ABSTRACT

Context. The largest dataset of stellar activity measurements available at present is the one obtained at the Mount Wilson Observatory, where high-precision Ca II H+K fluxes have been measured from 1966 for about 2200 stars. Since the Mg II h and k lines at $\lambda 2800 \text{ \AA}$ are formed in a similar way to the Ca II H+K emission lines, they are also good indicators of chromospheric structure. The *International Ultraviolet Explorer* (IUE) provides a large database of UV spectra in the band 1150–3350 \AA from 1978 to 1995, which can also be used to study stellar activity.

Aims. The main purpose of this study is to use the IUE spectra in the analysis of magnetic activity of main sequence F-K stars. Combining IUE observations of Mg II and optical spectroscopy of Ca II, the registry of activity of stars can be extended in time.

Methods. We retrieved all the high-resolution spectra of F, G, and K main sequence stars observed by IUE (i.e. 1623 spectra of 259 F to K dwarf stars). We obtained the continuum surface flux near the Mg II h+k lines near $\lambda 2800 \text{ \AA}$ and the Mg II line-core surface flux from the IUE spectra.

Results. We obtained a relation between the mean continuum flux near the Mg II lines with the colour $B - V$ of the star. For a set of 117 nearly simultaneous observations of Mg II and Ca II fluxes of 21 F5 to K3 main sequence stars, we obtained a colour dependent relation between the Mount Wilson Ca II S -index and the Mg II emission line-core flux. As an application of this calibration, we computed the Mount Wilson index for all the dF to dK stars which have high resolution IUE spectra. For some of the most frequently observed main sequence stars, we analysed the Mount Wilson index S from the IUE spectra, together with the ones derived from visible spectra. We confirm the cyclic chromospheric activity of ϵ Eri (HD 22049) and β Hydri (HD 2151), and we find a magnetic cycle in α Cen B (HD 128621)

1. Introduction

Stellar magnetic activity causes non-thermal heating of the outer atmospheres of cool stars. One of the principal diagnostics for solar and stellar chromospheric activity is the emission in the Ca II H and K resonance lines (at 3968 and 3934 \AA). In particular, the largest dataset of activity measurements available at present, comprising observations of over two thousands stars, is the one obtained with the Mount Wilson HK spectrophotometers, which since 1966 measure high precision Ca II H+K fluxes. As an indicator of stellar activity, an index S has been defined as the ratio between the emission line-core flux and the flux in the continuum nearby.

Since the Mg II h and k lines (at 2803 and 2796 \AA) are formed in a similar way to the Ca II H+K lines, they are also good indicators of the heating and the thermal structure of stellar atmospheres, especially from the high photosphere to the upper part of the chromospheric plateau. Furthermore, the Mg II resonance lines are more sensitive to weak chromospheric activity than the Ca II ones, because the adjacent near UV continuum is significantly weaker in the Mg II continuum and the photospheric line wings are darker at 2800 \AA .

In the solar case, the Mg II core-to-wing ratio defined by Heath & Schlesinger (1986), has become a valuable index of variability of the chromospheric radiation. For the last twenty years, solar activity has been monitored from space by many instruments (SBUV, SOLSTICE, SUSIM and GOME). These observations have provided valuable data from which the Mg II index can be derived.

In order to connect stellar and solar observations, Cerruti-Sola et al. (1992) compared IUE Mg II profiles with some *Skylab* spectra of solar regions. They showed that different Mg II emission levels observed in stars of similar spectral type are due to differing fractions of their surfaces covered by magnetic regions.

In previous studies, it was found that the radiative fluxes of the Ca II and the Mg II lines are highly correlated among themselves (Oranje & Zwaan 1985; Schrijver 1987; and Rutten et al. 1991). Using nearly simultaneous observations, Schrijver et al. (1992) derived a linear relationship between the Mg II h+k fluxes (F_{MgII}), measured using IUE¹ spectra, and the Mount Wilson Ca II H+K fluxes (F_{CaII}).

The study of chromospheric variability requires at least a decade of data to reveal variations with timescales similar to the 11 yr solar cycle. IUE provides an extensive homogeneous database of UV spectra covering the band 1150–3350 \AA , from

Fig. 1. IUE spectra of three representative stars: HD 22049 (K2V), HD 1835 (G3V) and HD 35296 (F8V). The windows used to integrate the continuum flux (2763–2778 Å and 2810–2825 Å) and the line-core emission (Mg II k: 2795.50–2797.20 Å and Mg II h: 2802.68–2804.38 Å) are marked.

1978 to 1995. The purpose of this study is to intercalibrate the Mg II and Ca II observations, to combine IUE observations of Mg II h+k and visible observations of Ca II H+K and to extend in time the registry of activity of solar-type and cooler stars.

In Sect. 2, we first analyse the UV continuum adjacent to the Mg II lines. In Sect. 3, we derive a relation to determine the Mount Wilson index from the Mg II line-core flux. Finally, in Sect. 4 we study, for several main sequence stars, the Mount Wilson indices we obtained indirectly from IUE observation, the ones published by Henry et al. (1996) from CTIO spectra and the indices obtained from CASLEO spectra.

2. UV continuum near the Mg II lines

In Fig. 1 we present some examples of the high resolution IUE spectra of three F, G and K main sequence stars. The spectra are available from the IUE public library (at <http://ines.laeff.esa.es/cgi-ines/IUEdbsMY>), and have been calibrated using the NEWSIPS (New Spectral Image Processing System) algorithm (Garhart et al. 1997). The internal accuracy of the high resolution calibration is around 4% (Cassatella et al. 2000).

The measured flux from the IUE spectra f was transformed to surface flux F using the Oranje et al. (1982) relation

$$\log(F/f) = 0.35 + 0.4(m_V + BC) + 4 \log T_{\text{eff}}, \quad (1)$$

where m_V is the visual apparent magnitude that we obtained from the *Hipparcos* and *Tycho* Catalogue (Perryman et al. 1997; Hoeg et al. 1997), BC is the bolometric correction obtained from Flower (1996) and T_{eff} is the effective temperature, from Boehm-Vitense (1981).

To analyse the UV continuum surface flux near the Mg II lines, we obtained all the high resolution spectra of F, G and K main sequence stars observed by IUE (i.e. 1623 spectra of 259 F to K dwarf stars), and we integrated the flux in two windows 15 Å wide centred at 2817.50 Å and 2770.50 Å (F_{contMgII} , Fig. 1). These windows are as wide as possible to obtain the best signal-to-noise relation, without including lines of chromospheric origin.

Fig. 2. $\log(F_{\text{contMgII}})$ vs. $B - V$ for 1623 high resolution IUE spectra of 259 stars. The solid line shows the best linear interpolation and the dashed line is the relation obtained by Rutten (1984) for the visible continuum surface flux. In the inset, we show the χ^2 contours of the 39.3% (full line) and 68.3% (dotted line) confidence levels for the two fitted parameters, assuming that they present normal distributions with mean values and standard deviations: $\bar{a} = -2.823$, $\sigma_a = 0.018$ and $\bar{b} = 9.376$, $\sigma_b = 0.013$.

In Fig. 2, the $\log(F_{\text{contMgII}})$ derived from each IUE spectrum is plotted against the colour $B - V$, from the *Hipparcos* and *Tycho* Catalogues. In our set of observations, the measured continuum flux presents a mean intrinsic variation of 30% for some stars; we will explore the source of this dispersion at the end of this section. For simplicity, we do not include the error bars in the figure. On the other hand, we neglect the errors in $B - V$ since they are very small.

For the data plotted in Fig. 2, we found a good linear regression $\log(F_{\text{contMgII}}) = b(B - V) + a$, with a correlation coefficient $R = 0.97$. The best fit is given by

$$\log(F_{\text{contMgII}}) = (-2.823 \pm 0.018)(B - V) + (9.376 \pm 0.013). \quad (2)$$

Therefore, we obtain an exponential relation between an average UV continuum surface flux and the colour $B - V$. The mean value $\langle F_{\text{contMgII}} \rangle$ and the standard deviation $\sigma_{F_{\text{contMgII}}}$ are:

$$\langle F_{\text{contMgII}} \rangle = 2.38 \times 10^9 \times 10^{-2.82(B-V)} \text{ erg cm}^{-2} \text{ s}^{-1},$$

$$\sigma_{F_{\text{contMgII}}}^2 = \langle F_{\text{contMgII}} \rangle^2 P_2(B - V),$$

$$\text{with } P_2(B - V) = [9.5 + 1.3(B - V) + 1.5(B - V)^2] \times 10^{-3}.$$

The regression in Eq. (3) is significant at nearly a 70% confidence level, which tests satisfactorily the linear fit in Fig. 2.

In contrast, Schrijver et al. (1989) assumed that the Mg II continuum surface flux has the same dependence on colour than the one obtained by Rutten (1984) for the Ca II continuum. Rutten found that the logarithm of the visible continuum surface flux was proportional to a third order polynomial on $B - V$. In Fig. 2 we represent this relation with a dashed curve. It can be seen that the linear relation we obtained fits the observations better.

To analyse whether the spread in the data in Fig. 2 could be due to a remaining colour-dependent component in the continuum flux, we plot in Fig. 3 the ratio of the UV emission F_{contMgII} to the value given by Eq. (3). The mean value of this ratio is 1.04 and the residuals present a flat distribution vs. $B - V$. We applied a Wilcoxon two-sample test (Frodesen et al. 1979) to the data plotted in Fig. 3 and we obtained that the fluctuations of the ratio $F_{\text{contMgII}}/\langle F_{\text{contMgII}} \rangle$ are within the statistical error with a

Fig. 3. The continuum surface flux F_{contMgII} normalized to the averaged surface UV continuum $\langle F_{\text{contMgII}} \rangle$ vs. $B - V$ for the 1623 high resolution IUE observations.

Fig. 4. F_{contMgII} vs. F_{MgII} , for a set of main sequence stars with $0.54 < B - V < 0.58$ (top), $0.68 < B - V < 0.72$ (middle) and $0.87 < B - V < 0.91$ (bottom).

confidence level of 90%. Therefore, we conclude that the spread in the data is not associated with a colour dependent component.

On the other hand, since the Mg II continuum is originated in the upper photosphere and the lower chromosphere of the star, it can be sensitive to activity. In fact, since the vertical spread for a specific colour $B - V$ in Fig. 3 corresponds, in most cases, to different observations of a single star, it is probably due to different levels of chromospheric activity.

To check this, in Fig. 4 we plot the continuum surface flux F_{contMgII} vs. the Mg II line-core emission F_{MgII} for three different colour bins. To integrate the Mg II line-core fluxes, we found that the best integration window in the lines for high resolution IUE spectra are two 1.70 \AA wide passbands centred at 2803.53 \AA and 2796.35 \AA (see Fig. 1). The position and the width of the integration windows were chosen to guarantee that the contribution of the integrated flux is merely chromospheric, beyond the basal contribution.

The Ca II continuum flux, used in the Mount Wilson index definition, is associated with photospheric emission and chromospheric activity is insignificant in this wavelength range. In contrast, in Fig. 4 we note that, independently from the colour, the F_{contMgII} increases with the Mg II line-core flux and, therefore, the continuum flux depends to some extent on the activity level. For this reason, we did not attempt to build an activity index as

Table 1. Stars used in the Mg II – Ca II calibration.

Stars HD	Spectral class and type	m_v	$B - V$	T_{eff} (K)

187013	F5V	4.99	0.47	6445

the ratio in the fluxes in the Mg II line-cores and the continuum, similar to the S index.

3. Mg II h+k and Ca II H+K emission index calibration

To obtain the Mount Wilson index S indirectly from the UV spectra, we analysed the relation between the Ca II index and the Mg II line-core flux. To guarantee that both diagnostics represent the same phase of activity of the star, we used 117 nearly simultaneous observations (i.e. with a time interval lower than 36 h) of Ca II and Mg II line-core surface fluxes.

These observations of 21 stars with $0.45 \leq B - V \leq 1.00$ (see Table 1) are included in the dataset used by Schrijver et al. (1992) to intercalibrate Ca II and Mg II surface fluxes. We excluded from Schrijver’s list HD 188512 due to its noisy IUE spectrum and some observations of HD 3651 where the ratio between the Mg II k to h line fluxes is greater than 1.55 (i.e. where the K/H ratio deviates in more than 2σ from the mean).

Rutten (1984) found a relation between the Ca II line-core surface flux and the Mount Wilson index S for main sequence stars with $0.30 \leq B - V \leq 1.60$

$$F_{\text{CaII}} = F_{\text{H}} + F_{\text{K}} = S C_{\text{cf}} T_{\text{eff}}^4 \times 10^{-14}, \quad (3)$$

where the conversion factor C_{cf} is given by

$$\log(C_{\text{cf}}) = 0.25(B - V)^3 - 1.33(B - V)^2 + 0.43(B - V) + 0.24,$$

and F_{H} and F_{K} are the Ca II H and K surface fluxes expressed in arbitrary units, which differ from an absolute calibrated scale by a multiplicative factor $1.29 \times 10^6 \text{ erg cm}^{-2} \text{ s}^{-1}$.

From the F_{CaII} values listed in Schrijver et al. (1992), we obtained the Mount Wilson S using Eq. (3). On the other hand, we measured the Mg II line-core flux F_{MgII} on the corresponding 117 high resolution IUE spectra. The results are shown in Fig. 5.

The main source of error in our data is the dispersion in F_{MgII} , due to the fact that there is a single value of F_{CaII} for IUE spectra differing in less than 36 h. We found that the standard

Fig. 5. S vs. F_{MgII} for three different colour bins: $B-V > 0.77$ (squares), $0.60 < B-V < 0.77$ (crosses) and $B-V < 0.60$ (triangles).

deviation of these F_{MgII} values could be up to 10%. Therefore, we used in the calibration an average of the F_{MgII} values which were assigned a single F_{CaII} and an error of 10% for F_{MgII} . Our dataset was consequently reduced to 93 points.

In Fig. 5 it can be seen that, as colour increases, the slope of the relation between the Mg II flux and the S index also increases. This could be due to different reasons: on one hand, the Mount Wilson index calculation involves the continuum flux near the Ca II lines, which of course depends on $B-V$. On the other hand, a colour dependent basal flux, independent from the activity level of the star, could also be present in the Mg II and the Ca II line-core emission. Many studies (e.g. Schrijver et al. 1989; Rutten et al. 1991) showed that the basal flux in the chromospheric lines decreases as $B-V$ increases and that the Mg II basal flux is lower than the Ca II one.

Therefore, a colour dependent $S - F_{\text{MgII}}$ calibration is needed for these data. Here, we proposed an $S - F_{\text{MgII}}$ calibration given by

$$S = a(B-V)^\alpha F_{\text{MgII}} + b, \quad (4)$$

with F_{MgII} expressed in $\text{erg cm}^{-2} \text{s}^{-1}$, and we found that the best correlation coefficient ($R = 0.95$) is obtained for $\alpha = (3.0 \pm 0.1)$. Considering the errors in both coordinates and minimizing the expression

$$\chi^2 = \sum_{i=1}^N \frac{(y_i - b - ax_i)^2}{\sigma_{y_i}^2 + a^2 \sigma_{x_i}^2}, \quad (5)$$

where $y \equiv S$ and $x \equiv F_{\text{MgII}}(B-V)^\alpha$, we obtained that the best parameters are $a = (2.310 \pm 0.052) \times 10^{-7}$ and $b = 0.109 \pm 0.004$, with a reduced $\chi^2 = 1.07$ for an uncertainty of 6% in the S values. In Fig. 6 we plot the Mount Wilson index S and the Mg II line-core surface flux corrected in colour and the best linear fit given by Eq. (4).

4. Application of the calibration

As an application of the calibration obtained in Eq. (4), we have measured the Mg II line-core flux on all the 1623 IUE high resolution spectra available for main sequence stars of spectral types F to K, and then converted the surface flux F_{MgII} to the Mount Wilson index. These results are presented in Table 3.

For several of the most observed main sequence stars, we analysed the Mount Wilson index S inferred from the IUE spectra, together with the ones obtained from CTIO spectra (Henry et al. 1996) and from CASLEO spectra with the calibration of Cincunegui et al. (2007). In this way our observations cover the period between 1978 and 2005. Even if, for most stars, the density of measurements along the years is low, we can infer the

Fig. 6. S vs. $F_{\text{MgII}}(B-V)^\alpha$ for the stars listed in Table 1. The errors are assumed to be 10% for F_{MgII} and 6% for S . The least square fit (solid line) has a correlation coefficient of 0.95. The dotted lines indicate $\pm 3\sigma$ from the fit.

Fig. 7. Data for HD 1835. We indicate the Mount Wilson index S obtained from the IUE spectra with triangles (Δ), the one obtained by Henry et al. (1996) from CTIO spectra with crosses (\times) and the one obtained from CASLEO spectra with square dots (\square).

level of activity and its variability for the whole period and during short intervals of time. For these stars, we list in Table 2 the average, maximum and minimum level of activity reached along decades (Cols. 4 and 5) and the variations recorded in particular years (Col. 6).

For those stars in Table 2 that were observed for decades and for which we have a large number of measurements, in what follows we plot the index S vs. time and we analyse their magnetic behaviour in detail.

HD 1835 – BE Ceti

As expected, the BY Dra stars (HD 1835 and HD 22049) show very strong chromospheric activity. In particular, HD 1835 (G3V) is a young star only 600 Myr old, with a rotation period of 7.78 days (see references in Table 2). Baliunas et al. (1995), studying data for the period 1966–1991, reported that it presents an activity cycle with a length of 9.1 ± 0.3 years. In Fig. 7 we show our data for this star. Unfortunately, we are not able to check this period from these data, as they are insufficient to build a periodogram and obtain a significant result. However, we can infer that the level of activity slightly increased in the period 2000–2005 with respect to the previous years. From Fig. 7 we obtain that HD 1835 reached a maximum level of activity $S_{\text{max}} = 0.354$, a minimum level $S_{\text{min}} = 0.244$ and a mean level $\langle S \rangle = 0.332$ between 1978 and 1995, while between 2000 and 2004 these values were $S_{\text{max}} = 0.389$, $S_{\text{min}} = 0.308$ and $\langle S \rangle = 0.347$.

HD 22049 – ϵ Eri

HD 22049 (ϵ Eri, K2V) is a young and chromospherically active star \sim 0.8 Gyr old with a rotation period of 11.28 days (see references in Table 2). Baliunas et al. (1995) reported that HD 22049 is a variable star without an evident cyclic behaviour, but Gray & Baliunas (1995) reported an underlying magnetic cycle with a period of the order of 5 years from 1986 to 1992. Hall et al. (2007) found that ϵ Eri is a high-activity variable star with a mean level of activity given by $\langle S \rangle = 0.516$ between 1994 and 2005. From our data, we obtained a $\langle S \rangle = 0.479$ for this time interval, which coincides with Hall et al.’s results within the statistical error.

In Fig. 8 we show our data for this star, where we observe appreciable short-scale (\sim months) variations from 10% to 25%.

For our time interval (1978–2004), we analysed the mean annual $\langle S \rangle$ as a function of time with the Lomb-Scargle periodogram (Scargle 1982; Horne & Baliunas 1986), using the algorithm given by Press et al. (1992). This periodogram is shown in Fig. 9a, where it can be seen that there is, indeed, a peak at 1788 days (\sim 4.9 years), with a false alarm probability (FAP)

Fig. 8. Data for HD 22049. Symbols as in Fig. 7.

of 22%. In Fig. 9b, we plot the mean annual $\langle S \rangle$ phased with the period obtained (1788 days) and we found that an harmonic function fits these points with a 60% confidence level.

HD 10700 – τ Ceti

HD 10700 (τ Ceti, G8V) is an old slow rotator (see Table 2), known to be rather constant in activity (Gray & Baliunas 1994).

Fig. 9. HD 22049. *Left:* Lomb-Scargle periodogram of the mean annual $\langle S \rangle$ of the data plotted in Fig. 8. The False Alarm Probability (FAP) levels of 30, 50 and 70% are indicated. *Right:* the mean annual $\langle S \rangle$ of the data plotted in Fig. 8 phased with the period of 1788 days. The solid line shows the harmonic curve that best fits the data with a 60% confidence level and the dashed lines indicate the points that apart $\pm 3\sigma$ from that fit.

Fig. 10. Data for HD 10700. Symbols as in Fig. 7.

In particular, [Baliunas et al. \(1995\)](#) analysed the Mount Wilson index from 1966 to 1991, and found that the chromospheric activity of this star is almost flat with a mean $\langle S \rangle = 0.171$. They proposed that it could be in a magnetic phase analogous to the solar Maunder minimum. They also found that HD 10700 is possibly increasing its level of activity since 1989.

[Judge et al. \(2004\)](#) compared solar UV spectra with several STIS spectra of HD 10700 from *Hubble Space Telescope* obtained in August, 2000, and concluded that its line spectrum may represent a solar spectrum corresponding to the Maunder minimum. On the other hand, they also found evidence of a weak magnetic field in HD 10700. Therefore, [Judge et al. \(2004\)](#) proposed that this star has temporally slipped into an extended magnetic quiescence (like the solar Maunder minimum) and has only occasional active regions because of a small-scale turbulent dynamo.

From the few data plotted in Fig. 10, we observe that the mean level of activity of HD 10700 seems to increase in 2001. In particular we obtained a mean $\langle S \rangle = 0.172 \pm 0.001$ between 1978 and 1995, in agreement with the value given by [Baliunas et al. \(1995\)](#), and $\langle S \rangle = 0.176 \pm 0.003$ between 2001 and 2005. We also note a $\sim 10\%$ variation from maximum to minimum between the end of 2001 and 2002, which could be attributed to faint magnetic events.

In summary, we find that HD 10700 could have increased its level of activity since 2001, and that its chromospheric variability in the period 2001–2005 is also appreciable. Therefore, our results are in agreement with the model proposed by [Judge et al. \(2004\)](#) of an underlying turbulent dynamo responsible for the few signs of magnetic activity in this star.

Fig. 11. Data for HD 2151 (β Hyi). Symbols as in Fig. 7.

Fig. 12. HD 2151 (β Hyi). *Left:* Lomb-Scargle periodogram of the mean annual $\langle S \rangle$ in Fig. 11. The False Alarm Probability levels of 40 to 80% are indicated. *Right:* the mean annual $\langle S \rangle$ of the data plotted in Fig. 11 phased with the period of 4117 days. The solid line represents the harmonic curve that best fits the data with a good confidence level and the dashed lines indicate the points that apart $\pm 3\sigma$ from that fit.

HD 2151 – β Hyi

[Dravins et al. \(1993\)](#) affirm that HD 2151 (β Hyi, G2IV) can be considered an evolved Sun, with a well-determined age of ~ 6.7 Gyr ([Dravins et al. 1998](#)), and a magnetic activity cycle probably longer than the solar one (15–18 years). In Fig. 11 we plot our data for this star. With these data, we obtain a mean chromospheric variation of 22% from 1978 to 1995. On the other hand, the short-scale variations registered in 1985, 1993 and 1994 do not exceed 17%.

To explore the magnetic behaviour of this star, we analysed the mean annual $\langle S \rangle$ with the Lomb-Scargle algorithm, and we obtained a cyclic behaviour with a period of 4117 days (~ 11.28 years), with a FAP of 35%. The periodogram is plotted in Fig. 12a. In Fig. 12b we show the mean annual $\langle S \rangle$ phased with this period and the harmonic curve that best fits the data with a good confidence level of 50%. Recently, [Metcalf et al. \(2007\)](#) also obtained a ~ 12 year-magnetic activity cycle for HD 2151 by analysing a Mg II index derived from the same IUE data plotted on Fig. 11 and they also found a faint correlation between this activity cycle and asteroseismic observations.

HD 128620 – α Cen A

The non-interactive 79.2 yr binary system α Centauri is composed by the G2V star HD 128620 (α Cen A) and the K1V star HD 128621 (α Cen B), with a relative distance of 23.50 AU ([Kamper & Wesselink 1978](#)). Both stars have different levels of activity. From 1978 to 2004, HD 128620 presented a mean annual index $\langle S \rangle = 0.167$ while HD 128621 presented $\langle S \rangle = 0.214$.

α Cen A is considered a good solar-twin (G2V, $\sim 1.09 M_{\odot}$, solar abundances). In particular, [Cerruti-Sola et al. \(1992\)](#) reported that it has a UV spectrum similar to the inactive Sun, and

Fig. 13. Data for HD 128620. Symbols as in Fig. 7.

Fig. 14. Data for HD 128621. Symbols as in Fig. 7.

Judge et al. (2004) concluded that HD 128620 provides a good proxy for the Sun's UV spectrum during an intermediate phase of the solar activity cycle. From our data, which is plotted in Fig. 13, we found that the mean annual $\langle S \rangle$ presented an 11% variation along 16 years (1978–2004), which is in agreement with the analogy of HD 128620 with a Sun of moderate activity. However, in Table 2 we observe an appreciable short-scale chromospheric variation ($\sim 44\%$) in the index S during 1995, much larger than what is observed in the Sun. Therefore, HD 128620 probably presents larger chromospheric features than the Sun.

Recently, Robrade et al. (2005) found that HD 128620 has decreased its X-ray flux by at least an order of magnitude during their observation program (from March 2003 to February 2005), and they attributed this variation to an irregular event or an unknown coronal activity cycle. To search for a magnetic cycle analogous to the solar one, we analysed the mean annual $\langle S \rangle$ of the data plotted in Fig. 13 with the Lomb-Scargle periodogram, but we did not find a periodic behaviour.

HD 128621 – α Cen B

From ROSAT observations, Schmitt & Liefke (2004) reported HD 128621 as a flare star as it presented variations of nearly 30% in its X-ray emission during 20 days in August 1996. The data for this star are shown in Fig. 14, where it can be seen that, during 1995, it presented a chromospheric variation close to 75%, which could be attributed to a flare-like process. However, the light-curve for this event, which is shown in Fig. 15, does not present the typical characteristics of flares.

To study if this variation is due to rotational modulation, we analysed the data in Fig. 15 with the Lomb-Scargle periodogram and we obtained a period of 35.1 days, similar to the values that can be found in the literature for the rotation period. In particular, Saar & Osten (1997) estimated a rotation period of 42 days for HD 128621, while Jay et al. (1997) obtained a value of ~ 37 days. Therefore, the variation found in Fig. 15 is probably due to rotation, for which we obtain a period of 35.1 days.

To analyse the magnetic behaviour of HD 128621, we studied the mean annual $\langle S \rangle$ of the data plotted in Fig. 14 with the Lomb-Scargle periodogram, shown in Fig. 16a. We obtained a

Fig. 15. Detail of Fig. 14 in 1995, showing a 35 day-modulation in the light-curve.

Fig. 16. HD 128621. *Left*: Lomb-Scargle periodogram of the mean annual $\langle S \rangle$ in Fig. 14. The False Alarm Probability levels of 30, 50 and 80% are indicated. *Right*: the mean annual $\langle S \rangle$ of the data plotted in Fig. 14 phased with the period of 3061 days. The solid line represents the harmonic curve that best fits the data with an 80% confidence level and the dashed lines indicate the points that apart $\pm 3\sigma$ from that fit.

Fig. 17. Data for HD 131156A. Symbols as in Fig. 7.

magnetic cycle with a period of 3061 days (~ 8.38 years) with a FAP of 24%. In Fig. 16b, we also show the $\langle S \rangle$ phased with this period and the harmonic curve that best fits these points with a confidence level of 80%. The point for $\langle S \rangle \sim 0.16$, which significantly deviates from the harmonic curve, corresponds to the only registry of activity we have for the year 2000 and it is, therefore, not statistically representative of the mean annual activity.

Our results are consistent with the decline in X-ray luminosity after 2005 reported by Robrade et al. (2007).

HD 131156 A – ξ Boo

HD 131156A is another flare star, which belongs to the visual binary system ξ Boo. It presented chromospheric variations of 55% during 1982 and of 90% during 1978. Baliunas et al. (1995) reported that HD 131156A is a variable star without any evident cyclic behaviour. We analysed the mean annual $\langle S \rangle$ of the data plotted in Fig. 17 with the Lomb-Scargle periodogram, but we did not obtain a significant period. Baliunas et al. (1995) reported an $\langle S \rangle = 0.461$ between 1966 to 1993 and we found an $\langle S \rangle$ 7% lower from 1978 to 1994 (Table 2). These values are similar within the standard deviation, a fact which supports our calibration.

5. Summary and conclusions

The main purpose of this work is to incorporate the UV spectroscopic observations available in the IUE archives, and, in particular, using the Mg II h and k lines, to the systematic studies of magnetic activity in solar-type stars. This allows us to extend the temporal span covered with these studies.

First, we analysed the ultraviolet continuum flux near the Mg II lines, and we obtained a relation between the mean UV continuum flux and the colour $B - V$ of the star. We also found that there is an activity component in this continuum flux. Therefore, an activity index constructed as the ratio of the fluxes in the Mg II line-cores and the continuum, similar to the Mount Wilson S -index, is not the best tool for the analysis of chromospheric activity, since part of the activity-related signal cancels out.

Subsequently, we analysed the relation between the Mount Wilson index and the Mg II line-core fluxes for a set of 117 nearly simultaneous observations of Mg II and Ca II fluxes of 21 F5 to K3 main sequence stars. We obtained that the relation between the Mount Wilson S -index and the Mg II fluxes depends on the stellar colour (i.e. spectral type), and we found the relation between the index S and the Mg II line-core flux and the stars's $B - V$.

From this calibration, we computed the Mount Wilson S -index for all high resolution IUE spectra of F, G and K main sequence stars, totaling 1623 spectra of 259 stars.

To study the evolution of activity levels for the most observed stars, we used these indices together with the Mount Wilson indices derived from several spectra in the visible wavelength range, obtained at CTIO (Henry et al. 1996) and at CASLEO (Cincunegui et al. 2007). In this way the data cover the period between 1978 and 2005.

For the most frequently observed stars of this sample, we analysed the level of activity over decades of time and also studied the short-scale variations. In particular, we analysed the data of each star with the Lomb-Scargle periodogram searching for periodic patterns analogous to the solar cycle. We confirmed that HD 22049 (ϵ Eri, K2V) and HD 2151 (β Hydri, G2IV) present chromospheric activity cycles of ~ 5 and ~ 12 years, respectively. We also found evidence of an activity cycle for HD 128621 (α Cen B, K1V), with a period of ~ 8 years, which, to our knowledge, has not been reported in the literature. In particular, from our registry of activity, we obtained a rotation period of ~ 35 days for HD 128621, similar to the one reported by Jay et al. (1997). On the other hand, we did not find a cyclic pattern in the periodogram of its companion HD 128620 (α Cen A, G2V).
