ABSTRACT

We report on the high-redshift blazar identification of a new gamma–ray source, Swift J1656.3–3302, detected with the BAT imager onboard the Swift satellite and the IBIS instrument on the INTEGRAL satellite. Follow-up optical spectroscopy has allowed us to identify the counterpart as at an R ∼ 19 mag source that shows broad Lyman-α, Si IV, He II, C IV, and C III emission lines at redshift z = 2.40 ± 0.01. Spectral evolution is observed in X-rays when the INTEGRAL/IBIS data are compared to the Swift/BAT results, with the spectrum steepening when the source gets fainter. The 0.7–200 keV X-ray continuum, observed with Swift/XRT and INTEGRAL/IBIS, shows the power law shape typical of radio loud (broad emission line) active galactic nuclei (with a photon index Γ = 1.6) and a hint of spectral curvature below ∼2 keV, possibly due to intrinsic absorption (N H ~ 7 x 10^22 cm^-2) local to the source. Alternatively, a slope change (∆Γ = 1) around 2.7 keV can describe the X-ray spectrum equally well. At this redshift, the observed 20–100 keV luminosity of the source is ~~10^49 erg s^-1 (assuming isotropic emission), making Swift J1656.3–3302 one of the most X-ray luminous blazars. This source is yet another example of a distant gamma-ray loud quasar discovered above 20 keV. It is also the faintest object, among the previously unidentified INTEGRAL sources, whose nature has been determined a posteriori through optical spectroscopy.

Key words. quasars: emission lines – quasars: individual: J1656.3–3302 – galaxies: high-redshift – galaxies: active – X-rays: galaxies – astrometry

1. Introduction

Blazars are distant and powerful active galactic nuclei (AGNs) which are oriented in such a way that a jet expelled from the central black hole is directed at small angles with respect to the observer’s line of sight (for a recent review, see Padovani 2007). In the widely adopted scenario of blazars, a single population of high-energy electrons in a relativistic jet radiates over the entire electromagnetic spectrum via synchrotron and inverse Compton processes, the former dominating at low energies, the latter being relevant at high energies (Ghisellini et al. 1998). The Compton processes, which are oriented in such a way that a jet expelled from the central black hole is directed at small angles with respect to the observer’s line of sight, are particularly important (especially if available over a broad energy range) as they allow the characterization of the inverse Compton peak and related parameters. More specifically, a flattening in the spectral distribution of the seed photons producing X-rays via inverse Compton is often observed at low energies in the X-ray spectra of these objects and can be measured only with broad band data (see e.g. Tavecchio et al. 2007, and references therein).

Unfortunately, the situation is far more complex, as absorption intrinsic to the source can also reproduce the spectral curvature observed in the X-ray band (e.g., Page et al. 2005; Yuan et al. 2006); in this case, information on the absorption is useful to understand the source environment and its relation to the jet. Besides this, X-/gamma-ray observations can provide evidence for the existence of extreme blazars, i.e. those with the synchrotron peak lying at X-ray energies (Giommi et al. 2007; Bassani et al. 2007).

Here, we report detailed information on a new, powerful and hard X-ray selected blazar, Swift J1656.3–3302, recently discovered through high-energy observations made with Swift/BAT

* Partly based on X-ray observations with INTEGRAL, an ESA project with instruments and science data centre funded by ESA member states (especially the PI countries: Denmark, France, Germany, Italy, Switzerland, Spain), Czech Republic and Poland, and with the participation of Russia and the USA, and on optical observations collected at ESO (La Silla, Chile) under programme 079.A–0171(A).
and INTEGRAL/IBIS. We present the results of our optical follow-up work, which has allowed the identification of the source with a blazar at redshift $z = 2.4$, along with an accurate analysis of the available Swift/XRT and INTEGRAL/IBIS data. We also construct a SED for Swift J1656.3–3302 and discuss the characteristics of the source broad band emission.

The paper is structured as follows: Sect. 2 reports a collection of the main results available in the literature on this source; Sects. 3 and 4 illustrate the optical and high-energy observations, respectively; Sect. 5 contains the results of this observational campaign, while a discussion on them is given in Sect. 6. Conclusions are outlined in Sect. 7. Throughout the paper, and unless otherwise specified, uncertainties are given at the 90% confidence level. We also assume a cosmology with $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_L = 0.7$ and $\Omega_m = 0.3$.

## 2. Previous information on Swift J1656.3–3302

The high-energy source Swift J1656.3–3302 was discovered with the BAT imager (Barthelmy et al. 2005) onboard the Swift satellite (Gehrels et al. 2004) during a survey performed between December 2004 and September 2005 (Okajima et al. 2006). The object was detected at coordinates RA = $16^h56^m19.2$, Dec = $-33^\circ01'48''$ (J2000), which are about 6.3 from the Galactic Plane, and with a positional uncertainty of 12'. Okajima et al. (2006) also reported that the 14–200 keV BAT spectrum was very hard with a photon index $\Gamma = 1.3 \pm 0.3$, and with a flux of $1.0 \times 10^{-10}$ erg cm$^{-2}$ s$^{-1}$. The source flux was variable by a factor of as high as 4.

Subsequent pointed observations (Tueller et al. 2006) with Swift/XRT (Burrows et al. 2005) performed in June 2006 located the X-ray counterpart at a position RA = $16^h56^m16.56$, Dec = $-33^\circ02'09.3'$ (J2000), with an uncertainty of 3.7. The XRT data were fitted with an absorbed power law with $\Gamma = 1.4 \pm 0.3$ and $N_H = (3.9 \pm 0.17) \times 10^{21}$ cm$^{-2}$. By comparing this value with the Galactic absorption column density along the direction of Swift J1656.3–3302 (2.2 $\times$ 10$^{21}$ cm$^{-2}$; Dickey & Lockman 1990), Tueller et al. (2006) suggested that it may be an extragalactic object. These authors also measured an absorbed flux in the 0.3–10 keV band of $5.6 \times 10^{-12}$ erg cm$^{-2}$ s$^{-1}$ and predicted a flux in the 14–195 keV band of $4.0 \times 10^{-11}$ erg cm$^{-2}$ s$^{-1}$, comparable with the BAT detection of Okajima et al. (2006).

Tueller et al. (2006) detected no sources with Swift/UVOT (Roming et al. 2005) in the XRT error circle at a limiting magnitude of $20$ in the ultraviolet filters. The soft X-ray position of Swift J1656.3–3302 is consistent with the radio source NVSS J165616–330211 (having a 1.4 GHz flux density of 410.7 $\pm$ 12.3 mJy; Condon et al. 1998) and (albeit marginally) with the faint ROSAT source 1RXS J165616.6–330150 (Voges et al. 2000). According to Tueller et al. (2006) the ROSAT data indicate that, if the two sources are the same, spectral variability may be present. A second, weak X-ray source was also found with XRT within the BAT error circle, but Tueller et al. (2006) judged it too soft and faint to be the soft X-ray counterpart of the BAT source.

Swift J1656.3–3302 was also found to be associated with an unidentified INTEGRAL source in the 3rd IBIS survey of Bird et al. (2007), with average 20–40 keV and 40–100 keV fluxes of $9.1 \times 10^{-12}$ erg cm$^{-2}$ s$^{-1}$ and $1.4 \times 10^{-11}$ erg cm$^{-2}$ s$^{-1}$, respectively, assuming a Crab-like spectrum. According to these observations, the source lies at coordinates RA = $16^h56^m26.4$, Dec = $-33^\circ02'49.7''$ (J2000). The error circle is 2.5 in radius. This position is consistent with the BAT and XRT positions reported above.

In the following, we further analyze this source over a broad range of frequencies.

## 3. Optical observations

Medium-resolution optical spectra of the objects in the Swift/XRT error circle (see Fig. 1) were acquired between 04:24 and 06:23 UT of 21 June 2007, and between 03:34 and 04:04 UT of 24 June 2007 with the 3.6 m ESO telescope located in La Silla (Chile). This telescope carried the EFOSC2 instrument, equipped with a 2048 $\times$ 2048 pixel Loral/Lesser CCD. The use of grating #13 and a slit of 1.0 provided a 3685–9315 Å nominal spectral coverage. This setup gave a dispersion of 2.8 Å/pix.

The spectra (Fig. 2), after correction for cosmic-ray rejection, bias and flat-field, were optimally extracted (Horne 1986) using IRAF$^1$. Wavelength calibration was performed using He-Ar lamps, while flux calibration was accomplished by using the spectrophotometric standard Feige 110 (Hamuy et al. 1992, 1994). The wavelength calibration uncertainty was $\sim 0.5$ Å; this was checked by using the positions of background night sky lines.

A 20 s R-band acquisition image of the field, secured again with the 3.6 m ESO telescope plus EFOSC2 under a seeing of 0.9, was also reduced and analyzed. The image, 2 $\times$ 2 pixels binned, had a scale of 0.31/pix and covered a field of 5.2$\times$5.2. It was corrected for bias and flat field and processed with DAOPHOT (Stetson 1987) within MIDAS$^2$ using a PSF-fitting procedure. The choice of this photometric approach over the simple aperture photometry was dictated by the crowding of the field (see Fig. 1).

---

1. IRAF is the Image Analysis and Reduction Facility made available to the astronomical community by the National Optical Astronomy Observatories, which are operated by AURA, Inc., under contract with the U.S. National Science Foundation. It is available at [http://iraf.noao.edu/](http://iraf.noao.edu/).

2. MIDAS (Munich Image Data Analysis System) is developed, distributed and maintained by ESO and is available at [http://www.eso.org/projects/esomidas/](http://www.eso.org/projects/esomidas/).
The spectrum has been smoothed with a running boxcar of 5 pixels serving mode). Counting mode (see Burrows et al. 2005, for details on this observation started at 03:32 UT on 9 June 2006, and the second at \( t_0 = 20 - 200 \) keV. Events coming from both fully-coding and partially-coded observations of the field of view of Swift J1656.3–3302, were included in the analysis. Details on the whole extraction procedure can be found in Bird et al. (2007). A time-averaged spectrum was obtained from the available data using the method described in Bird et al. (2006, 2007); that is, the spectra were reconstructed using the information obtained from the flux maps acquired in several bands between 20 and 200 keV. Data for a total exposure of 2.3 Ms, collected in the time interval October 2002–April 2006, were used for this task.

5. Results

The 0.3–10 keV image of the region around Swift J1656.3–3302 is shown in Fig. 3 with the IBIS and BAT error circles superimposed. Three objects are clearly detected within the BAT error circle. However, only one, which is also the brightest, lies within the smaller INTEGRAL error circle. This object is the soft X-ray counterpart of Swift J1656.3–3302 reported in Tueller et al. (2006).

With the data of both XRT observations we have determined its position using the most recent version of the xrtcentroid (v0.2.7) task. The correction for the misalignment between the telescope and the satellite optical axis was taken into account (see Moretti et al. 2006 for details). The position we obtained for the source is RA = 16^h 56^m 16.83s, Dec = −33°02′12″3 (J2000), with an uncertainty of 3′′ on both coordinates. This is fully consistent with the preliminary results of Tueller et al. (2006).

As mentioned above, in addition to the bright X-ray source, two fainter sources are detected by XRT (see Fig. 3). One of them (the westemmost one) can readily be excluded as the soft X-ray counterpart of Swift J1656.3–3302 because it is positionally inconsistent with the IBIS error circle. The other lies 2′/2 from the center of the IBIS error circle, near its border but formally outside it. This object has coordinates RA = 16^h 56^m 28.1s, Dec = −33°05′25″/2 (J2000), with a conservative error of 6″ on both. To further exclude any association between this source and the hard X-ray emission seen by BAT and IBIS, we examined its XRT spectrum. We found that it is very soft, as no emission is detected above 2.5 keV. Indeed, it could be fitted with a blackbody with \( kT = 0.5 \pm 0.3 \) keV (\( \chi^2/\text{d.o.f} = 3.8/3 \)). The corresponding 2–10 keV flux is \( 1.3 \times 10^{-13} \text{ erg cm}^{-2} \text{s}^{-1} \), thus (see Table 2) it is about 30 times fainter than the aforementioned bright XRT source, which is located within the INTEGRAL error circle.

The positional coincidence of this faint X-ray source with an \( R \sim 11.4 \) mag star in the DSS-II-red survey suggests that this soft X-ray emission comes from a stellar corona. Indeed, medium-resolution optical spectroscopy acquired at La Silla (Chile) with

\[\text{Fig. 3.} \quad \text{Swift/XRT 0.3–10 keV image of the field of Swift J1656.3–3302 acquired on 13 June 2006. The larger circle indicates the BAT positional uncertainty and the smaller circle the IBIS one. Swift J1656.3–3302 is the brightest source in the image.}\]
the NTT equipped with EMMI on 2007 July 28 shows that this source is an A-type star with no peculiar spectral features.

Given all of the above multiwavelength information, we can confidently exclude the two fainter objects, detected by XRT and shown in Fig. 3, as the possible soft X-ray counterparts of Swift J1656.3–3302, and we confirm that the object reported in Tueller et al. (2006) is the soft X-ray counterpart of the source detected by BAT and IBIS.

Of the 5 optical objects within or close to the XRT error circle of Swift J1656.3–3302 (see Fig. 1), only that indicated with the tick marks in this figure shows peculiar optical spectroscopic characteristics, namely broad emission lines (Fig. 2). We identify these features as Lyman-α, Si IV λ1394, 1403, C IV λλ1548, 1551, He II λ1640 and C III] λ1910, at an average redshift \( z = 2.40 \pm 0.01 \). This corresponds to a luminosity distance \( d_L = 19.4 \) Gpc within the assumed cosmology. Table 1 reports the main properties of the emission lines detected in the optical spectrum of Swift J1656.3–3302.

We note that the Lyman-α, He II and C III] emission lines have much broader Full Widths at Half Maximum (FWHMs) than the other lines. Given the resolution and the signal-to-noise ratio of the optical spectrum, this may be due to the fact that these lines may be blended with the N V λ1240, O III] λ1663 and Si III] λ1892 emissions, respectively.

The \( R \)-band acquisition image was processed to obtain an astrometric solution based on several USNO-A2.0\(^{\ast}\) reference stars in the field of Swift J1656.3–3302. This yields for the optical counterpart of this source the coordinates RA = 16°56′16′′553, Dec = −33°02′11″.08 (J2000). The conservative error on the optical position is 0″.31, which has to be added to the systematic error of the USNO catalogue (0″.25 according to Assafin et al. 2001 & Deutsch 1999). The final 1-σ astrometric uncertainty on the optical position of Swift J1656.3–3302 is thus 0″.40.

This position is consistent with that of the radio source NVSS J165616.3–330211, indicating that the two sources are the same. This is also consistent with the position of the faint ROSAT source reported by Tueller et al. (2006). We instead exclude that the optical source USNO-A2.0 0525-24886745 (i.e. the brightest object within the XRT error circle in Fig. 1, proposed by Tueller et al. (2006), as a possible optical counterpart) is related with Swift J1656.3–3302 on the basis of its optical spectrum, which is typical of a Galactic star.

Again using USNO-A2.0 field stars as calibrators, we obtained for the true counterpart a magnitude \( R = 19.1 \pm 0.1 \).

\(^{\ast}\) Possibly blended with a fainter emission line (see text).

Towards the line of sight of the source, the Galactic foreground reddening is \( E(B-V) = 0.624 \) mag (Schlegel et al. 1998). Using the law by Cardelli et al. (1989), this implies that the Galactic extinction in the \( R \) band is \( A_R = 1.6 \). Thus, the reddened R-band magnitude of the source is \( R_0 = 17.5 \).

A simple power law model (as employed by Okajima et al. 2006) to characterize the BAT spectrum provides a good description of the IBIS data but yields a steeper spectrum \( (\Gamma = 1.9 \pm 0.3) \), combined with a lower (by a factor of 3 compared to the BAT measurement) \( 14–195 \) keV flux \( (3.4 \times 10^{-11} \text{ erg cm}^{-2} \text{s}^{-1}) \). Thus, the source appears to experience spectral evolution.

We then used the Swift/XRT data to describe the X-ray spectrum of Swift J1656.3–3302, employing first a simple power law in the source rest frame (2powerlaw model in XSPEC) absorbed by the Galactic column density (reported in Sect. 2). This model provides consistent results for the two observations \( (\Gamma = 1.22 \pm 0.16 \) for the first one and \( \Gamma = 1.13 \pm 0.16 \) for the second). No significant flux variations are observed either during each XRT pointing or between them. Thus, to improve the statistics, we have stacked the two XRT spectra and repeated the analysis. The simple power law again provides an acceptable fit \( (\chi^2/d.o.f. = 24.8/25) \) and yields a flat spectrum \( (\Gamma = 1.18 \pm 0.11) \).

Next, we have combined the XRT spectrum with that from IBIS, introducing a constant to allow for intercalibration differences between the two instruments; this constant was left free to vary in the fits. We are aware that, since the XRT and IBIS observations were not simultaneous, flux variations are

**Note:** In the above fits, when needed, we fixed the redshift of the source at \( z = 2.40 \) and the Galactic hydrogen column at \( N_H^\text{Gal} = 2.2 \times 10^{21} \text{ cm}^{-2} \). The reported fluxes (in the observer’s frame) are in erg cm^{-2} s^{-1} and are corrected for the total intervening absorption column density. For the broken power law model, the fit parameters are computed in the observer’s frame, and not in the source rest frame.
plausible given the blazar nature of the object, and may also be
the cause of different normalizations. Given that our past
experience tells us that the intercalibration constant between these two
instruments is ~1, we suggest that different values for this con-
stant are likely to be due to the flux variability mentioned above.

Again using an absorbed power law fit with the \( N_H \) value
fixed to the Galactic one along the source line of sight, we
obtained a best-fit photon index \( \Gamma = 1.28 \pm 0.10 \) \( (\chi^2/d.o.f. =
45.6/34) \). However, this model results in fit residuals (see Fig. 4,
upper panel) that show some curvature on the lower energy side,
possibly due to intrinsic absorption in the source rest frame. The
addition of this extra absorption component (\( zwabs \) in \( xspec \))
provides a fit improvement which is significant at the 95% confi-
dence level according to the F-test (Bevington 1969). This leads
to a more typical AGN spectrum (\( \Gamma = 1.64 \pm 0.16 \)) and gives a
relatively high column density (\( N_H = 6.7^{+3.2}_{-2.3} \times 10^{22} \text{ cm}^{-2} \))
local to the blazar (Fig. 4, central panel).

Alternatively, one may assume that the turnover in the X-ray
spectrum is produced by an intrinsic slope change: in this case,
by fitting the XRT and IBIS data using a broken power law
absorbed by the Galactic hydrogen column, we find a spectral
steepening \( \Delta \Gamma = 0.95 \) occurring at energy \( E_{\text{break}} = 2.7 \text{ keV} \)
(Fig. 4, lower panel). Again using the F-test, we find that the
improvement significance of this spectral description over the
simple power law with Galactic absorption is 95% in this case also.

The XRT+IBIS global fit results for the three models above
are reported in Table 2. With the assumed cosmology and using
the redshift of the source, we get 2–10 keV and 20–100 keV
observer’s frame luminosities of \( 2 \times 10^{47} \text{ erg s}^{-1} \) and \( 9.9 \times
good independent of the assumed spectral model.

6. Discussion

Within our optical spectroscopy program aimed at the identifi-
cation of the nature of sources detected at high energies with
\textit{INTEGRAL} (see Masetti et al. 2006, and references therein), we
discovered that the object Swift J1656.3–3302 is a high-redshift
blazar, located at \( z = 2.40 \). This source is thus another case be-
longing to the small but growing class of distant gamma–ray
emitting blazars, which are being discovered by \textit{Swift}/BAT and
\textit{INTEGRAL}/IBIS (Sambruna et al. 2006; Sambruna et al. 2007;
Bassani et al. 2007; Bird et al. 2007). Swift J1656.3–3302 is
moreover the farthest object, among the previously unidentified
\textit{INTEGRAL} sources, whose nature has been determined a poste-
riori through optical spectroscopy.

The better optical position has allowed us to associate it with
a fairly bright NVSS radio source and with a faint \textit{ROSAT} object.
The NVSS image of the source shows that it is core-dominated
with no extended radio features. The optical R-band information
reported in Sect. 4, combined with the radio flux density, sug-
gests that \( \text{Log}(S_{1.4\text{ GHz}}/S_R) \sim 3.3 \) for this object. Although this
ratio is not conventionally used to characterize the radio loud-
ness of a source, it can nevertheless be used to quantify the
strength of the radio emission compared to the optical. In this
estimate we did not consider any contribution from the optical
extinction local to the source: to take this issue into account, we
can assume for Swift J1656.3–3302 the lower extreme in the
range of the optical-to-X-ray slopes typical for this kind of ob-
ject (e.g., Stocke et al. 1991). This gives a strict upper limit to the
R-band flux of the source, and hence a lower limit for the radio-optical flux density ratio: with this procedure, we obtain that
\( \text{Log}(S_{1.4\text{ GHz}}/S_R) > 2.5 \). In summary, the considerations
above point to the fact that Swift J1656.3–3302 is very likely to
be radio loud.

If we compare the source unabsorbed monochromatic X-ray
flux at 1 keV to the radio flux at 1.4 GHz, we find that their
ratio is around 150 or, following the notation of Giommi et al.
(2007), \( \sim 2 \times 10^{12} \text{ erg cm}^{-2} \text{ s}^{-1} \text{ Jy}^{-1} \), i.e. similar to blazars
with the inverse Compton peak in the gamma–ray band. The source is
indeed very powerful at high energies, which explains the detec-
tion by BAT and IBIS. The above properties suggest that Swift
J1656.3–3302 is a distant blazar in which the emission is rela-
tivistically beamed and with a double-peaked SED.
To verify this, we constructed the non-simultaneous SED of Swift J1656.3–3302 by combining all the available data in order to cover as many frequencies as possible (see Fig. 5). Along with the optical and X-/gamma-ray information obtained in the present work, we have used the 1.4 GHz NVSS radio flux from Condon et al. (1998), the IRAS infrared upper limits (IRAS 1988) in the mid-infrared bands (12, 25, 60 and 100 $\mu$m), the ROSAT 0.1–2.4 keV flux (Voges et al. 2000) and the upper limit at MeV energies from the EGRET survey (Hartman et al. 1999). When plotting the SED, we respectively corrected the optical and the X-ray spectra from the contribution of the foreground Galactic extinction using the $E(B-V)$ and $N_{H}$ values reported in Sects. 5 and 2, respectively. Moreover, the optical spectrum was rebinned at $\sim$60 Å to smooth out the noise of the continuum, and the most evident emission lines were removed.

Looking at the SED of this object, two things are immediately clear: (i) it is indeed double peaked as expected from a blazar; and (ii) it is typical of a powerful blazar with the synchrotron peak somewhere in the infrared range and that of the inverse Compton component just above the ISGRI band (20–100 keV). Thus, given the source luminosity, the optical/radio information and the overall SED, it is likely that Swift J1656.3–3302 belongs to the class of FSRQs. An interesting point to recall here is the fact that, as mentioned in Sect. 5, the high-energy spectrum of this source shows a deficit of soft X-ray photons. This could be produced by either an intrinsically curved shape of the spectrum itself, or absorption local to the AGN. This feature is becoming common place, rather than the exception, for high redshift blazars and it is a widely debated issue at the moment. Observations of intrinsic absorption in high redshift blazars have been reported for many objects (Page et al. 2005; Yuan et al. 2006, and references therein): the common interpretation is that this absorption originates from the material present in the AGN environment.

From the above mentioned literature there is some evidence of a correlation between absorption and redshift, with the more distant sources being more absorbed. The increase in $N_{H}$ with $z$ seems to occur starting at $z \sim 2$. Moreover, at this redshift one sees a change in the fraction of radio loud quasars showing X-ray absorption, being lower at lower $z$. Finally, there is a tendency for objects with intrinsic absorption to have systematically higher X-ray fluxes. All this evidence suggests that there may be a strong cosmic evolution effect that takes place at $z \sim 2$.

Within this scenario Swift J1656.3–3302 is quite interesting, because it has a redshift larger than 2 and also because it has a relatively high column density compared to the objects discussed by Yuan et al. (2006, see their Fig. 6).

The absorption scenario is however far from being confirmed: the fact that absorption is more often seen in radio loud objects, i.e. those which more likely host a relativistic jet, raises the question of why these jets are not able to remove the gas in their vicinity. Another problem is the apparent absence of extinction at lower energies (that is, UV and optical), if absorption is indeed present in these objects, and in particular in Swift J1656.3–3302: indeed, the shape of its optical spectrum, once corrected for the Galactic extinction, suggests a local column density which is much lower than that inferred from the X-ray data analysis (this value would imply a $V$-band rest-frame extinction $A_{V} \sim 40$ mag, assuming the Galactic extinction law). This effect may however be partly alleviated by the fact that, at high redshift, the chemical composition of the dust is substantially different from that of the Milky Way, thus producing an optical-UV extinction law radically at variance with that of our Galaxy (e.g., Calzetti et al. 1998; Maiolino et al. 2001).

An alternative interpretation for the deficit of soft photons has been put forward for blazars, i.e. that the observed shape is due to intrinsic curvature of the inverse Compton emission (Fabian et al. 2001; see also Tavecchio et al. 2007, for a recent investigation made using this model). Indeed, a low energy cutoff in the relativistic particle distribution at $\gamma_{\text{cut}}$ would produce a flattening in the scattered spectrum below $\nu_{\text{abs}} \sim \nu_{\text{ex}} \cdot \Gamma_{0}^{2} \cdot \gamma_{\text{cut}}^{2} \cdot (z+1)^{-1}$, where $\Gamma_{0}$ is the Lorentz factor, $\nu_{\text{ex}}$ the frequency of the seed photons and $z$ the redshift of the source. If $\gamma_{\text{cut}} \approx 10^{15}$ Hz, the break observed in Swift J1656.3–3302 implies, for Lorentz factors in the range 10–50, that $\gamma_{\text{cut}} \approx 10^{5}$. A different description of the source SED, again in the assumption of the intrinsic curvature hypothesis, can be made assuming a log-parabolic distribution for the emitting electrons, in the form $F(E) = K \cdot E^{-(a+b \cdot \log E)}$ (Massaro et al. 2006; Tramacere et al. 2007), where $a$ is the power law slope at 1 keV and $b$ is the curvature below this energy. As an example, in Fig. 5 we overplotted on the SED a log-parabolic distribution with $a = 0.55$ and $b = 0.6$. We however defer the detailed analysis of the intrinsic curvature of the X-ray spectrum of Swift J1656.3–3302 to a subsequent paper.

We conclude this section by briefly commenting on the spectral evolution seen when comparing the IBIS and the BAT spectra: apparently, the source X-ray spectrum steepens when it gets fainter. The observed X-ray variability in both flux and spectrum reported here for Swift J1656.3–3302 is unusual, though not unprecedented in FSRQs. Indeed, a number of other high-$z$ blazars show the same behavior, such as RX J1028.6–0844 ($z = 4.2$; Yuan et al. 2005) and GB 1412+4217 ($z = 4.7$; Worsley et al. 2006) and, in more recent studies, RBS 315 ($z = 2.7$; Tavecchio et al. 2007) and QSO 0836+710 ($z = 2.2$; Sambruna et al. 2007). This variability could be due to changes in the electron distribution at low energies, or may be a hint of the presence of an extra component, which becomes stronger or weaker as the source brightness changes.
7. Conclusions

Through optical follow-up observations we have been able to identify the newly discovered hard X-ray source Swift J1656.3–3302 with a blazar at $z = 2.4$. Spectral evolution is observed when comparing the Swift/BAT and INTEGRAL/IBIS data, with the X-ray spectrum undergoing softening when the emission becomes fainter. The source broadband X-/gamma-ray spectrum is well described by a power law of index $\Gamma \sim 1.6$. The source is extremely bright with a 20–100 keV observer’s frame luminosity of $\sim 10^{46}$ erg s$^{-1}$, assuming isotropic emission.

The source SED is typical of high luminosity blazars, as it has two peaks: the lower (synchrotron) one likely located at infrared frequencies, and the higher (inverse Compton) one positioned above a few hundred keV. The spectral curvature detected in the X-ray spectrum of the object can either be intrinsic and due to the distribution of the emitting electrons, or associated with the presence of absorption local to the source and produced by a column density of a $\sim 7 \times 10^{22}$ cm$^{-2}$, higher than that typically observed in high-$z$ blazars.

All of the observational evidence gathered so far therefore points to Swift J1656.3–3302 being another case of a distant luminous blazar selected at gamma-ray energies. It is also the farthest object, among the previously unidentified INTEGRAL sources, whose nature has been determined a posteriori through optical spectroscopy.
