ABSTRACT

Context. The [CII] 158 µm line is the most important coolant of the interstellar medium in galaxies but substantial variations are seen from object to object. The main source of the emission at a galactic scale is still poorly understood and candidates range from photodissociation regions (PDRs) to the cold neutral or diffuse warm ionized medium. Previous studies of the [CII] emission in galaxies have a resolution of several kpc or more so the observed emission is an average of different ISM components. Aims. The aim of this work is to study, for the first time, the [CII] emission at the scale of a spiral arm. We want to investigate the origin of this line and its use as a tracer of star formation. Methods. We present [CII] and [OI] observations of a segment of a spiral arm of M 31 using the Infrared Space Observatory. The [CII] emission is compared with tracers of neutral gas (CO, Hα) and star formation (Hα, Spitzer 24 µm). Results. The similarity of the [CII] emission with the Hα and 24 µm images is striking when smoothed to the same resolution, whereas the correlation with the neutral gas is much weaker. The [CII] cooling rate per H atom increases dramatically from ∼2.7 × 10−26 erg s−1 atom−1 in the border of the map to ∼1.4 × 10−25 erg s−1 atom−1 in the regions of star formation. The [CII]/FIR24−122 ratio is almost constant at 2%, a factor 3 higher than typically quoted. However, we do not believe that M 31 is unusual. Rather, the whole-galaxy fluxes used for the comparisons include the central regions where the [CII]/FIR ratio is known to be lower and the resolved observations neither isolate a spiral arm nor include data as far out in the galactic disk as the observations presented here. A fit to published PDR models yields a plausible average solution of G0 ∼ 100 and n ∼ 3000 for the PDR emission in the regions of star formation in the arm of M 31.

Key words. galaxies: spiral – galaxies: ISM – infrared: ISM – stars: formation – ISM: molecules – galaxies: individual: Messier 31

1. Introduction

The [CII] 158 µm fine structure line is the strongest spectral line in the universe, carrying typically close to 1% of the energy emitted in the Far-IR from galaxies. This line has a critical density for excitation around 1000 cm−3, and is therefore widespread in galaxies. Previous studies of [CII] emission in spiral galaxies include Madden et al. (1993), Nikola et al. (2001), Kramer et al. (2005), and Braine & Hughes (1999) for respectively NGC 6946, M 51, M 83, and NGC 4444, and Malhotra et al. (2001) for a statistical study. All of these have a resolution of several kpc and thus average a wide variety of environments within the beam. Carbon is ionized more easily than hydrogen so [CII] emission, although from an ion, can arise from ionized HII regions to mainly neutral photo-dissociation regions (PDR; e.g. Tielens & Hollenbach 1985) at the border of molecular clouds, exposed to UV radiation from young massive stars. A significant contribution could also come from the diffuse atomic interstellar gas, as shown by Crawford et al. (1985) and Madden et al. (1993), or the diffuse ionized medium (Heiles 1994). However, the main contributions are not known in detail, especially at high spatial resolution.

Far from the first study of [CII] emission, the present work is unique in that we study emission at the scale of a spiral arm, only possible in the very nearby spirals M 31 or M 33. M 31 is the nearest density-wave spiral galaxy, where we can test large-scale dynamics and star formation. It is the only density-wave galaxy where spiral arms are resolved by ISO (M 33 being more stochastic), as shown in Fig. 1. The scale of the [CII] observations presented here is new and allows us to study the spiral arm environment separate from the rest of the galaxy. With a focus on testing the origin of the [CII] line, we compare the [CII] emission across an arm in M 31 with the CO and HI, tracing the neutral gas, the Hα emission tracing ongoing star formation but suffering from extinction, and the Spitzer 24 µm image tracing the warm dust heated by recent star formation. [CII] emission as a tracer of star formation has the advantage of not being affected by interstellar extinction.

2. Observational data

We have observed a portion of the northern spiral arm of M 31 in the [CII] 157.7 µm and [OI] 63.8 µm lines using the Long Wavelength Spectrometer (LWS) onboard the Infrared Space Observatory (ISO). The observed region, which is shown in Fig. 1 on a 175 µm image by Haas et al. (1998), is the most intense region of star formation in M 31 and contains a large concentration of HII regions...
3. Origin of the [C II] emission

Figure 2 shows the contour map of the [CII] line integrated intensity overlaid on different images of other tracers of neutral (H\textalpha, CO) and ionized gas (H\textalpha) and dust continuum emission at 24 \textmu m and the combined 60 and 100 \textmu m IRAS maps. All the images have been reprojected using an orthographic projection with center in RA = 00\textdegree44\textsec38.736s and Dec = 41\textdegree27\textarcsec17.208\textarcsec (J2000) and 12 × 4 points centered at RA = 00\textdegree45\textsec7.514\textsec and Dec = 41\textdegree35\textsec46.896\textsec (J2000). The ISO observation numbers (TDT numbers) of those observations are 58001701 and 58001801, respectively. In addition, we have mapped the [O\texti] 63.8 \textmu m line in the central positions of the [CII] maps with two small rasters of 2 × 2 points (TDTs 58001703 and 58001903). The raster maps were oriented along the spiral arm at an angle of 63 deg. For all the maps, the observed points are separated by 1'. Tables 1 and 2 give the exact observed positions.

The lines were scanned in the LWS 02 mode at a spectral resolution of 0.29 and 0.6 \textmu m for the [O\texti] 63 \textmu m and the [CII] 158 \textmu m lines, respectively. The effective aperture of the LWS detectors is 87'' for the [O\texti] line and 69.4'' for the [CII] line (Gry et al. 2003). The observations were processed through the off-line processing (OLP) software version 10. Further reduction was done with ISAP. The data reduction consists basically in dropping bad data points, shifting the different scans taken with each detector to a common level and averaging all the data for each detector. In addition, with ISAP we have deblurred the spectra to get rid of the well-known interference pattern for the long wavelength detectors. We fitted order 1 baselines to the spectra in the vicinity of the lines and Gaussian curves to the lines using ISAP. Tables 1 and 2 give the [CII] line fluxes and errors as derived from the Gaussian fits. The absolute flux calibration uncertainties for the LWS01 mode are smaller than 20% (Gry et al. 2003).

We also present an archival Spitzer Space Telescope image of the same region taken with the MIPS instrument at 24 \textmu m, with a spatial resolution of about 5''. The other data sets used here are H\textalpha from Devereux et al. (1994), HI from Brinks & Shane (1984), CO(1–0) emission from Nieten et al. (2005), and the combined 60 and 100 \textmu m IRAS maps.

4. The [C II]/FIR ratio

We have used the IRAS fluxes to calculate the [CII]/FIR ratio in the same way as earlier works. It should be noted that “FIR” here refers to the 42–122 \textmu m flux, roughly half the total thermal dust emission. The [CII]/FIR_{42–122} ratio in the mapped region is almost constant at 2%, well above the value in the central regions of M 31 (0.6%; Mochizuki 2000). In the Milky way, the [CII]/FIR ratio also increases from 0.2% in the center (Rodríguez-Fernández et al. 2004) to 0.6% in the

![Fig. 1. Thermal dust continuum emission at 175 \textmu m in M 31 from Haas et al. (1998). The two empty rectangles show the region mapped in the [CII] line while the two solid squares represent the region mapped in the [O\texti] line.](image-url)
We have calculated the 60\,\umu\,m line flux in units of 10^{-20}\,W cm^{-2}. The values range from 0.2 at the [C II] line to estimate the [C II]/[O III] ratio in the region of the PDRs where the [C II] line is the main contribution to the [C II] line. However, it is unclear what physical mechanisms are responsible for this behavior. Statistical studies of different galaxies (Malhotra et al. 2001) have shown a tendency for the [C II]/[FIR] ratio to decrease with increasing IRAS 60/100 ratios, i.e., when the dust temperature increases. As discussed by Contursi et al. (2002), this effect is also weakly present along the disks of NGC 1313 and NGC 6946. A possible explanation is that strong UV fields heat the dust to higher temperatures (high 60/100 ratio) than weaker fields but they can also increase the positive charge of the dust grains and reduce the efficiency of the photoelectric effect, which is the main heating mechanism in the region of the PDRs where the [C II] dominates the cooling. As a result, the [C II]/[FIR] ratio decreases.

We have calculated the 60/100 ratio in the range of the [C II] map. The values range from 0.2 at the [C II] minima to 0.5 at the [C II] (or FIR) peaks (which trace star formation). The sources of Malhotra et al. (2001) and Contursi et al. (2002) with a 60/100 ratio in the range 0.2–0.5 have [C II]/[FIR] ratios of 0.4–1.0. In contrast, the [C II]/[FIR] ratio in the regions studied in this paper is constant at 2%. Therefore, no correlation is present between the [C II]/[FIR] and the 60/100 ratios and the [C II]/[FIR] ratio is higher than in other sources with the same 60/100 ratio (Fig. 4 of Contursi et al. 2002).

5. Physical conditions

In this section we compare significant line-to-line and line-to-continuum ratios with other observations and PDR model calculations in order to derive the physical conditions of the [C II] emitting gas. The [C II]/CO(1–0) ratio is particularly interesting, since it varies from about 1300 for galactic disks (Nakagawa et al. 1998; Braine & Hughes 1999), to about 6000 in starbursts (Stacey et al. 1991) and up to 23000 for the Large Magellanic Cloud (Mochizuki et al. 1994). Even in the same galaxy, this ratio can vary in large proportions. The Milky Way, Fixsen et al. (1999) find that the [C II]/CO ratio at large scale decreases from about 2000 in the inner galaxy to 1000 in the outer galaxy. Averaged over the [C II] map, the [C II]/CO(1–0) ratio in the spiral arm of M 31 is 3600, ranging from about 1500 to 6000 near the bright regions of star formation. If the [C II] were observed at higher resolution still, presumably yielding a brightness distribution similar to the 24 \umu m or Hz, the [C II]/CO ratio would probably rise further still as the CO maxima are not positioned on the maxima in star formation as traced by the 24 \umu m or Hz.

One can use the [C II]/[FIR] and [C II]/CO ratios to study the physical conditions in the spiral arm of M 31. In addition, the [O I] 63 \umu m line, which comes from the dense neutral surface of PDRs, can be used in conjunction with the [C II] line to estimate the density of the emitting region – the higher the density, the higher the [O I] to [C II] ratio. We have measured [O I]/[C II] ratios for 79
Fig. 2. CII map (black contours) on the CO(1–0), HI, Hα, 24 µm, and combined 2.58S_60 + S_100 IRAS images. Panels on the left: original resolution. Panels on the right: smoothed to the angular resolution of the CII observations (70′′) and with the same transfer function shown in the wedge to the right. CII contours are at 3, 6, 9, 12, 15, 18, 21, 24, and 27 × 10^{−13} erg cm^{−2} s^{−1}. Units for the maps are in K km s^{−1} for the CO(1–0), 10^{21} cm^{−2} for the HI, arbitrary units for the Hα (log scale), MJy/sr for the 24 µm, and in units of 10^{−3} erg cm^{−2} s^{−1} sr^{−1} for the IRAS map. The ISM tracers (CO, HI) are shown with a linear scale and the tracers of star formation (Hα, 24 µm, and IRAS) are shown with a logarithmic scale.

of 0.51 ± 0.08 in (x, y) ~ (5.5, −0.5) and 0.64 ± 0.06 in (x, y) ~ (4.5, 0.5). Such ratios are higher than for an average spiral disk ([OⅠ]/[CⅡ] ~ 0.3, Braine & Hughes 1999) and are predicted by the Kaufman et al. (1999) models for densities lower than the critical density of the [OⅠ] line (~10^{4} cm^{−3}) and FUV fields at the PDR surface, G_0, of 30–300 in units of the FUV intensity in the local ISM (1.3 × 10^{−4} erg s^{−1} cm^{−2} sr^{−1}, Habing 1968) or for higher densities and very low incident fields (G_0 ≤ 1). However, the comparison of the measured [CⅡ]/CO(1–0) ratio with the Kaufman et al. (1999) predictions constrain the PDR parameters to G_0 = 30–300 and n = 10^{3}–10^{3.5} cm^{−3}. The measured ([OⅠ]+[CⅡ])/FIR_{42–122} ratio, close to 0.03, is also in agreement with the model prediction in this region of the parameters space.
result of $G_0 = 30–100$ and $n = 10^{3.5}–10^4$ cm$^{-3}$. The corrected ([OI]+[CII])/FIR$_{22-122}$ ratio is also consistent with this result. Therefore, taking into account the uncertainties on the [CII] flux that arises in the PDR, the solution space from the Kaufman et al. (1999) Figs. 4, 9, and 6 is around $G_0 \sim 30–300$ and $n(H) \sim 10^3–10^4$ cm$^{-3}$ and fits the ([CII]+[OII])/FIR, [OII]/[CII], and the [CII]/CO ratios.

In contrast, the predicted [CII] intensity in this region of the parameter space is higher than the measured one. For instance, the predicted intensity for $n = 2000$ and $G_0 = 100$ is $\sim 2 \times 10^{-4}$ erg s$^{-1}$ cm$^{-2}$ sr$^{-1}$, 10 times higher than that observed; the [CII] intensity at the positions observed in [OII] is $1.2–1.5 \times 10^{-5}$ erg s$^{-1}$ cm$^{-2}$ sr$^{-1}$. This can be accounted for assuming that the [CII] emission is diluted in the ISO beam by a factor of $\sim 10$. Thus, instead of $70'' \times 70''$, the angular extent of the [CII] emitting regions would be $20'' \times 20''$, which is similar to the size of the intense sources detected in the 5'' (20 pc) resolution 24 μm image. The [CII]/FIR ratio varies very little over the region observed in [CII]. Assuming the FIR emission is also diluted by a factor 10, one gets a corrected FIR$_{22-122}$ intensity of $\sim 10^{-2}$ erg s$^{-1}$ cm$^{-2}$ sr$^{-1}$. For OB stars the FUV heating represents about half of the total grain heating so the incident field $G_0$ is about $G_0 / n \simeq 1/2 \times \lambda_{\text{total}}$ FIR$/1.3 \times 10^{-4} \sim \lambda_{\text{FIR}}(42-122)/1.3 \times 10^{-4} \sim 80$.

Finally, one can estimate the column density of atomic hydrogen in the PDR, which can be expressed in analytical form as $N_{\text{HI}} \approx 5 \times 10^{20} \ln(90^{[20]} + 1)$ cm$^{-2}$ (Sternberg & Dalgarno 1989). For $G_0 / n$ ratios of 0.01–0.1, $N_{\text{HI}} \sim 3–12 \times 10^{20}$ cm$^{-2}$. Roughly half of the observed Hα along the inner part of the spiral arm would then be the product of photodissociation of molecular gas by the star formation within the arm. PDRs observed in the Galaxy have $G_0 / n \gtrsim 0.1$, implying a greater Hα column density from photodissociation but over a much smaller area.

6. [CII] cooling rate

In order to understand how to place these observations in the general framework, we determine the cooling rate of [CII] per atom of H by $\Lambda = 4\pi I_{\text{CII}}/(N(\text{HI}) + 2N(\text{H}_2))$, measured at the resolution of the [CII] observations. The Hα column density was taken from Brinks & Shane (1984), calculated using the standard formula for optically thin Hα, and we assume a $N(\text{H}_2)/I_{\text{CO}}$ factor of $2 \times 10^{20}$ cm$^{-2}$/(K km s$^{-1}$). The image of the cooling rate $\Lambda$ is plotted in Fig. 5 as contours over the Hα and 24 μm smoothed images. A varies from $-1.4 \times 10^{-25}$ erg s$^{-1}$ atom$^{-1}$ in the maxima at $x = 1.5$ and $x = -6.5$ to $-2.7 \times 10^{-26}$ erg s$^{-1}$ atom$^{-1}$ in the minima located around the upper border of the map. Thus, the [CII] emission per H atom is much higher near zones of star formation, and varies roughly within the ranges expected for PDR gas (e.g. Wolfire et al. 1995; Boulanger et al. 1996) but higher than expected for the CNM (Wolfire et al. 1995).

There is little difference between $\Lambda$ and $\Lambda'$ except near the main CO maximum because the Hα column dominates almost everywhere after smoothing to the resolution of the [CII]. Because the CO maximum is not a [CII] maximum, the cooling rate $\Lambda'$ is particularly low there. The level of star formation is the important parameter for the [CII] emission, not the CNM column density.
7. Conclusions

[CII] emission is an excellent tracer of star formation. The [CII] cooling rate per proton increases greatly with the level of star formation. Comparison with models indicates that a coherent picture can be obtained assuming the main source of spiral arm [CII] emission is moderately dense PDRs. We estimate that the characteristic density and FUV radiation field at large scales are roughly \( 2000 \text{ cm}^{-3} \) and \( G_0 \sim 100 \), providing a satisfactory fit to the [CII], [OI], CO, and FIR emission.

The [CII]/FIR ratio in the spiral arm region we observed in M 31 is high, about 2%, well above the typically quoted values of \([\text{CII}]/\text{FIR} \approx 0.3-1\%\) for galaxies. This is a major result as both the [CII] and FIR data are well-calibrated. Looking at values and data found in the literature, the increase in the [CII]/FIR ratio with distance from the center can be seen in earlier observations but little attention was called to the variation as the uncertainties were very high. The part of the arm we observed is much further out than any other [CII] observations, which may help explain the high ratio. Furthermore, it is clear that in the centers of spiral galaxies the [CII]/FIR ratio is lower than in the disk so surveys of unresolved galaxies sample a combination of disk and nuclear emission and as such can be expected to yield lower [CII]/FIR values than the disks alone.

It is also interesting that even at the 5″ resolution of the Spitzer 24 µm image, the FIR and Hα views of star formation are extremely similar – very little star formation is hidden, despite the nearly edge-on orientation of M 31.

Acknowledgements. We would like to thank Nicolas Devereux for the Hα map of M 31, Martin Haas for the ISOPHOT data, Elias Brinks for the HI observations, and Nikolaus Neininger and Michel Guélin for permission to use the CO data.
