ABSTRACT

Aims. We challenge the accepted distance of 3.2 kpc of GRO J1655-40. We present VLT-UVES spectroscopic observations to estimate the absorption toward the source, and determine a maximum distance of GRO J1655-40.

Methods. We show that the accepted value of 3.2 kpc is taken for granted by many authors. We retrieved in the ESO archive UVES spectra taken in April 2004 when GRO J1655-40 was in quiescence to determine the spectral type of the secondary star. For the first time we build a flux-calibrated mean (UVES) spectrum of GRO J1655-40 and compare its observed flux to that of five nearby stars of similar spectral types. We strengthen our results with the traditional pair method, using published photometric data of the comparison stars.

Results. We show that the distance of 3.2 kpc is questionable. We determine a spectral type F6IV for the secondary star. We demonstrate in details that the distance of GRO J1655-40 must be smaller than 1.7 kpc.

Conclusions. The runaway black hole GRO J1655-40 could be associated with the open cluster NGC 6242 which is located at 1.0 ± 0.1 kpc from the Sun. At D ≤ 1.7 kpc the jets are not a superluminal, and GRO J1655-40 becomes one of the closest known black holes to the Sun.

Key words. stars: binaries: eclipsing – stars: distances – dust, extinction – ISM: supernova remnants – stars: individual: GRO J1655-40

1. Introduction

GRO J1655-40 (a.k.a Nova Sco 94) is a Soft X-ray transient (SXT) in our Galaxy (l = 345.0°, b = 2.2°; RA = 16°54’00”, Dec = −39°50’45”). It has been discovered on July 27, 1994 with BATSE on board the Compton Gamma Ray Observatory (Zhang et al. 1994). Optical photometry of GRO J1655-40 revealed a double-waved modulation with a period of 2.6 days (Bailyn et al. 1995b; van der Hooft et al. 1997). Strong evidence that the compact object in GRO J1655-40 is a black hole was presented by Bailyn et al. (1995b) who established a spectroscopic period of 2.601 ± 0.027 days. Shahbaz et al. (1999) published the masses of the black hole and the secondary star: 5.5–7.9 M⊙ and 1.7–3.3 M⊙ respectively. Given a distance of about 3 kpc, the jets appeared to be superluminal: 1.5 ± 0.4 c (Tingay et al. 1995), 1.05 c (Hjellming & Rupen 1995), where c is the speed of light. Various spectral types of the secondary star have been published. We mention in particular: F3–F6 IV (Orosz & Bailyn 1997), and F7IV–F6III (Israelian et al. 1999). The distance of GRO J1655-40 that is used in the literature is 3.2 ± 0.2 kpc, although Mirabel et al. (2002) pointed out that a distance of about 1 kpc cannot be ruled out with the current data. The aim of this paper is to show that none of the distance estimate methods used for GRO J1655-40 is good enough to claim a distance of 3.2 kpc, and that this distance is actually based on one very uncertain interpretation. We present unpublished optical data of GRO J1655-40 to show that the distance of the source is certainly smaller than 1.7 kpc.

2. The problem of the distance

The distance of GRO J1655-40 usually quoted in the literature is the one determined by Hjellming & Rupen (1995) who present new radio data obtained with the VLA and VLBA. The authors build a kinematic model of the radio jets of GRO J1655-40 and obtain a distance of 3.2 ± 0.2 kpc. The authors do not actually measure the distance directly, but refer to McKay & Kesteven (1994), Tingay et al. (1995) and Harmon et al. (1995). Their model provides a refinement of the distance range obtained by the cited authors. Harmon et al. (1995) rely as well on McKay & Kesteven (1994) and Tingay et al. (1995) for the distance.

The paper by McKay & Kesteven (1994) simply states: “HI observations of GRO J1655-40 made with the AT Compact Array show solid absorption in the velocity range +10 to −30 km s−1, with a further isolated weak feature at −50 km s−1. The balance of probabilities is that the distance is around 3.5 kpc, unless the −50 km s−1 feature is due to an atypical cloud.” Although providing important information on the absorbing material in the direction of GRO J1655-40, this IAU Circular is not a measurement of the distance.

Independently, Tingay et al. (1995) presented new VLBI and ATCA data of GRO J1655-40. Their HI spectrum obtained with ATCA (see their Fig. 2) shows a multi-component profile, with a weak feature at −50 km s−1 too. They intended to interpret the various components in terms of HI clouds and HII regions.

* Based on data obtained at the Very Large Telescope, European Southern Observatory, under program ID 073.D-0473(A).
participating to the mean Galactic rotation, and concluded that a minimum distance of 3.0 kpc can be inferred. They finally give a range of 3 to 5 kpc possible for GRO J1655-40. This estimated distance range is relying on the assumption that the weak feature observed at ~50 km s$^{-1}$ is not moving with a peculiar velocity. Although it looks reasonable, this assumption might simply not be true. These measurements are very dependent on the distribution and velocities of various HI clouds along the line of sight; a difficulty that has been claimed to be important by Mirabel et al. (2002) who note that, in this direction, there are clouds with anomalous velocities up to ~50 km s$^{-1}$ (Crawford et al. 1989), i.e., with an amplitude similar to that of the weak feature observed in the ATCA spectrum.

Moreover, Mirabel et al. (2002) have shown that the above radio data of Hjellming & Rupen (1995) allow to derive with certainty only a relativistic upper limit of $D \leq 3.5$ kpc, since the relativistic time delay of the motion of the ejecta in the sky is given by two equations with three unknowns: the angle with the line of sight of the jet axis $\theta$, the velocity of the jet $v/c$ and the distance $D$. Hjellming & Rupen (1995) obtained a distance of 3.2 kpc by assuming $\theta \approx 84^\circ$, which actually corresponds only to the upper limit allowed for GRO J1655-40 by the above equations (see also Mirabel & Rodríguez 1994). However, Mirabel et al. (2002) claimed that the assumption that the jet axis is parallel to the axis of the orbital plane (i.e. to the contrary of Hjellming & Rupen) is equally consistent with the observations at radio wavelengths.

A distance of ~3.0 kpc was also proposed on the basis of optical data by Bailyn et al. (1995a). The method used is the “D” method, following Jonker & Nelemans (2004). They have first measured the equivalent widths (EW) of NaI-D lines, from which they claim a color excess $E(B - V)$ of 1.15. They used the results of Barbon et al. (1990), who studied the type-Ia supernova 1989B in NGC 3627. These latter authors mention that the color excess can be properly derived by studying the detailed structure of the interstellar CaII and NaI-D lines, but to do so, a high-resolution and high Signal-to-Noise ratio spectrum is needed, which is not their case nor the one of the spectrum of Bailyn et al. (1995a) that has a resolution of ~10 Å. Consequently, Barbon et al. (1990) determined an empirical and roughly linear relation between the equivalent width of the NaI-D lines and the color excess $E(B - V)$ for six supernovae. Although not precisely stated, Bailyn et al. (1995a) must have used this empirical relation to determine their value of the color excess, and claimed that the results is consistent with the EW of other interstellar lines in the optical domain. To obtain the distance, they use the standard relations between the absorption, the reddening, the colors and the apparent and absolute magnitudes (see e.g. Allen 1973). Finally, they conclude that the distance of the source is compatible with $D \sim 3$ kpc, “in agreement with the radio observations” of Tingay et al. (1995).

We note that their result is based on the assumption that the absorbing material is distributed homogeneously between the source and the observer. This has been again challenged by Mirabel et al. (2002) who mention in particular that the reddening in this region of the sky occurs in the local arm within 700 pc from the Sun.

Similarly, Bianchini et al. (1997) measured the color excess also by measuring the equivalent widths through Gaussian fitting of the interstellar 5980 Å NaI-D doublet and the 6613 Å line in their “higher resolution” data. They use the relationships between equivalent widths and color excess given by Herbig (1975) and della Valle & Duerbeck (1993) to obtain a (mean) color excess of 1.13, in agreement with the value found by Bailyn et al. (1995a). With a resolving power of about 3700, not only their spectrum cannot resolve the multi-component profile of the NaD lines, but also miss the fact that the lines appear saturated (see our Fig. 1), and therefore, simply cannot be used to measure the extinction.

On the other hand, Greiner et al. (1995) presented new ROSAT X-ray data, from which they infer a distance of “about 3 kpc”. Their method consists of fitting the halo of the observed radial profile of the source, produced by the scattering of the X-rays by the interstellar dust. To fit the radial profile of GRO J1655-40 they assume an uniform dust distribution between the observer and the source. From this fit, they obtain, a value of the effective optical depth at 1 keV of $\tau_{\text{eff}} \sim 0.3$.

Furthermore, they used the results of Predehl & Schmitt (1995) who have studied in details X-ray halos in ROSAT sources. From the fractional halo intensity it is possible to derive the dust column density. The authors show that a good correlation exists between the simultaneously measured dust and hydrogen column densities, indicating that gas and dust must be to a large extent copatial. From this correlation that depends on the optical depth $\tau_{\text{opt}}(1 \text{keV})$, Greiner et al. (1995) obtain for GRO J1655-40 an absorption of $A_V = 5.6$ mag and a hydrogen column density of $N_H = 7.0 \times 10^{21}$ cm$^{-2}$. However, as emphasized by Jonker & Nelemans (2004), their implicit assumption is that the sight-line for GRO J1655-40 has the same gas-to-dust ratio as the sight-lines for which the relations between $A_V$ and $N_H$ have been established. To finally compute the distance, Greiner et al. (1995) use the mean extinction law given by Allen (1973): $A_V = 1.9$ mag kpc$^{-1}$. As noted by Mirabel et al. (2002), GRO J1655-40 is in the Scorpius region of the sky which contains rather clumpy optical dark clouds in the foreground. Thus the mean extinction law might not be accurate enough in this case.

Similar, Orosz & Bailyn (1997) could have used the “B” method of distance determination (Jonker & Nelemans 2004), but they assumed a distance of 3.2 kpc again citing Hjellming & Rupen (1995), and a color excess of $E(B - V) = 1.3 \pm 0.1$; this latter value being obtained by Horne et al. (1996) who used high-quality UV spectra obtained with HST. However, the cited paper of Horne et al. (1996) is an IAU circular where it is simply stated that “deep 220-nm absorption in the HST spectrum suggests $E(B - V) = 1.3$ mag”.

Hynes et al. (1998) presented a multi-wavelength dataset, obtained with HST, AAT, RXTE and CGRO. The distance is quoted from Hjellming & Rupen (1995). The authors discuss carefully the problem of the extinction. They have measured the reddening of the source by using a power-law fit to the UV data. As they mention, “no other assumptions about the properties of GRO J1655-40 are required, although [they] do need to assume an extinction curve”. They used the mean Galactic extinction curve of Seaton (1979) and the $E(B - V)$ value of 1.3 mag for GRO J1655-40, which is very different from the mean Galactic extinction curve is valid in that particular direction.

The authors also computed the absolute magnitude of the secondary star. They follow Orosz & Bailyn (1997) for the spectral type of the secondary (F5IV). They rescale the magnitude to the effective radius of GRO J1655-40, and obtain an absolute magnitude of $M_V = 0.7 \pm 0.5$, which is very different from...
the absolute magnitude of an F5IV star as given by, e.g., Gray (1992): 3.2 mag. In particular, it is not clear if they assumed that the star was filling its Roche-lobe or not. If true, it is rather straightforward to compute the radius (see e.g. Paczyński 1971; Jonker & Nelemans 2004). Then, Hynes et al. (1998) corrected the apparent magnitude (17.12) of Orosz & Bailyn (1997) to 17.18 ± 0.06. Adopting the distance of 3.2 kpc by Hjellming & Rupen (1995), and an average reddening law (RV = 3.2), they obtain E(B − V) = 1.25 ± 0.17 in agreement with previous publications.

Beer & Podsiadlowski (2002) reanalyzed the lightcurve in quiescence obtained by Orosz & Bailyn (1997). In their models, the distance is said to be a free parameter, although it is not clear if this parameter has been allowed to go as low as 1.0 kpc. Moreover, in many places they claim that the distance of 3.2 kpc of Hjellming & Rupen (1995) has been used “to tighten” their results. They also mention that they obtain a reasonable model of the lightcurves with a rather cool disc, with a distance “much closer than the distance of 3.2 kpc” (and with a higher β2). For that reason (i.e. the distance is too small compared to 3.2 kpc), they discarded the model.

The authors emphasize that their model is very dependent on the extinction curve. They note that if the extinction curve were incorrect, the fitting procedure would compensate by choosing different values for the distance, temperature of the secondary star and the color excess E(B − V). Although the temperature must be consistent with the spectral type of the secondary, the distance and extinction could both be wrong and compensate each other. The authors claim to obtain values for D and E(B − V) in agreement with the (possibly incorrect) 3.2 kpc distance and (again) a mean Galactic extinction curve. However, even reasonable, a such mean extinction curve cannot be used to strengthen the confidence of the results.

3. New observational material

Our dataset on GRO J1655-40 consists of VLT-UVES spectra available in the ESO archive1 (prog. ID 073.D-0473(A), P.I. Rebolo). The spectra were obtained in 2004 with three different central wavelengths: 4025 Å on the UVES blue side, 5265 Å comprising Hβ and 6300 Å comprising Hz on the UVES red side. The observations were carried out on April 16, 18, 19, 22 and 25, and also June 18 of 2004. Apart from April 22, two spectra of 1440 s were obtained for each of the three central wavelengths. For every setting, we have retrieved in the archive all possible calibrations: biases, wavelength calibration frames, flat-fields, order definition frames and format check frames.

All the spectra have been reduced using the UVES pipeline (see e.g. Ballester & Hensberge 1995). The reduction process includes bias and inter-order background subtraction (object and flat-field), optimal extraction of the object (above sky, removing sky lines and rejecting cosmic ray hits), division by a flat-field frame extracted with the same weighted profile as the object, wavelength calibration, rebinning to a constant wavelength step and merging of all overlapping orders. The spectra have been shifted to the heliocentric restframe, and smoothed with a boxcar of 10. We emphasize that the sky line subtraction performed by the pipeline is made through the detection of a line that cross the whole slit and is producing a flat contribution to the flux across the slit. This important point is discussed below.

For the flux calibration, we have used the method described in the UVES quality control pages2. This consists of normalising each reduced spectrum by the exposure time, correcting for the gain of each CCD and correcting for the atmospheric transmission3. The final step consists of taking the UVES master response curve to provide the F-λ flux-calibrated and (atmospheric) extinction-corrected spectra. We used the latest master response curve, obtained in September 28, 2004. It provides a flux calibration with a relative error less than 10% (see the indicated webpage).

Since the Signal-to-Noise ratio (S/N) of the blue spectra (with a central wavelength of 4025 Å) was very close to unity, they have been discarded from our analysis. The individual red “Hβ” and “Hz” spectra have a S/N ratio between 7 and 20 (before smoothing). They respectively cover the wavelength range from 4785 to 5755 Å and 5835 to 6805 Å, both with a dispersion of 0.014740 Å/pix. The resolving power of all spectra is 45 000. This is, in this case, good enough to resolve the NaI-D lines, that appear saturated (see Fig. 1).

According to Brocksopp et al. (2005), GRO J1655-40 remained in quiescence since its discovery outburst by BATSE in July 1994 until 2005 February 17, when an increase in X-ray flux was detected by RXTE. Therefore, we can expect that our UVES spectra of GRO J1655-40 were taken when the source was in quiescence. We show below that this is indeed the case.

4. Analysis

4.1. Spectral separation

In order to build a clean mean spectrum of the secondary star of GRO J1655-40 and determine its spectral type, we fitted the continuum of individual spectra and attempted a separation using the iterative reconstruction method described in Demers et al. (2002), further enhanced and applied to a Wolf-Rayet+O binary by Foellmi et al. (2006). The reader is referred to the latter paper for a detailed description of the method. It has been in this case applied individually to the serie of spectra around Hβ and Hz, and allow us to not only “clean” the spectrum of the source by

---

2 See http://www.eso.org/instruments/uves/

---

1 http://archive.eso.org
removing any features unrelated to the companion (i.e. a possible contribution of a disk, and/or features that may have been left by the 2D background subtraction of the pipeline), but also to build a correct mean spectrum by aligning the lines of the moving secondary along the orbital motion.

We started by roughly measuring the positions of the center of the Hβ/Hα absorption profile, and transformed them into radial-velocities (RVs). We used these RVs to shift the spectra, and build a high-S/N absorption-component spectrum. The result is a good first-guess spectrum of the stellar object that produces these absorption lines (that is, the secondary), whereas all unrelated features are smeared out (as much as the RV differences are large). It is then shifted back to the original positions and subtracted from the original spectra. This provides a first-guess of the “second-component” spectrum, clearly revealing narrow emission peaks in all individual spectra.

We used a cross-correlation (CC) technique to measure the position of the emission peak that is on top of Hβ/Hα, and continued the extraction process. We also used CC for measuring RVs on the extracted absorption-component spectra during the next iterations. We performed in total 3 iterations, since no noticeable changes were visible on the results of subsequent ones. The resulting mean extracted spectra are shown in Fig. 2.

With the RVs of the absorption lines obtained via the CC measurements, we tried to compute an orbital solution with the period given by Orosz & Bailyn (1997, P = 2.62157 days). We obtained a solution with an orbital K amplitude of 225 ± 10 km s\(^{-1}\) in excellent agreement with that of Orosz & Bailyn (228.2 ± 2.2 km s\(^{-1}\)). Our systemic velocity (∼88 ± 5 km s\(^{-1}\)) is however not in agreement with them (∼142.4 ± 1.6 km s\(^{-1}\)). Since we have very few points and we did not calibrate in an absolute manner our RVs, our value is of course less reliable.

The RVs of the narrow emission peaks found in the Hα and Hβ extracted spectra show no RV variations at all within errors (i.e. <5 km s\(^{-1}\)). Some of these emission lines clearly have a multi-component profile. It is very likely that these lines are either faint and narrow sky lines missed by the UVES pipeline, or formed by some “warm interstellar medium” (WIM) (see e.g. Reynolds 1985; Domgorgen & Mathis 1994; Sembach et al. 2000). We are confident that they do not belong to the GRO J1655-40 system, because of their constancy in RVs, and since their (main) velocity is never consistent with the systemic velocity of GRO J1655-40. In particular, we identified the lines [O I] \(\lambda\lambda5577,6300,6364\), [O II] \(\lambda\lambda6498,6560\), [N II] \(\lambda\lambda6548,6563,6583,6717\) (see Fig. 2). We also visually checked that these lines are actually seen in the 2D images of our spectra. Not only do all of them clearly cross the whole slit length, but they also appear too faint and noisy to be caught by the pipeline.

We found no evidences in our spectrum of any lines moving in anti-phase, nor lines that could not be explained by the sky or WIM. In other words, the contribution from a disk around the black hole, if any, is not seen in our spectra.

4.2. The spectral type of the companion star

In order to study the spectrum of the secondary star in GRO J1655-40, we first performed a spectral synthesis of the Hα region. For that we used the UVES POP database of spectra (Bagnulo et al. 2003), taking advantage of the fact that this provides spectra taken with the same instrument and central wavelength. We used the slowly rotating star HD 156098 as a template (F6IV, \(V = 5.537\) mag, \(T_{\text{eff}} = 6480\) K, log \(g = 3.94\), Fe/H = 0.09; Edvardsson et al. 1993), which corresponds almost exactly to the model used by Israelian et al. (1999). The synthesis and spectral subtraction was done using STARMOD (Barden 1985; Montes et al. 1995, 2000).

We obtained a very good match to the spectrum of GRO J1655-40, as shown in Fig. 3. A rapid check with other F-star templates (see below) confirm that the best match is done with HD 156098, in excellent agreement with the F6III-F7IV spectral types of Shahbaz et al. (1999), although we cannot exclude an uncertainty of at most one subclass. This uncertainty has no significant consequences, as already emphasized by Israelian et al. (1999) in their abundance analysis of GRO J1655-40.

There is no sure indication (within the errors) of emission fill-in of Hα (the equivalent width of the “emission” in the residual of Hα is 0.1 Å). Since we used an averaged spectrum, we could expect to see a overall smeared out (over the line) contribution from any accretion disk. This is not the case, and we can conclude that the disk has a negligible contribution (in emission) and that our quiescence spectra are completely dominated by the secondary. In our best fit, we obtain a rotational
velocity $v \sin i = 94 \pm 8$ km s$^{-1}$, in excellent agreement with that of Israelian et al. (1999, $v \sin i = 93 \pm 3$ km s$^{-1}$).

Therefore, we conclude that the secondary star of GRO J1655-40 shows a spectral type F6IV, as observed in our 2004 data.

4.3. Obtaining the distance from the UVES spectra

Our approach to determine the distance of GRO J1655-40 is based on the comparison of the flux of GRO J1655-40 in quiescence with that of a nearby single star of the same spectral type. This is basically the method “A”, following Jonker & Nelemans (2004). Since there is an uncertainty on this spectral type, we also explore the results with different spectral types of the comparison star. We strengthen our results by using published photometric data of the comparison stars.

We have flux-calibrated our UVES spectra of GRO J1655-40 following two methods: using the UVES response curve and using spectrophotometric standard stars observed during the same nights. The comparison between the two methods is relevant because the first method is theoretically not producing an absolute flux-calibration (see e.g. Bagnulo et al. 2003). Since we will compare the flux of GRO J1655-40 with that of F stars who have been calibrated with one of the methods only (namely the method of the master response curve), we must ensure that both methods are equivalent.

The first calibration method uses the master response curves, and is described above. The second method was to retrieve observations of standard stars with identical setups from the archive, taken the same nights of observations of GRO J1655-40. These observations were available only for the nights of April 16 and 18, 2004, and the spectrophotometric standard star used is LTT 3218. To make the comparison between the two methods, we used the spectra of these two nights only. We might argue that slit losses make the comparison pointless. However, it occurred that the seeing was significantly smaller than the slit width (1.6") for the observation of GRO J1655-40 and 5.0" for the spectrophotometric standard stars) for the two nights of April 16 (seeing ~0.7) and 18 (seeing ~1.1)\(^5\). We are therefore confident that the calibration with standard stars is reliable. We finally corrected the spectra for the airmass and the (tabulated) atmospheric extinction. Figure 4 shows the flux of the UVES spectrum calibrated with response curve, versus the flux of the mean UVES spectrum calibrated with standard stars.

The difference between the two calibrations are roughly within one $\sigma$ for the so-called H$\alpha$ spectra only, whereas it is not the case for the H$\beta$ spectra. When dividing the two calibrated spectra, for each of the H$\beta$ and H$\alpha$ sets, we obtain the respective ratios: $1.10 \pm 0.01$ and $1.00 \pm 0.02$. We note that the difference between the two methods observed in the “H$\beta$” region is known, as seen in the UVES response curve webpage. We thus decided to pursue the analysis with the H$\alpha$ spectra only.

In order to determine the amount of absorption towards GRO J1655-40, we searched for an F6IV star with a known distance. For that matter we used again the spectrum of HD 156098 that has the crucial advantage of having been obtained with the

---

\(^5\) Technically speaking, it seems not necessary to compare the two methods, as long as we use the same master response curve for both GRO J1655-40 and the comparison F stars. However, it gives a much stronger confidence to the results if we can show that the flux calibration of GRO J1655-40 is actually good.

\(^6\) The values are obtained from the ESO archive DIMM seeing values, available at the time of observations.
Table 1. The five F stars used to compute the maximum distance of GRO J1655-40 are summarized. The star’s name, its spectral type, distance (computed from the HIPPARCOS parallax), absolute magnitude, \((B - V)\) color (obtained from SIMBAD) and the ratio of the calibrated spectrum of GRO J1655-40 with that of the star are indicated. The last two columns indicate the ranges of maximum distance \(D_1\) of GRO J1655-40 obtained through the constraint of \(a \geq 0\) with the two limits of the absolute magnitude \(M_1\) and for both methods. See text for details. The uncertainty on the distance values is \(\pm 0.2\) kpc.

In order to see the dependence of the results with the spectral type, we made these calculations for five different F stars with no known peculiarities (such as a binary or variable status), all retrieved from the UVES POP (and used above for spectral synthesis). The five F stars are summarized in Table 1, where we indicates the star’s name, its spectral type, parallax distance and absolute magnitude. The ratio \(f\) between the spectrum of GRO J1655-40 and the spectrum of the F star is indicated. We are confident that these ratios can be considered as constant throughout the wavelength range, since slopes of the ratio spectra were extremely small (comprised between \(-1 \times 10^{-7}\) and \(2 \times 10^{-8}\)).

The last columns give the ranges of maximum distance of GRO J1655-40 computed from the constraint that \(a \geq 0\), using the lower and upper limits of the absolute magnitude of \(M_1\). We note that an HIPPARCOS parallax error of 1 mas translates into an uncertainty of roughly \(\pm 3\) pc for the distance \(D_2\). The source of uncertainty on the distance of GRO J1655-40 is therefore dominated by that on the flux ratio \(f\). An uncertainty of 20% on the flux ratio (taking into account 10% for each of the flux of GRO J1655-40 and the comparison star) implies an uncertainty of roughly \(\pm 0.2\) kpc on the distance \(D_1\).

In Table 1, none of the upper values of the spectroscopic ranges of maximum distance exceeds 3.2 kpc. Interestingly, using the absolute magnitude \(M_1 = 0.7\) given by Orosz & Bailyn (1997), Eq. (5) implies a distance ranging from 0.15 to 1.43 kpc for the five F stars. Apart from the range obtained with the star HD 16673 (F5V), the overall mean maximum distance, that is for obtaining a null absorption \((a = 0)\), is 1.7 kpc (i.e. equivalent to the distance at null absorption for the star HD 156908 only, which has the same spectral type as the secondary star in GRO J1655-40). We thus consider this value as a strong upper limit to the distance of GRO J1655-40, since the absorption is certainly not strictly zero. We emphasize here that the only assumption we made is the absence of extinction toward the comparison star (but even a small absorption toward the sources would not challenge our conclusion), and that the absolute magnitude of the F6IV star in GRO J1655-40 is that of HD 156908 within two magnitudes.

To strengthen these results, we used published photometric data of the comparison stars and applied the pair method. More precisely, we can estimate a \(B\) magnitude of GRO J1655-40 in quiescence of \(\sim 16.65\) from the lightcurves published by Orosz & Bailyn (1997). Using their \(V\) magnitude (17.12), we obtain \((B - V)_{GRO} = 1.53\). On the other hand, \((B - V)\) colors of the comparison \(F\) stars can be retrieved from SIMBAD, and assuming that there are unreddened because of their close distance (hence \((B - V)_{F*} = (B - V)_{F*0}\)), we can use the following equations (Olson 1975; Lang 1999, Vol. II, p. 33):

\[
R = 3.25 + 0.25 \cdot (B - V)_{F*0} + 0.05 \cdot (B - V)
\]
where $E(B - V) = (B - V)_{GRO} - (B - V)_{F_0.0}$. Using the same assumption about the absolute magnitude of the secondary star of GRO J1655-40, ranges of maximum distance can be computed using the standard equation: $V - M_V - A_V = 5 \log D - 5$. These ranges are given in the last column of Table 1. It can be seen that they agree with the ranges given by the spectral flux method, although the mean distance (excepting HD 16673) is slightly larger: 2.25 kpc.

5. Discussion

No astrophysical link has been invoked in the literature between GRO J1655-40 and its environment, except Mirabel et al. (2002) who mention the possible link of the source with the open cluster NGC 6242, since the opposite direction of the proper motion vector of GRO J1655-40 that they determined with HST is clearly pointing to the cluster. This open cluster lies at a distance of 1.02 ± 0.1 kpc from the Sun according to the photometric and radial-velocity measurements of Glushkova et al. (1997). Although the association of GRO J1655-40 with the open cluster cannot be proven with our data, the upper limit for the distance of GRO J1655-40 is fully consistent with the distance of the cluster. Assuming that the link is true, using the proper motion values published by Mirabel et al. (2002) and the distance between the source and the cluster NGC 6242, we can compute the time at which GRO J1655-40 would have been ejected from the star cluster: ~6.6 × 10^3 years ago. Since the actual age of the cluster is known: 40.55 ± 10^6 years (Kharchenko et al. 2005), we can deduce that the age of NGC 6242 when the progenitor of GRO J1655-40 exploded is roughly 40 millions years. Using the canonical isochrones of Pietrinferni et al. (2004) for a solar metallicity, it is possible to obtain the turn-off mass of a cluster with the given age: between 6.7 and 7.2 M⊙ (assuming that the progenitor of the black hole in GRO J1655-40 has followed a single-star evolution). If correct, this result favors the lower end of the mass range given by Shahbaz et al. (1999), and is incompatible with the values obtained by Orosz & Bailyn (1997). Finally, using the radial velocity of the system (~142.4 ± 1.6 km s⁻¹ Orosz & Bailyn 1997), and assuming the age given above, we note that GRO J1655-40 is closer to the Sun than NGC 6242 by about 100 pc.

6. Conclusion

We have shown that the distance of GRO J1655-40 of 3.2 kpc quoted in the literature has been obtained through a refinement of a distance range, which was in turn not well established. We have determined a spectral type F6IV for the secondary star using UVES spectra.
