ABSTRACT

Aims. The cluster 1ES0657-556 is an ideal astrophysical laboratory to study the distribution and the nature of Dark Matter because this last component is spatially separated from the intracluster gas. We show that microwave observations can provide crucial probes of Dark Matter in this system.

Methods. We calculate the expected SZ effect from Dark Matter annihilation in the main mass concentrations of the cluster 1ES0657-556, and we estimate the sources of contamination, confusion and bias to assess its significance.

Results. We find that SZ observations at ν ≈ 223 GHz can resolve both spatially and spectrally the SZDM signal and isolate it from the other SZ signals, and mainly from the thermal SZ effect which is null at ν ≈ 220–223 GHz for the case of 1ES0657-556. We conclude that SZ observations with arcmin resolution and ≈μK sensitivity of 1ES0657-556 are crucial, and maybe unique, to find direct astrophysical probes of the existence and of the nature of Dark Matter, or to set strong experimental limits.

1. Introduction

Dark Matter (DM) annihilations in the halo of galaxies and galaxy clusters have crucial astrophysical implications. In fact, if DM is constituted by weakly interacting massive particles (for which the leading candidate is the lightest supersymmetric particle, plausibly the neutralino \(χ\)), their annihilation produces secondary particles (e.g., neutral and charged pions, secondary electrons and protons, neutrinos) that give rise to various astrophysical signals. These are, among others, observable fluxes of positrons, antiprotons, gamma rays, neutrinos, as well as signals due to secondary electrons which cover the whole e.m. spectrum (see, e.g., Colafrancesco et al. 2006, for details): synchrotron radio emission (in the intra-cluster magnetic field), bremsstrahlung emission (if there is co-spatial intra-cluster gas), inverse Compton emission due to the up-scattering of CMB photons and hence a specific SZ effect (as first noticed and derived by Colafrancesco 2004). The spatial and spectral intensity of the astrophysical signals coming from \(χχ\) annihilation is expected, however, to be confused or even overcome by other astrophysical signals originating from the intracluster (IC) gas and/or from the relativistic plasmas present in the cluster atmospheres, especially when all these components are co-spatially distributed with the DM component. This situation occurs in most galaxy clusters (see discussion by Colafrancesco et al. 2006 for the case of Coma).

An ideal system to detect DM annihilation signals would, therefore, be a cluster with a clear spatial separation between the various matter components. This is, indeed, the case of the cluster 1ES0657-556 where the spatial distribution of DM is clearly offset w.r.t. that of the IC gas (Clowe et al. 2006).

The two baryonic clumps of hot gas emit X-rays by (thermal) bremsstrahlung, as observed by Chandra (Markevitch et al. 2002, 2004). The shock observed in the western-most region of the cluster (Markevitch et al. 2002) might be the site of high energy emission from particles accelerated at the shock. Hard X-ray emission from the direction of 1ES0657-556 has been marginally detected by Rossi-XTE (Petrosian et al. 2006) but its angular resolution is not sufficient to give any information on the spatial distribution of this emission. No gamma-ray emission has been detected from this system with EGRET. The extended radio halo associated to this cluster (Liang et al. 2000) has a surface brightness slightly elongated along the direction of the two X-ray clumps, but without clear signatures of radio-brightness enhancements at the DM clump locations. Finally, the SZ maps of 1ES0657-556 obtained with ACBAR (with \(\sim 4.5 \,\text{arcmin} \, FWHM\) resolution, Gomez et al. 2003) are quite smooth and regular with no evidence of enhancement at both X-ray and/or DM clump locations. In this Letter, we will compute the specific feature of the SZ effect (hereafter SZE) produced by DM annihilation, \(SZ_{\text{DM}}\), in the cluster 1ES0657-556 and we will show that it is possible to detect such \(SZ_{\text{DM}}\) signal with a specific observational strategy. The relevant physical quantities are calculated using \(H_0 = 70 \,\text{km} \,\text{s}^{-1} \,\text{Mpc}^{-1}\) and a flat, \(\Lambda\)CDM (\(\Omega_m = 0.3, \Omega_{\Lambda} = 0.7\)) cosmological model.

2. The complex SZ effect in 1ES0657-556

The various SZ signals expected from the subsystems of the cluster 1ES0657-556 are: i) the \(SZ_{\text{DM}}\) effect, which is expected to be located at the two DM clumps; ii) the thermal SZ effect (\(SZ_{\text{th}}\)) which is expected to be located at the two X-ray clumps.
We will compute in the following these two sources of SZE and we will also discuss the possible sources of contamination, bias and confusion. The general expression for the SZE which is valid in the Thomson limit for a generic electron population in the relativistic limit and includes also the effects of multiple scatterings and the combination with other electron population in the cluster atmospheres has been derived by Colafrancesco et al. (2003). This approach is the one that will be used for the derivation of the SZE effect induced by the secondary electrons produced by $\chi\chi$ annihilation (see the original derivation by Colafrancesco et al. 2004) as well as for the SZE produced by the hot X-ray emitting gas. According to these results, the spectral distortion of the CMB spectrum induced by a population of electron with momentum distribution $f_e(p)$ can be written as

$$\Delta T(x) = 2\frac{(k_BT_0)^3}{(hc)^2} \frac{\int P_e\delta t}{\int P_e\delta t},$$

where $T_0$ is the CMB temperature and

$$\delta = \frac{\sigma_T}{m_e c} \int P_e\delta t,$$

in terms of the pressure $P_e$ contributed by the specific electron population. The spectral function $\delta(x)$, with $x = hv/k_BT_0$, can be written as

$$\delta(x) = \frac{x^2}{(e-1)^2} \left\{ \frac{1}{\tau} \left[ \int_{x^{-1}}^{x} \frac{\chi_0(x^{-1}s^{-1})P(x)dx - \chi_0(x)}{e^{-1}} \right]\right\}.$$

in terms of the photon redistribution function $P(s)$ and of $\chi_0(x_{-1}) = 2(k_BT_0)^3/(hc)^2 \cdot x^3/(e-1)$. Here $\tau = \int dt \chi_0$ is the optical depth of the electrons with number density $n_e$, and $e$ is the average energy of the electronic plasma. The photon redistribution function $P(s)$ of a class of the CMB photon frequency increase factor $\nu'/\nu$, depends on the electron momentum distribution $f_e(p)$, where the momentum $p$ is normalized to $m_e c$. The CMB temperature change produced by the SZE is finally given by

$$\Delta T = \frac{\int \Delta T}{T_0} \frac{\Delta T}{T_0} = \frac{\Delta T}{T_0}.$$

The specific SZE effects for the various electronic components in the cluster 1ES0657-556 are computed following the approach previously described.

2.1. The SZE effect in the cluster 1ES0657-556

The calculation of the secondary electron spectrum from $\chi\chi$ annihilation in galaxy clusters has been already presented in details by Colafrancesco & Mele (2001) and Colafrancesco et al. (2006), and here we will only recall the relevant steps necessary for the present purposes.

We assume, for simplicity, a spherical DM halo model for each DM clump of the cluster 1ES0657-556, as indicated by the lensing maps derived by Clowe et al. (2006), with DM density profile given by $\rho(x) = x^{-3}(1+x)^{\xi}$, with $x \equiv r/r_s$. Values $\eta = 1$ and $\xi = 3$ reproduce the Navarro et al. (1997) density profile.

The neutralino number density profiles $n_0(E, r) = n_{0,0}(E)g(r)$ of the two DM clumps have been calculated following the approach described in Colafrancesco et al. (2006) with a NFW DM density profile and the following structure parameters: $M_{cl} = 10^{15} M_{\odot}$, $R_{cl} = 1.97$ Mpc and $c_{vir} = R_{vir}/r_s = 5.66$ for the larger East DM clump; $M_{cl} = 6.25 \times 10^{13} M_{\odot}$, $R_{cl} = 0.784$ Mpc and $c_{vir} = 7.56$ for the “bullet” West DM clump.

The $\chi$ annihilation rate in the DM clumps is $R = n_0(\sqrt{\sigma v})_{\chi\chi}$, where $\chi(\chi)$ is the $\chi$ annihilation cross section averaged over a thermal velocity distribution at freeze-out temperature. The range of neutralino masses and pair annihilation cross sections in the most general supersymmetric DM setup is extremely wide (see discussion in Colafrancesco et al. 2006, 2007). We consider here, specifically, the neutralino models worked out in Colafrancesco et al. (2006) with $M_{\chi} = 20, 40$ and 81 GeV and with their specific values of $(\sigma v)_{\chi\chi}$.

The electron source functions $Q_{\nu}(E, r) \propto (\sigma v)_{\chi\chi}^2(E, r)$ for the specific neutralino model considered here have been derived in Colafrancesco et al. (2006) and the time evolution of the electron spectrum is given by the equation

$$\frac{\partial n_e(E, r)}{\partial t} - \frac{\partial}{\partial E} \left[ n_e(E, r) b(E) \right] = Q_{\nu}(E, r),$$

where spatial diffusion can be safely neglected in cluster-size DM clumps (Colafrancesco et al. 2006). The function $b(E) = b_0^I \frac{E}{GeV} + b_0^S \beta \left( \frac{E}{GeV} \right)^2$ gives the energy loss per unit time at energy $E$ where $n_0$ is the mean number density of thermal electrons in cm$^{-3}$, $\gamma \equiv E/m_e c^2$ and $b_0^I \equiv 0.25, b_0^S \equiv 0.0254, b_0^I \equiv 6.13, b_0^I \equiv 1.51$, all in units of 10$^{-16}$ GeV s$^{-1}$. The equilibrium spectrum $n_0(E, r)$ obtained solving Eq. (5) allows to calculate the SZE effect. Figure 1 shows the SZE effect evaluated at the centers of the two DM clumps for different values of $M_{\chi}$. The SZE effects are overcame by the SZE signals at low ($\nu \lesssim 200$ GHz) and high ($\nu \gtrsim 230$ GHz) frequencies, where they dominate in the frequency range where the zero of SZE is found, i.e. at $\nu \approx 223$ GHz for the East clump and at $\nu \approx 219$ GHz for the West clump. At such frequencies the SZE effect decreases as $\frac{\chi}{M_{\chi}}$ takes values $\approx \frac{1}{211}, \frac{1}{10.6}, \frac{1}{0.3}$ (East clump) and values $\approx -8.4, -4.2, -0.1 \mu K$ (West clump) for $M_{\chi} = 20, 40, 81$ GeV, respectively.

2.2. The SZE effect in the cluster 1ES0657-556

The SZE from the two X-ray clumps of the cluster 1ES0657-556 is also computed from the general approach delineated in Eqs. (1)–(4). Following Markevitch et al. (2002, 2004) and Tucker et al. (1998), we use the simplifying assumption that the IC gas distribution can be described by isothermal spheres fitted by a $\beta$-profile. For the East X-ray clump we adopt $kT_e = 14$ keV (Markevitch et al. 2002, 2004) and a $\beta$-profile with $r_s = 257$ kpc, $\beta = 0.62$ and a central IC gas density $n_{\text{IC},0} = 7.6 \times 10^{-3} \text{ cm}^{-3}$. For the West X-ray clump we adopt $kT_e = 6$ keV and a $\beta$-profile with $r_s = 125$ kpc, $\beta = 0.7$ and a central IC gas density $n_{\text{IC},0} = 2 \times 10^{-2} \text{ cm}^{-3}$, neglecting the additional central power-law density profile induced by the presence of the shock (Markevitch et al. 2002, 2004). Thus, SZE from this last X-ray clump should be considered as slightly underestimated.

The possible non-equilibrium and non-thermal effects induced by the merging shock are not crucial for the aims of this paper since the shock is located outside the two X-ray clumps and at a large angular distance from the two DM clumps (see
Markevitch et al. 2002, 2004). Possible non-thermal SZE produced by shocks is, however, expected to be at most at a level of a few $\mu$K (see Colafrancesco et al. 2003), and therefore it could be, at most, a source of bias for the thermal SZE at the location of the X-ray clumps. The SZA temperature change for the two X-ray clumps is also shown in Fig. 1. A major difference between the SZ$_{th}$ and SZ$_{DM}$ spectral functions is the different position of the zero of the SZE which is moved to higher frequencies in the case of the DM produced electrons with respect to the case of the thermal distribution. As a consequence, the SZ$_{DM}$ effect appears as a negative contribution to the overall SZE at all the frequencies which are relevant for the SZ experiments, $\chi \sim 0.5$–10.

2.3. Contamination, bias and confusion

Possible sources of confusion for the microwave search for DM in 1ES0657-556 are: CMB anisotropy, emission of the IC medium, emission of galaxies and AGNs along the line of sight, thermal and kinematic SZE from the X-ray clumps. For the estimates of the foreground contamination we consider as peaks of the DM distribution producing SZE the regions included in the $\kappa = 0.3$ contour of Fig. 1 in Clowe et al. (2006). These are roughly 1.3’ in diameter, and are separated by ~4.8’.

The measurement we propose must be carried out with an instrument with angular resolution of ~1’ FWHM, able to resolve the two SZ$_{DM}$ peaks, and to distinguish them from the thermal and kinematic SZE of the two X-ray clumps. Larger scales are not significant for the measurement, and must be removed either in the measurement or in the data analysis. This will remove most of the CMB anisotropy. In fact, integrating over the power spectrum of CMB anisotropy best fitting current measurements (including lensing effects), we find that an angular high-pass filter removing scales $\gtrsim 3'$ will cut multipoles $\ell \lesssim 3600$, leaving a residual rms fluctuation of primary CMB anisotropy of 0.8 $\mu$K rms. This is further reduced by the finite angular resolution of the telescope.

In the two SZ$_{DM}$ peaks we find 14 galaxies in the area of the East peak and 6 galaxies in the area of the West peak (see Barrena et al. 2002). To obtain an estimate of the mm-wave emission of these galaxies, we take the mm-wave spectrum of an “average”, “normal” galaxy (like M99) and redshift it to $z = 0.3$. Then we compute the flux in the bands centered at 90, 145, 217, 270, 345, 545 GHz and we find the total flux by multiplying it by the number of galaxies counted in the West and East SZ$_{DM}$ peaks. In the West peak, we obtain a total flux of 0.2, 0.4, 1.0, 1.6, 3.4, 19 mJy, respectively, in the bands quoted above. These signals correspond to a CMB anisotropy of 4.0, 8.0, 13, 40, and 760 $\mu$K for a 1’ FWHM beam. These are comparable in size to expected SZ$_{DM}$ signal, at least in the 90, 145, and 217 GHz bands, but are positive signals, while the SZ$_{DM}$ signal is negative at the same frequencies. The same holds for AGNs; there is only one known radio source (SUMSS J065837-555718) listed in the NED database in the area of the East peak, and none in the area of the West peak. This source has been observed with the MOST radio telescope, and features a power law SED, with slope $\alpha \sim -0.9$. If the same SED is used to extrapolate to the frequencies of interest here, the total flux is safely negligible with respect to the expected SZ$_{DM}$ in all the bands considered here: for a 1’ FWHM beam the signal is below 1 $\mu$K in the 145, 217, 270 and 345 GHz bands.

Unresolved background galaxies produce a flux with positive and negative fluctuations with respect to the average. For a 1’ beam at 220 GHz, we get a rms signal of ~3 $\mu$K, estimated using the model of Lagache et al. (2004).

The SZA emission from the IC gas is offset with respect to the DM peaks, so that only the tail of the signal is present in the SZ$_{DM}$ peaks. The SZA emission is certainly affected by the complex temperature distribution of the X-ray clumps (see Markevitch et al. 2002) producing fluctuations in the SZ maps (since $\Delta T \propto \int n_e T_e$). This makes the maps at low (150 GHz) and high (350 GHz) frequency shown in Fig. 2 as only indicative of the observable SZ signal. However, we stress that the SZ maps at $\nu \approx 219–223$ GHz are quite realistic because at 223 (219) GHz for the East (West) X-ray peak, the SZA is null, and temperature uncertainties do not sensitively alter this result (see Fig. 1): this is, henceforth, the privileged band for this measurement.

The $(\Delta T/T_0)_{kin}$ at the clump centers is $2.7\times 10^{-7}(r/10^3)(V_p/10^3 \text{ km s}^{-1})$ and is maximum at 217 GHz. Small values of $(\Delta T)_{kin}$ are found at the location of the two DM clumps because: i) the optical depth of the secondary electrons is small $\leq$ few $10^{-5}$; ii) the optical depth of the residual IC gas at the DM peak locations is small $\leq$ few $10^{-5}$, and iii) the peculiar velocity of the X-ray clumps and DM clumps along the line of sight is relatively small (Markevitch 2004), since the major merging event occurs almost completely on the plane of the sky, i.e. mostly perpendicular to the line of sight. Even an extreme value $V_p \approx 600 \text{ km s}^{-1}$ (well above the rms value $\approx 300 \pm 80 \text{ km s}^{-1}$ found for galaxy clusters, see Giovannelli et al. 1998) would produce a total $(\Delta T)_{kin} \approx 0.4 \mu$K (~0.2 $\mu$K) in the East (West) DM clump. In conclusion, being
signals of \( \text{SZ}_{\text{DM}} \). Similar considerations apply to the Atacama Cosmology Telescope (Kosowsky 2003), to the APEX bolometer arrays (Lee et al. 2004) and to the BOLOCAM instrument at the CSO (Glenn et al. 1998). Figure 2 shows the CMB maps expected from an observation of \( 1\text{ES0657-556} \) at \( \nu = 150, 223 \) and \( 350 \) GHz (with bandwidths of \( \approx 25\% \)) with the SPT. The \( \text{SZ}_{\text{DM}} \) effect clearly emerges localized at the two DM clumps for \( \nu = 223 \) GHz where \( \text{SZ}_{\text{th}} \) vanishes for the brighter X-ray clump with \( kT_e = 14 \) keV. This is the optimal frequency to detect the \( \text{SZ}_{\text{DM}} \) from the cluster \( 1\text{ES0657-556} \). Such an experiment is able to set strong constraints on DM particle mass in the range \( M \sim 20-50 \) GeV, while the SZ signals for \( M \gtrsim 80 \) GeV are unobservable. Higher frequency measurements are needed to monitor foreground contamination. Observations of \( 1\text{ES0657-558} \) with the OLIIMO experiment (Masi et al. 2005), using bolometer arrays at 145, 217, 345 and 545 GHz, with beam \( \text{FWHM} \) of \( 3.3', 2.2', 2.2', 2.2' \) respectively, will be able to resolve the two SZE peaks, and will not be hampered by atmospheric fluctuations even in the highest frequency bands. In 10 h of integration over the cluster area, the sensitivity of OLIIMO in the 217 (345) GHz band will be \( \approx 1.5 (3.0) \) µK per pixel (with a pixel side of \( 1' \)). These measurements will nicely complement those of the ground based instruments, allowing an effective separation of the different astrophysical components, with special sensitivity to the fluctuating background from unresolved galaxies. An exciting perspective is the upgrade of a space-borne telescope with a Fourier Transform Spectrometer. This can provide the combination of high throughput and spectral resolution needed to compare the \( \text{SZ}_{\text{th}} \) null to the surrounding frequencies, thus providing convincing evidence to distinguish between the different signal components (see Fig. 1). A first test can be carried out already with the OLIIMO experiment, preparing the way for a future satellite mission.

3. Conclusions

The \( \text{SZ}_{\text{DM}} \) effect is an inevitable consequence of the presence and of the nature of DM in large-scale structures. Its analysis in the special case of \( 1\text{ES0657-556} \) can provide a direct physical probe for the presence and for the nature of DM in cosmic structures.

How these observations compare to other possible DM signal detections? In general, both gamma-ray and radio observations of DM annihilation are quite powerful to set constraints on the neutralino mass and composition (see, e.g., Colafrancesco et al. 2006, 2007). However, in the case of \( 1\text{ES0657-556} \) the expected gamma-ray emission associated to the DM clumps is too low (\( \lesssim 1 \) count vs. \( \sim 10 \) background counts at \( E > 1 \) GeV) and cannot be resolved by GLAST from other possible sources of gamma-ray emission, both from the cluster \( 1\text{ES0657-556} \) and from AGNs in the field. In addition, the GLAST spatial resolution (\( \sim 9-18 \) arcmin at 10 and 1 GeV, respectively) cannot provide any clear spatial separation between the DM gamma-ray signals (expected to be concentrated at the DM clumps) and other possible gamma-ray signals originating within the atmosphere of \( 1\text{ES0657-556} \). Radio telescopes have, in principle, excellent resolution and sensitivity to probe the different spectra and brightness distribution of the DM-induced synchrotron emission. For the sake of illustration, we evaluated that the DM-induced synchrotron emission from the East DM clump is \( \sim 3-10 \) mJy (for a smooth or smooth plus 50\% mass clumpiness NFW DM profile, \( M_1 = 40 \) GeV, \( \langle \sigma v \rangle = 4.7 \times 10^{-23} \) cm\(^3\) s\(^{-1}\) model used by Colafrancesco et al. 2006 for Coma, with a 1 \( \mu \)G magnetic field) at \( \nu = 100 \) MHz, still marginally detectable by

---

**Fig. 2.** Left: simulated SZ maps of the cluster \( 1\text{ES0657-556} \) as observable with the SPT at \( \nu = 150 \) GHz (upper panel), \( \nu = 223 \) GHz (mid panel), \( \nu = 350 \) GHz (lower panel). A value \( M_1 = 20 \) GeV has been adopted here. Right: simulated SZ maps of the cluster \( 1\text{ES0657-556} \) as observable with the SPT at \( \nu = 223 \) GHz for three different \( \chi \) masses: \( M_1 = 20 \) GeV (upper panel), 40 GeV (mid panel) and 81 GeV (lower panel).
LOFAR. Theoretical uncertainties associated to the amplitude of the magnetic field in the DM clumps of 1ES0657-556 render, however, the prediction of the expected signals quite uncertain. In such a context, the possible detection of the $SZ_{DM}$ effect will provide an important complementary, and maybe unique, probe of the nature of DM.
