing effect for the higher modes caused by the magnetic tension due to the stream-wise magnetic field component, even if we observe that $\Gamma_{\text{FFC}} > \Gamma_{\text{PBC}}$.

Furthermore for $\sigma = 0^\circ$ and $\pi/2$, the FFC is intrinsically symmetric with respect to the stream-wise direction, while this system does not have a defined symmetry for $0^\circ < \sigma < 90^\circ$. For the PBC configuration, the system is always symmetric and in correspondence of the jet we always have a neutral point. This initial parity property of the two configurations determines the evolution of the HCS, since in the FFC we have a preferential side for magnetic islands formation and a differential acceleration of the wake even if the effect, of course, decreases with the increasing σ . These results can explain observations of a displacement of the HCS with respect to the plasma sheet (Winterhalter et al. 1994), but this effect is completely absent in the PBC. This evolution of a warped HCS could cause the acceleration not only of the slow component of the solar wind, but also of smaller scale structures, like spicules or prominences

Fig. 10. Jet case: *on the left*, the first 6 modes of the cross-stream velocity component (averaged along the cross-stream direction), $\langle V_x^k \rangle_{1d}$, for the run D3WN; *on the right*, the quadratic fluctuation of the cross-stream velocity component as a function of time for the run D3WN.

originating in the chromosphere. We need to perform detailed 3D simulations to account not only for the triggers of compressive modes, but also for considering all the instability modes of the system: in particular all the modes that are orthogonal to the basic flow that in the FFC case should be the most relevant.

Our 2D simplified model of the 3D configuration of the heliospheric jet shows a typical Kelvin-Helmholtz sinuous evolution, so starting from the data of Opher et al. (2003), we reproduced the general behavior observed in their MHD simulations. Moreover, we determined the characteristic linear growth rate of the instability and the corresponding wavelength: these results confirm their first assessments of these quantities. The variation of the current sheet size does not produce any effect on the instability evolution of the jet, hence on the behavior of the neutral sheet in the Heliosheath region. On the other hand, an increase in the thickness of the neutral sheet at the TS can have a strong influence on the jet stability property, an effect that could be produced by the tilt of the solar magnetic axis to the rotation one, which wasn't accounted for by the simulations performed by Opher et al. (2004). If we consider that the characteristic time of our system is now about $t^* = a_V/v^* \sim 30 \text{ AU}/210 \text{ km s}^{-1} = 2 \times 10^7 \text{ s}$ and thus larger than the period of the HCS oscillation, which should be on the order of $T \approx 30 \text{ days} \sim 3 \times 10^6 \text{ s}$, then it is reasonable to assume that at the TS we have a mean effect producing an heliospheric jet structure as large as the one assumed in the basic configuration of D3WN (see Table 2). In fact, despite the difficulties detecting the exact position of the TS, recent observations by Voyager 1 have been interpreted as either a TS crossing (Krimigis et al. 2003) or a close approach to this first boundary of the heliosphere (McDonald et al. 2003). Thus, we can assume that the distance of the TS from the Sun is on the order of 100 AU and, if we consider the angle of the tilt to be about 15° (Fisk 1996), we can estimate an amplitude of about $a_B \sim 52.34 \text{ AU}$ for the neutral sheet at the TS. As in the untilted case, the solar wind should stream freely inside the neutral sheet, and it is reasonable to assume that the width of the jet, a_V , is roughly the same as a_B . Moreover, even if the HS region is poorly known, there are both theoretical and observational

indications (Suess & Nerney 1997; Gurnett et al. 1993) that its length is about 50–60 AU. This dimensional analysis of the solar magnetic tilt seems to confirm the hypothesis of the stabilization of the heliospheric jet and agrees with the first MHD simulations (Opher M., private communication). In order to improve our model, we have to point out that the temperature profile and initial hypothesis of constant density are only rough approximations, and we should consider analytical profiles that fit the results in Opher et al. (2003) more closely and that maintain the condition of constant total pressure.

To test our model further for the slow solar wind and for the heliospheric jet, we first need to extend our computational studies and techniques and, second, to compare the results with new observations of the regions of interest, that is, the streamer belt and the outer Heliosphere. For the former we have the highest expectations for the future Solar Probe Mission, which will go for the first time as close to the Sun as 3 solar radii. In fact, one of the goals of the mission is to observe the production and expulsion of plasmoids from the active regions, observations that could be compared with the images of outwardly moving blobs already given by SOHO/LASCO (Sheeley et al. 1997). Instead, it is necessary for the latter region to exactly determine the time-dependent behavior of the Termination shock, the effects caused by its curvature near the equatorial plane, and the 3D configuration of the Heliosheath region to obtain a detailed 3D instability analysis. In this way we obtain the constraints and the physical quantities to compare with the measurements provided by space missions like Voyager 1 and 2, which are crossing the TS and moving through the Heliosheath, so they will keep on sending us data until ~ 2020 . Besides, the IBEX (Interstellar Boundary Explorer) Mission will provide global maps of the global interaction between the solar wind and the interstellar medium. IBEX observations will complement to the detailed single-direction measurements provided by Voyager.
