ABSTRACT

We investigate the dynamical evolution of the terrestrial planets during the planetesimal-driven migration of the giant planets. A basic assumption of this work is that giant planet migration occurred after the completion of terrestrial planet formation, such as in the models that link the former to the origin of the late heavy bombardment. The divergent migration of Jupiter and Saturn causes the g_5 eigenfrequency to cross resonances of the form $g_5 = g_k$ with k ranging from 1 to 4. Consequently these secular resonances cause large-amplitude responses in the eccentricities of the terrestrial planets if the amplitude of the g_5 mode in Jupiter is similar to the current one. We show that the resonances $g_5 = g_4$ and $g_5 = g_3$ do not pose a problem if Jupiter and Saturn have a fast approach and departure from their mutual 2:1 mean motion resonance. On the other hand, the resonance crossings $g_5 = g_2$ and $g_5 = g_1$ are more of a concern: they tend to yield a terrestrial system incompatible with the current one, with amplitudes of the g_1 and g_2 modes that are too large. We offer two solutions to this problem. The first solution states that a secular resonance crossing can also damp the amplitude of a Fourier mode if the latter is large originally. We show that the probability of the $g_5 = g_2$ resonance damping a primordially excited g_2 mode in the Earth and Venus is approximately 8%. Using the same mechanism to also ensure that the $g_5 = g_1$ resonance keeps the amplitude of the g_1 mode in Mercury within 0.4 reduces the overall probability to approximately 5%. However, these numbers may change for different initial excitations and migration speeds of the giant planets. A second scenario involves a "jumping Jupiter" in which encounters between an ice giant and Jupiter, without ejection of the former, cause the latter to migrate away from Saturn much faster than if migration is driven solely by encounters with planetesimals. In this case, the $g_5 = g_2$ and $g_5 = g_1$ resonances can be jumped over, or occur very briefly. We show that, in this case, the terrestrial system can have dynamical properties comparable to what is exhibited today. In the framework of the Nice model, we estimate that the probability that Jupiter had this kind of evolution is approximately 6%.

Key words. solar system: formation – planets and satellites: formation

1. Introduction

In this paper we continue our effort to understand the origin of the orbital architecture of the planets of the solar system. In a previous work (Morbidelli et al. 2009), which is henceforth called Paper I, we analysed the secular architecture of the outer solar system and concluded that, in addition to radial migration, encounters between Saturn and one of the ice giants needed to have occurred in order to explain the current properties of the secular dynamics of the outer solar system. Here we investigate the orbital evolution of the terrestrial planets during the changes that occurred in the outer solar system.

A prerequisite for this study is a discussion of whether or not the terrestrial planets existed at the time the giant planets changed their orbital architecture. According to our best models (Chambers & Wetherill 1998; Agnor et al. 1999; Chambers 2001; Raymond et al. 2004, 2005, 2006, 2007; O'Brien et al. 2006; Kenyon & Bromley 2006), the terrestrial planets formed by collisions among a population of intermediate objects called planetary embryos, with masses of the order of $0.01-0.1$ Earth masses. This process should have lasted several tens of millions to a hundred million years, in agreement with modern results from the analysis of radioactive chronometers (Touboul et al. 2007; Allègre et al. 2008). In contrast, the giant planets had to

have formed in a *few* million years; otherwise, they could not have trapped the gas from the primordial solar nebula, which typically disappears on this timescale (e.g. Haisch et al. 2001). Once triggered, the migration and the other changes in the orbital structure of the giant planets typically take a few tens of million years (Gomes et al. 2004). Putting all these timescales together, it is legitimate to think that, by the time the terrestrial planets had completed their formation, the giant planets were already on their current orbits. If this is indeed the case, then there is no object for the present study.

However, there is an emerging view that the re-organisation of the orbital structure of the giant planets might have had a delayed start (Gomes et al. 2005; Strom et al. 2005; see also Levison et al. 2001) and therefore it might have postdated the formation of the terrestrial planets. The reason to think so is that the terrestrial planets underwent a late heavy bombardment (LHB) of small bodies. The temporal evolution of this bombardment is still the subject of debate (see for instance Hartman et al. 2000, for a review), but the majority of the evidence points to a cataclysmic nature of the LHB, i.e. to a spike in the cratering rate occurring approximately 3.85 Gyr ago (e.g. Ryder et al. 2000) i.e. approximately 600 Myr after terrestrial planet formation. If this is true, then something "major" had to happen in the solar system at that time, and the late change in the orbital

structure of the giant planets seems to be a plausible explanation (although, see Chambers, 2007, for an alternative scenario that does not involve a change in the giant planets' orbits).

The study of the evolution of the terrestrial planets during the putative changes of the giant planets' orbits is therefore a key to unveiling the real evolution of the solar system. For instance, if we find that the current orbital architecture of the terrestrial planets is incompatible with giant planet migration, then explanations of the LHB based on a late migration of Jupiter and Saturn (Gomes et al. 2005; Strom et al. 2005) should be rejected. If, on the contrary, we find that some giant planet evolutions, consistent with the constraints of Paper I, are also consistent with the current architecture of the terrestrial planets, then we have made another important step towards building a coherent and consistent scenario of the dynamical history of the solar system. This is precisely the purpose of the present paper.

In the next section, we explain the challenges set by the migration and the orbital excitation of the giant planets on the stability of the terrestrial planets. Then, in Sect. 3 we look in detail at the evolution of the Earth-Venus couple and of Mercury and how their current secular dynamics could be achieved or preserved. Section 4 is devoted to Mars. Section 5 will briefly discuss the evolution of the inclinations. Finally, Sect. 6 is devoted to the discussion of the relative timing of giant planets' migration versus terrestrial planets' formation. The conclusions in light of our results are presented there as well.

2. Giant planet migration and the evolution of the terrestrial planets

2.1. Overview

The evolution of the eccentricities and longitudes of perihelia of the four terrestrial planets can be described, in first approximation, by the Lagrange-Laplace solution of the secular equations of motion (see Chapter 7 in Murray & Dermott 1999):

$$e_i \cos \varpi_i = \sum_k M_{i,k} \cos \alpha_k$$
$$e_i \sin \varpi_i = \sum_k M_{i,k} \sin \alpha_k, \quad (1)$$

where the index i refers to the planet in consideration and k ranges from 1 to 8 with $\alpha_k = g_k t + \beta_k$. The g_k are called proper frequencies of the secular perihelion-eccentricity motion of the planets. The frequencies g_5 to g_8 are those characterising the system of the giant planets from Jupiter to Neptune; they appear also in the equations describing the evolution of the terrestrial planets because the latter are perturbed by the former. In reality, the amplitudes of the terms corresponding to g_6, g_7 and g_8 are very small in the terrestrial planets and can be neglected to first approximation. However, this is not the case for the terms corresponding to g_5. The frequencies g_1 to g_4 are proper of the terrestrial planets. Table 1 reports the current values of g_1 to g_5 and Table 2 gives the coefficients $M_{i,j}$ with non-negligible amplitude in Eq. (1). The coefficients of the terms with frequencies g_6 to g_8 are omitted because their amplitudes are much smaller than the ones given here. Data for both tables are taken from Laskar (1990) and Morbidelli (2002). As one sees from Table 1, the frequencies g_1 to g_4 can be partitioned into two groups: g_1 and g_2 are low, approximately $5-7''/\text{yr}^{-1}$, but nevertheless they are higher than the current value of g_5; on the other hand, g_3 and g_4 are much higher than g_1, g_2 or g_5, and are approximately $17-18''/\text{yr}^{-1}$.

Table 1. Frequencies and phases for Mercury to Jupiter on their current orbits.

Frequency	Value (″/yr)	β (°)
g_1	5.60	112.08
g_2	7.46	200.51
g_3	17.35	305.12
g_4	17.92	335.38
g_5	4.26	30.65

Table 2. Coefficients $M_{j,k}$ of the Lagrange-Laplace solution for the terrestrial planets.

$j \backslash k$	1	2	3	4	5
1	0.1854	−0.0277	0.0015	−0.00143	0.0363
2	0.0067	0.0207	−0.0117	0.0135	0.0196
3	0.0042	0.0161	0.00941	−0.0132	0.0189
4	0.0007	0.00291	0.0401	0.0490	0.0203

Notice that, because the terrestrial planets exhibit weakly chaotic dynamics (Laskar 1990), the frequencies g_1 to g_4 and their amplitudes and corresponding phases are not constant with time. The changes are particularly relevant for the frequency g_1. Thus, Tables 1 and 2 should be considered as indicative, and only reflect the current dynamics. Their values might have been different in the past, even since the giant planets achieved their current orbital configuration. Consequently, the maximal eccentricities that the planets attain during their secular oscillation could change over time. For instance, the current maximal eccentricity of Venus is 0.072 (as it can be seen by adding together the absolute values of the coefficients of the second line in Table 2). However, over the last 4 Gyr, the eccentricity of Venus had a 10% probability to exceed 0.09; similarly, with the same probability the eccentricity of Mercury could have exceeded 0.4, that of the Earth 0.08 and that of Mars 0.17 (Laskar 2008). Correia & Laskar (2004) argued that some time in the past the eccentricity of Mercury had to be greater than 0.325 to allow it to be captured in its 3:2 spin-orbit resonance. As Mercury should have been in synchronous rotation before the formation of the Caloris basin (Wieczorek et al. 2009), one of the latest big impact events recorded on Mercury, this high-eccentricity phase should have occurred after the LHB.

2.2. Evolution of g_5 and its implications

When Jupiter was closer to Saturn, the value of the g_5 frequency had to be higher than it is today. Figure 1 shows the value of g_5 as a function of the orbital period ratio between Saturn and Jupiter (P_S/P_J). The values of g_5 have been obtained by numerical Fourier analysis of the outputs of a sequence of 1 Myr integrations of the Jupiter-Saturn pair. The two planets were migrated from just outside their 3:2 mean motion resonance to a final, pre-determined period ratio, and subsequently the end result of that migration run was integrated for 1 Myr to obtain the Fourier spectrum.

If the period ratio between Saturn and Jupiter had evolved from $P_S/P_J \lesssim 2.15$ to its current value, at least the secular resonances $g_5 = g_2$ and $g_5 = g_1$ had to be crossed at some time, as one can see from the figure. This effect has already been pointed out by Agnor (2005) and Agnor & Lin (2007). For reference, the minimal amplitude of planet migration deduced by Malhotra (1995) from the analysis of the Kuiper belt sets the initial P_S/P_J equal to ~2.05; Minton & Malhotra (2009) in their
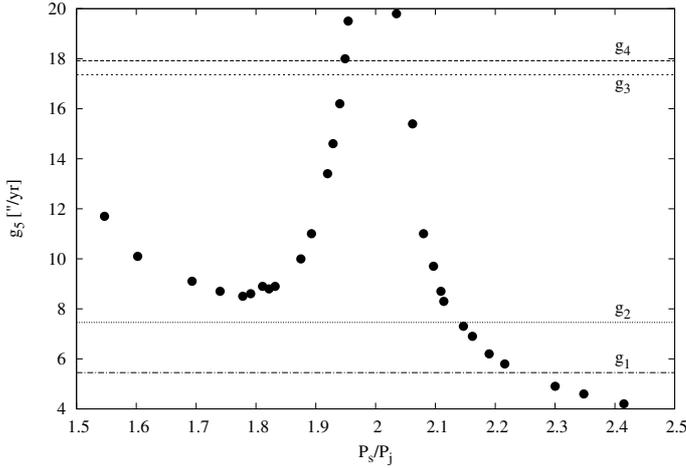

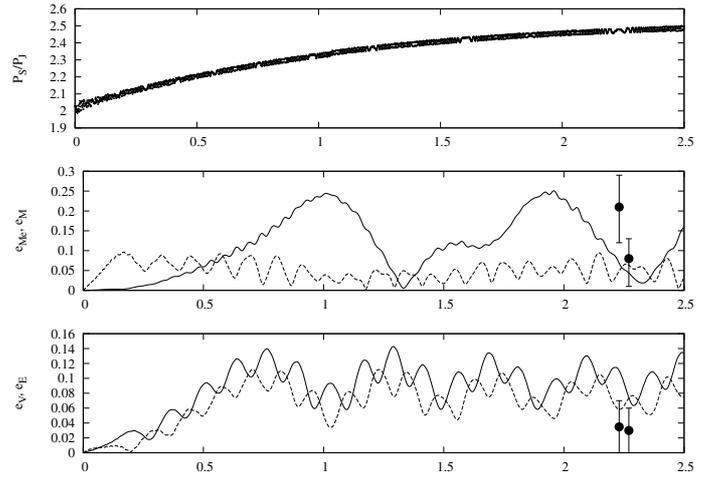

Fig. 1. The frequency g_5 as a function of P_S/P_J. The horizontal lines denote, *from top to bottom*, the values of g_4, g_3, g_2 and g_1.

Fig. 2. Evolution of the terrestrial planets during the $g_5 = g_2$ and $g_5 = g_1$ resonance crossings. *The top panel* shows the evolution of P_S/P_J. *The middle panel* shows the evolution of the eccentricities of Mercury (solid) and Mars (dashed). *The bottom panel* shows the eccentricities of Venus (solid) and Earth (dashed). The solid circles, accompanied by vertical bars, represent the range of variation of the respective planetary element, as given by a 10 Myr simulation of the current solar system (data taken from Laskar 1988).

recent analysis of the evolution of the asteroid belt, also adopted this initial orbital period ratio. Figure 1 shows that the g_5 frequency increases when Jupiter and Saturn are closer to their mutual 2:1 resonance ($P_S/P_J = 2$). This effect is well known and is caused by the divergence of the quadratic terms in the masses of the two planets, which are generated when the equations of motion are averaged over the orbital periods (see for instance Knežević et al. 1991). As a consequence, if Jupiter passed through or was originally close to the 2:1 resonance with Saturn, as in the Nice model (Tsiganis et al. 2005; Gomes et al. 2005; Morbidelli et al. 2007) or in the scenario of Thommes et al. (2007), also the secular resonances $g_5 = g_4$ and $g_5 = g_3$ had to be crossed.

A secular resonance crossing can significantly modify the amplitudes of the proper modes in the Lagrange-Laplace solution, i.e. the $M_{i,k}$'s. In fact, the Lagrange-Laplace solution of the secular dynamics is only a good approximation of the secular motion when the planets are far away from secular or mean motion resonances. Thus, if the system passes through a resonance $g_5 = g_k$, the terrestrial planets follow a Lagrange-Laplace solution before the resonance crossing and another Lagrange-Laplace solution after the resonance crossing, with the two solutions differing mostly in the amplitudes $M_{i,k}$ of the terms with corresponding frequencies g_k. Thus, the crucial question is: are the current amplitudes of the g_1 to g_4 terms in the terrestrial planets (i.e. the M coefficients in Table 2) compatible with secular resonance crossings having occurred?

As a demonstration of the effect of secular resonances sweeping through the terrestrial planets system during the migration of Jupiter and Saturn, we performed a simple experiment: Mercury, Venus, Earth and Mars were placed on orbits with their current semi-major axes and inclinations, but with initial eccentricities equal to zero. Jupiter and Saturn were forced to migrate smoothly from $P_S/P_J \sim 2.03$ to their current orbits (Fig. 2, top), so that g_5 sweeps through the g_4-g_1 range (see Fig. 1). Migration is enacted using the technique discussed in Paper I, with a characteristic e-folding timescale $\tau = 1$ Myr, which is somewhat faster than the fastest time found in Tsiganis et al. (2005). The initial eccentricities and longitudes of perihelion of the giant planets were chosen so that the amplitude of the g_5 term in Jupiter was close to the current one. We refer the reader to Paper I as to why this is a valid choice.

Unlike in Paper I, in all the simulations presented in this work, we included in the equations of motion the terms resulting from the additional potential

$$V_{GR} = -3\left(\frac{\mathcal{G}M_\odot}{c}\right)^2 \frac{a(1-e^2)}{r^3}, \qquad (2)$$

where $M_\odot$ is the mass of the Sun, $\mathcal{G}$ is the gravitational constant, c is the speed of light and r is the heliocentric distance. This was done to mimic the effect of General Relativity. Indeed, averaging the potential over the mean anomaly and computing the change in the longitude of pericentre yields

$$\langle \dot{\varpi}_{GR} \rangle = 3\frac{\mathcal{G}M_\odot}{c^2} \frac{n}{a(1-e^2)} = 0.0383 \left(\frac{1\,\text{AU}}{a}\right)^{5/2} \frac{1}{1-e^2} \,''/yr, \quad (3)$$

in accordance with Nobili & Will (1986). This potential term yields a precession rate of the longitude of perihelion of Mercury of 0.43″/yr. A more complex post-Newtonian treatment of General Relativity is possible (see for instance Saha & Tremaine 1994), but the additional terms account for short periodic effects or secular changes in the mean motions of the planets, so they are not important in our case. Conversely in the current solar system, accounting for Eq. (2) is important because it increases g_1 so that it is further away from the current value of g_5 (and hence from the asymptotic value of g_5 in a migration simulation like ours), which helps in stabilising the motion of Mercury (Laskar 2008).

Returning to Fig. 2 we see that Mercury's eccentricity reaches 0.25 (solid line; middle panel), which is consistent with its current orbit. The current mean value and range in eccentricity of Mercury is displayed by the first, higher bullet with error bars. We should stress that some other simulations, with a similar set up to this one, led to an eccentricity of Mercury exceeding 0.5. Mars' eccentricity (dashed line; middle panel) is excited up to 0.1 very early in the simulation and then oscillates in the 0−0.1 range i.e. slightly smaller in reality (depicted by the second, lower bullet with error bars). Alternatively, Venus acquires a mean eccentricity around 0.1, with a maximal value as large

as 0.14 (bottom panel; solid line), while the maximal eccentricity of the Earth exceeds 0.1 (bottom panel; dashed line). Thus, the Earth and Venus become significantly more eccentric than they are, or can be, in the current solar system (Laskar 2008).

The reason for this behaviour is that the amplitudes corresponding to the g_1 and g_2 frequencies have been strongly excited in Mercury, Venus and Earth by the passage through a resonance with the g_5 frequency. Similarly, the g_4 mode in Mars is excited very early on by the same mechanism. A Fourier analysis done on a 4 Myr continuation of the simulation, with Jupiter and Saturn on non-migrating orbits, reveals that the amplitude of the g_2 term in Venus is about 0.1, i.e. five times larger than the current value. The amplitude of the g_1 term in Mercury is also ~0.1, which is less than its current value. The evolution of Mercury, though, is not only influenced very strongly by Jupiter, but also by Venus. Thus, the amount by which the g_1 term is excited is very sensitive to the phase that the g_2 term has in Mercury when the $g_5 = g_1$ resonance occurs. Consequently, it is very easy to excite the amplitude of the g_1 mode in Mercury to a much greater value by slightly changing the set-up of the simulation so that the time at which the resonance occurs is somewhat different. In addition, if the terrestrial planets are started on co-planar orbits, g_1 is faster and therefore closer to g_2 and consequently the g_1 term is excited more easily because of a quasi-resonance between g_1 and g_2. Conversely, since g_5 passes very quickly through the values of g_4 and g_3, the amplitudes of the corresponding terms in Mars and the Earth are only moderately excited (0.015 for g_3 and 0.04 for g_4 in Mars). Since the final amplitude of the g_2 term is much larger than that of the g_3 term, the Earth and Venus are in apsidal libration around 0°, as explained in Paper I.

Thus, this simulation shows that, at least in the case of a fast migration (see Sect. 4), the $g_5 = g_4$ and $g_5 = g_3$ resonances are not a severe problem. But the $g_5 = g_2$ and $g_5 = g_1$ resonances, occurring towards the end of the migration, are a more serious concern for reconstructing the current secular architecture of the terrestrial planets. For a fast migration speed the excitation of the g_2 mode is a linear function of the migration timescale, τ[1]. Consequently, given that with $\tau = 1$ Myr the amplitude of the g_2 term approximately 0.1, achieving the current excitation would require $\tau = 0.2$ Myr. This value of τ is unrealistic for planetesimal-driven migration of the giant planets. For example, in the preferred case of Hahn & Malhotra (1999), in which planet migration is driven by a 50 $M_\oplus$ planetesimal disc, it takes more than 30 Myr for the planets to reach their current orbits. Assuming an exponential fit to the migration and allowing the migration to be essentially finished after 3 e-folding times, will yield $\tau \sim 10$ Myr. A similar result can be found in Gomes et al. (2004). The Nice model is the scenario in which the fastest migration is allowed because the entire planetesimal disc is destabilised at once. Even in this model, the shortest possible e-folding time measured is $\tau \approx 4$ Myr (Tsiganis et al. 2005; Morbidelli et al. 2005).

The above analysis implies that the current orbital architecture of the terrestrial planets is incompatible with a late migration of the giant planets. However, this may not be the ultimate answer. In fact, it might be possible that the eccentricities of the terrestrial planets had been damped after the secular resonance sweeping, due to dynamical friction exerted by the planetesimals scattered by the giant planets during their migration. Moreover, as shown in Paper I, the evolution of the giant planets was not simply a smooth radial migration, as in the simulation we just

presented. Potentially, the excitation of the g_5 mode might have happened late, relative to the $g_5 = g_2$ and $g_5 = g_1$ crossings. Moreover, encounters had to have happened among the gas giants and the ice giants (see Paper I), so that the radial migration of Jupiter and Saturn might not have been smooth. Also, unlike the giant planets, the terrestrial planets might not have formed on circular orbits. As we reviewed in the Introduction, the terrestrial planets formed by collisions among massive planetary embryos. As a result of collisions and encounters among massive bodies, the final orbits might have been relatively eccentric. The early simulations of this process (e.g. Chambers 1999) predicted that the orbits of the terrestrial planets were ~5 times more eccentric than the current ones when their accretion ended. More modern simulations (e.g. O'Brien et al. 2006), accounting for dynamical friction, succeed in producing terrestrial planets on orbits whose eccentricities and inclinations are *comparable* to the current values. But nothing guarantees that they had to be the *same* as now, as well as nothing indicates that they had to be *zero*. The initial orbital excitation might have been somewhat smaller than now or even greater, probably within a factor of ~2−3. This opens a new degree of freedom to be explored while addressing the effects of secular resonance sweeping.

Below, we will consider all these caveats, while analysing in detail each secular resonance crossing.

3. The $g_5 = g_1$ and $g_5 = g_2$ resonance crossings

In this section we discuss possibilities to alleviate or circumvent the effects of the secular resonances between the fundamental frequencies of the perihelion of Jupiter (g_5) and those of Venus (g_2) and Mercury (g_1). We discuss these two resonances together, because g_2 and g_1 have similar values and consequently these resonances both occur during the same phase of Jupiter's evolution. Below, we discuss in sequence four potential mechanisms: (i) the terrestrial planets' eccentricities were damped due to dynamical friction after being excited by the resonance crossing; (ii) the amplitude of the g_5 mode in Jupiter, $M_{5,5}$, was pumped after the secular resonances were crossed; (iii) the amplitudes of the g_1 and g_2 modes where larger originally, and they were damped *down* by the secular resonance crossings; (iv) Jupiter and Saturn migrated discontinuously, with jumps in semi-major axes due to encounters with a Uranus-mass planet, so that the $g_5 = g_1$ and $g_5 = g_2$ resonances occurred very briefly or did not occur at all.

3.1. Dynamical friction on the terrestrial planets

It might be possible that the eccentricities of the terrestrial planets evolved as in the simulation of Fig. 2, but were then subsequently decreased due to dynamical friction, exerted by the large flux of planetesimals scattered by the giant planets from the outer disc. In all models (Hahn & Malhotra 1999; Gomes et al. 2004; Tsiganis et al. 2005) the mass of the planetesimal disc driving giant planet migration was 30−50 $M_\oplus$. About a third of the planetesimals acquired orbits typical of Jupiter family comets (JFCs; perihelion distance $q < 2.5$ AU) some time during their evolution (Levison & Duncan 1997), corresponding to 10−16 $M_\oplus$. The other planetesimals remained too far from the terrestrial planets to have any influence on them. Given that the $g_5 = g_2$ and $g_5 = g_1$ resonances occurred when approximately 2/3 of the full migration of Jupiter and Saturn was completed (see Fig. 1), the total amount of mass of the planetesimals on JFC orbits that could exert some dynamical friction on the terrestrial planets after their excitation was about 3−5 $M_\oplus$.

---

[1] We have verified this in our simulations.

We investigated the magnitude of this dynamical friction in a follow-up simulation of that presented in Fig. 2. A population of 2000 massive objects – with a total mass of 3.5 $M_\oplus$ – was added on orbits representative of the steady state orbital distribution of JFCs (Levison & Duncan 1997) and the simulation was continued for 1 Myr. During that time ~85% of the JFCs were lost, after being scattered away by the planets. The rest survived on distant orbits. At the end of the simulation, the amplitude of the g_2 eccentricity term had changed only by 1.5% in Earth and 4% in Venus. This result is expected to scale linearly with the mass of the JFCs. Hence, to have a significant dynamical friction that can reconcile the final orbits of the terrestrial planets with the observed ones, one would need an enormous and unrealistic mass in the planetesimal population. Thus we conclude that dynamical friction cannot be the solution for the excessive excitation of the terrestrial planets.

3.2. Late excitation of the g_5 mode in Jupiter

The resonances that are responsible for the excitation of the eccentricities of the terrestrial planets are secular resonances. Thus, their effects on the terrestrial planets are proportional to the amplitude of the g_5 mode in the secular evolution of the perturber i.e. Jupiter.

We have seen in Paper I that the amplitude of the g_5 mode had to have been excited by close encounters between Saturn (or Jupiter itself) with a planet with a mass comparable to the mass of Uranus. In principle, one could think that these encounters happened relatively late, after the ratio P_S/P_J exceeded 2.25 which, as shown in Fig. 1, corresponds to the last secular resonance crossing ($g_5 = g_1$). If this were the case, when the resonance crossing occurred, the effects would have been less severe than shown in Fig. 2.

In the framework of the Nice model, we tend to exclude this possibility. In the simulations performed in Tsiganis et al. (2005) and Gomes et al. (2005), the encounters between gas giants and ice giants start as soon as Jupiter and Saturn cross their mutual 2:1 mean motion resonance ($P_S/P_J = 2$) and end before $P_S/P_J = 2.1$. In the variant of the Nice model proposed in Morbidelli et al. (2007), the encounters start even earlier, when $P_S/P_J < 2$. We do not know of any other model in which these encounters start after a substantial migration of the giant planets.

As a variant of this "late g_5 excitation scenario" we can also envision the possibility that the radial migration of the giant planets and the excitation of their eccentricities started contemporarily, but the initial separation of Jupiter and Saturn was such that $P_S/P_J \gtrsim 2.25$ from the beginning. For instance, in some of the simulations of Thommes et al. (1999) where Uranus and Neptune are originally in between Jupiter and Saturn, initially $P_S/P_J = 2.21$. It is likely that the initial separation of Jupiter and Saturn could have been increased in these simulations to satisfy the condition $P_S/P_J \sim 2.25$, without significant changes of the results. However, the presence of Uranus and Neptune should increase the value of g_5 relative to that shown in Fig. 1 for the same value of P_S/P_J. Hence the initial value of P_S/P_J should have been even larger than 2.25 in order to avoid secular resonances with g_1 and g_2. Moreover, we have to re-iterate what we already stressed in Paper I: hydro-dynamical simulations of the evolution of the giant planets when they are embedded in the gas disc show that Jupiter and Saturn should have evolved until they got trapped in their mutual 3:2 resonance ($P_S/P_J = 1.5$; Pierens & Nelson 2008). Initial conditions with $P_S/P_J > 2.25$ are definitely inconsistent with this result. Hence, the possibility

of pumping the g_5 mode late i.e. when $P_S/P_J \gg 2.25$, should probably not be considered as a viable option.

3.3. Decreasing the amplitudes of the g_1 and g_2 modes

It is a wide-spread misconception that perihelion secular resonances excite the eccentricities (or, equivalently, the amplitudes of the resonant Fourier modes). This is true only if the initial eccentricities are close to zero: in this case, obviously, the eccentricities can only increase.

The misconception comes from an un-justified use of the Lagrange-Laplace solution as an adequate integrable approximation, i.e. as the starting point for studying the full dynamics with perturbation theory. This linear approach assumes that the frequency of the eccentricity oscillations is independent of its amplitude, as is the case with a *harmonic oscillator*. This leads to the false prediction that the amplitude of the resonant mode diverges to infinity at the exact resonance. However, in reality the dynamics inside or near a secular resonance resemble those of a *pendulum* (see e.g. Chapter 8 of Morbidelli 2002), which is a non-linear oscillator. Strictly speaking, motion takes place *inside* a resonance when the corresponding resonant angle, ϕ, *librates*. Let us take as an example the motion of a test particle, with proper secular frequency g, perturbed by the planets. For a resonance between g and g_k, $\phi = (g - g_k)t + (\beta - \beta_k)$. Correlated to the librations of ϕ are large-amplitude *periodic* variations of the "angular momentum" of the pendulum, which is a monotonically increasing function of the eccentricity of the particle. On the other hand, when we are outside but near the $g = g_k$ resonance, ϕ slowly circulates and the eccentricity oscillations are of smaller amplitude. Thus, each resonance has a specified *width*, which determines the maximum allowable excursion in eccentricity. Following this general scheme, a secular resonance between two of the planetary proper modes (e.g. $g_2 = g_5$) can be thought of as a dynamical state, in which two modes exchange energy in a periodic fashion, according to the evolution of ϕ. As ϕ moves towards one extreme of its libration cycle, one mode gains "energy" over the other, and the eccentricity terms related to the "winning" mode increase, in expense of terms related to the "losing" mode. The situation for the two modes will be reversed, as ϕ will move towards the other extreme of the libration cycle. The total amount of "energy" contained in both modes has to be conserved. Hence, the eccentricity variations are determined by the initial conditions, which define a single libration curve.

The above scheme is correct in the conservative frame, i.e. as long as the planets do not migrate. When migration occurs, the system may be slowly driven from a non-resonant to a resonant regime. This situation is reminiscent of the one examined in Paper I, where the slow crossing of a mean motion resonance (MMR) was studied. However, there is a fundamental difference between the two phenomena, related to the vastly different libration time-scales. In the case of a MMR crossing, the migration rate is significantly slower than the libration frequency of the MMR. Thus, MMR crossing is an *adiabatic* process, and adiabatic invariance theory can be used to predict the final state of the system. When a secular resonance is crossed, things are not so simple. The crossing time is of the same order as the libration period. Thus, each moment the planets follow an "instantaneous" secular libration curve (i.e. the one that they would follow if the migration was suddenly stopped), which itself changes continuously as the planets move radially. Therefore, depending on the initial phases (i.e., ϕ) when the resonance is approached, a given eccentricity mode can decrease or increase, the final amplitude

can also do this, depending on the crossing time. If migration is very slow, the eccentricities may perform several oscillations, due to repeated libration cycles. Once the resonance is far away, the Lagrange-Laplace solution is again valid, but with different amplitudes of the former-resonant modes.

From the above discussion it is clear that the result of a secular resonance crossing does not always lead to increasing the amplitude of a given secular mode. The final result depends mostly on the initial conditions (eccentricity amplitudes and phases) as well as on the migration speed. In practice, if the initial amplitude of a mode is small compared to possible eccentricity excursion along the libration curve (or, the width of the resonance) the result will be a gain in eccentricity. If, conversely, the initial eccentricity is similar to, or greater than, the resonance width and the migration speed is not too slow, then there can be a large interval of initial phases that would lead to a net loss in eccentricity.

With these considerations in mind, we can envision the possibility that, when they formed, the terrestrial planets had somewhat greater amplitudes of the g_1 and g_2 modes than now, and that these amplitudes were damped during the g_5 secular resonance sweeping. To test this possibility, and estimate the probability that this scenario occurred, we have designed the following experiment.

As initial conditions for the terrestrial planets, we took the outcome of a simulation similar to that presented in Fig. 2, so that the amplitude of the g_2 mode in Mercury, Venus and Earth is large ($\sim$0.1); the initial eccentricity of Mercury is 0.12. The amplitudes of the g_3 and g_4 frequencies are, respectively, comparable (g_3) and smaller (g_4) than the current ones in all planets. Jupiter and Saturn were started with a period ratio $P_S/P_J = 2.065$ and migrated to their current orbits, so that g_5 passes through the values of the g_2 and g_1 frequencies but avoids resonances with g_3 and g_4. As before, the migration timescale τ was assumed equal to 1 Myr and the initial eccentricities and longitudes of perihelia were chosen so that the amplitude of the g_5 mode in Jupiter is correct. With this setup, we did several simulations, which differ from each other in a rotation of the terrestrial planet system relative to the Jupiter-Saturn system. This rotation changes the initial relative phase of the g_5 and g_2 terms and consequently changes the phase at which the secular resonance $g_5 = g_2$ is met. The same principle applies to the $g_5 = g_1$ resonance.

Regardless of what happens to Mercury, we found that in about 8% of the simulations the amplitude of the g_2 term in Venus was smaller than 0.025 at the end i.e. just 25% of the initial value and comparable to the current one.

To measure the probability that also the final orbit of Mercury is acceptable, we used a successful simulation that damped the g_2 mode to construct a new series of simulations as follows. We first measured the value of $g_5 - g_2$ for the initial configuration. This was done by numerical Fourier analysis of a 8 Myr simulation with no migration imposed on Jupiter and Saturn. Defining $P_{5,2} = 2\pi/(g_5 - g_2)$, we then did a simulation, still without migration of the giant planets, with outputs at multiples of $P_{5,2}$. All these outputs had, by construction, the same relative phases of the g_5 and g_2 terms, but different relative phases of the g_1 term. We used five consecutive outputs, covering a full 2π range for the latter, since $P_{1,2} = 2\pi/(g_2 - g_1) \sim 5P_{5,2}$. Each of these outputs was used as an initial condition for a new migration simulation, with the same parameters as before. All of these simulations led essentially to the same behaviour (i.e. damping) of the g_2 mode, because the secular resonance $g_5 = g_2$ was encountered at the same phase. But the behaviour of Mercury
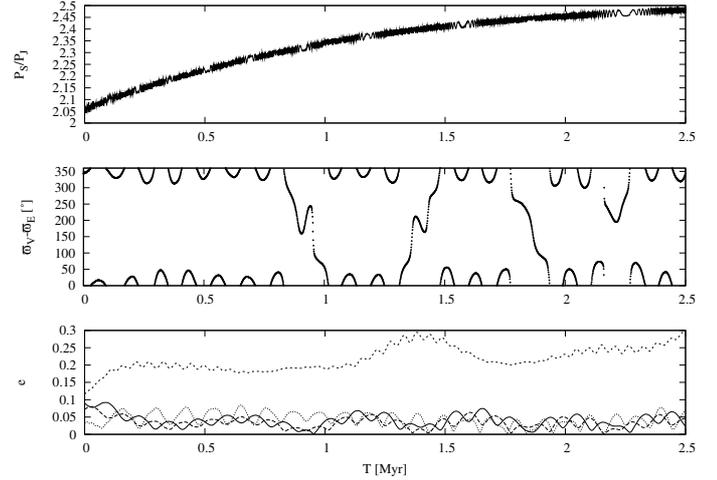

Fig. 3. Evolution of the terrestrial planets during the $g_5 = g_2$ and $g_5 = g_1$ resonance crossings in where the g_2 mode is damped down. *The top panel* shows P_S/P_J. *The middle panel* shows the evolution of $\varpi_V - \varpi_E$. *The bottom panel* shows the eccentricities of the Earth (long dashed), Venus (solid), Mercury (short dash) and Mars (dotted). Notice the evident reduction of the amplitude of oscillation of the eccentricities of Earth and Venus near the beginning of the simulation.

was different from one simulation to another. We considered the simulation successful when the eccentricity of Mercury did not exceed 0.4 during the migration simulation, as well as during a 8 Myr continuation with no migration of the giant planets; the latter was performed to determine the Fourier spectra at the end. In total we found that the evolution of Mercury satisfied these requirements in 60% of the simulations. Figure 3 shows an example of a successful simulation. In this run, the amplitude of the g_2 mode in Venus is damped from 0.1 to 0.025 and the amplitude of the g_1 mode in Mercury increases from 0.169 to 0.228.

In summary, we find that there is a probability of $0.08 \times 0.6 = 4.8\%$ that the migration of the giant planets leads to a damping of the g_2 mode and to an acceptable final orbit of Mercury. This probability should not be taken very literally. Although it has been measured carefully, it clearly depends on the properties of the system of terrestrial planets that we start with and on the migration rate. From the considerations reported at the beginning of this section we expect that the probability decreases for reduced initial excitations of the g_1 and g_2 modes; also, the probability should decrease if slower migrations are enacted, unless the initial excitations are increased, approximately in proportion with τ. We stress that the amplitude of the g_2 mode cannot much exceed 0.1, otherwise the system of the terrestrial planets becomes violently unstable. Mercury is chaotic and potentially unstable on a 4 Gyr timescale even in the current system (Laskar 1990, 1994); if the amplitude of the g_2 mode exceeds the current one, it becomes increasingly difficult to find solutions for Mercury that are stable for $\sim$600 Myr, which is the putative time at which the migration of the giant planets occurred, as suggested by the LHB.

To conclude, we consider this scenario viable, but with a low probability to have really occurred. An additional puzzling aspect of this mechanism that makes us sceptical, is that it requires the original amplitude of the g_2 mode to exceed the amplitude of the g_3 mode. As we said above, it is unclear which orbital excitation the terrestrial planets had when they formed. However, given the similarity in the masses of the Earth and Venus, nothing suggests that there should have been a significant imbalance between the amplitudes of these two modes. Actually, it would

be very difficult to excite one mode without exciting the other one in a scenario in which the excitation comes from a sequence of collisions and encounters with massive planetary embryos. In fact, as explained in Paper I for the case of Jupiter and Saturn, even if only one planet has a close encounter with a third massive body, both amplitudes abruptly increase to comparable values.

3.4. A jumping Jupiter scenario

In Paper I we have concluded that the current excitation of the g_5 and g_6 modes in Jupiter and Saturn could be achieved only if at least one of these planets had encounters with a body with a mass comparable to that of Uranus or Neptune. These encounters would have not just excited the eccentricity modes; they would have also provided kicks to the semi-major axes of the planets involved in the encounter. In this section we evaluate the implications of this fact.

If Saturn scatters the ice giant onto an orbit with a greater semi-major axis, its own semi-major axis has to decrease. Thus, the P_S/P_J ratio decreases instantaneously. Instead, if Saturn scatters the ice giant onto an orbit with a smaller semi-major axis, passing it to the control of Jupiter, and then Jupiter scatters the ice giant onto an orbit with a larger semi-major axis, the semi-major axis of Saturn has to increase, that of Jupiter has to decrease, and consequently P_S/P_J has to increase. This opens the possibility that P_S/P_J jumps, or at least evolves very quickly, from less than 2.1 to larger than 2.25, thus avoiding secular resonances between g_5 and g_2 or g_1 (see Fig. 1).

We now turn to the Nice model, because this is our favoured model and the one on which we have data to do more quantitative analysis. In the Nice model, only in a minority of the successful runs (i.e. the runs in which both Uranus and Neptune reach stable orbits at locations close to the current ones) there are encounters between Jupiter and an ice giant without ejecting it. For instance, this happened in one simulation out of six in Gomes et al. (2005), and in two simulations out of 14 in Nesvorný et al. (2007). So, the probability seems to be approximately 15%. In all other runs, only Saturn encounters an ice giant, which, as we said above, decreases the P_S/P_J ratio instead of increasing it.

We point the attention of the reader to the fact that Nesvorný et al. (2007) showed that encounters with Jupiter would explain the capture of the irregular satellites of this planet and their orbital properties. If Jupiter never had encounters, only Saturn, Uranus and Neptune should have captured irregular satellites (unless Jupiter captured them by another mechanism, but then it would be odd that the system of the irregular satellites of Jupiter is so similar to those of the other giant planets; see Jewitt & Sheppard 2006). Moreover, in the Nice model, the cases where Jupiter has encounters with an ice giant are those which give final values of P_S/P_J which best approximate the current solar system, whereas in the other cases Saturn tends to end its evolution a bit too close to the Sun (Tsiganis et al. 2005). These two facts argue that, although improbable, this kind of dynamical evolution, involving Jupiter encounters with an ice giant, actually occurred in the real solar system.

As an example of what can happen in the Nice model when Jupiter encounters an ice giant, the top panel of Fig. 4 shows the evolution of P_S/P_J; the middle panel displays the evolution of the semi-major axis of Jupiter and in the bottom panel that of Saturn. The time resolution of the output is 100 yr, though only every 1000 years is shown here. This new simulation is a "clone" of one of the original simulations of Gomes et al. (2005). The positions and velocities of the planets were taken at a time when Jupiter and Saturn had just crossed their 2:1 MMR, but had not

yet experienced encounters with the ice giants – this time is denoted by $t = 0$ in Fig. 4 and corresponds to $t = 875.5$ Myr in the simulation of Gomes et al. (2005) where the giant planet instability occurred at a time that roughly corresponds to the chronology of the LHB.

As one can see in Fig. 4, P_S/P_J evolves very rapidly from $P_S/P_J < 2.1$ to $P_S/P_J > 2.4$ around $t = 0.25$ Myr. Then P_S/P_J decreases again below 2.4, has a rapid incursion into the 2.3−2.4 interval around $t = 0.75$ Myr and eventually, after $t = 2.5$ Myr, increases smoothly to 2.45. The latter value is a very good approximation of the current value of P_S/P_J. The striking similarity of the curves in the top and middle panels demonstrates that the orbital period ratio is essentially dictated by the dynamical evolution of Saturn. Nevertheless, Saturn can have this kind of early evolution only if Jupiter has encounters with an ice giant, which justifies the name of "jumping Jupiter scenario" used in this section. This can be understood by looking at the evolution of the two planets and of Uranus in details, as we describe below with the help of the magnification of the dynamics, which is provided in Fig. 5.

Saturn first has an excursion in semi-major axis from approximately 8.5 AU to 8.8 AU at $t = 0.215$ Myr. This happens

because it has repeated encounters with Uranus, which lead to a temporary exchange of their orbits, placing Uranus at $a = 8.4$ AU. Then Saturn kicks Uranus back outwards, which again puts Saturn at ~8.5 AU. This series of events shows that, if Jupiter does not participate in this phase of encounters, the dynamics are characterised by energy exchange between Saturn and Uranus: if one planet is scattered outwards, the other is scattered inwards and vice-versa. Given that Uranus was initially much closer to the Sun than it is now, the net effect on Uranus had to be an outwards scattering; consequently, in the absense of encounters with Jupiter, Saturn would have had to move inwards. So, this evolution could not have led to an increase in P_S/P_J.

The situation is drastically different if encounters between Jupiter and Uranus occur. In Fig. 5, this starts to happen at $t \sim 0.25$ Myr), when Saturn's semi-major axis evolves rapidly to ~9.2 AU and Uranus' semi-major axis to ~6.5 AU. Jupiter first exchanges orbits with Uranus: Jupiter moves out to 5.52 AU while a_U reaches 3.65 AU and the perihelion distance of Uranus, q_U, decreases to ~2 AU. However, notice that the intrusion of Uranus into the asteroid belt is not a necessary feature of the jumping Jupiter scenario; some simulations leading only to $q_U \sim 3-4$ AU. Then Jupiter scatters Uranus outwards to $a_U \sim 50$ AU, itself reaching $a_J \sim 5.2$ AU. The situation is now very different from the one before: Uranus is back on a trans-Saturnian orbit and, because this was the result of a Jupiter-Uranus encounter, Saturn has not moved back to its original position. Thus, this series of encounters has led to an irreversible increase of the orbital separation (and period ratio) of Jupiter and Saturn. The subsequent evolution of the planets, shown in Fig. 5, is dominated by encounters between Saturn and Uranus. These encounters push Uranus' semi-major axis to beyond 200 AU at $t = 0.35$ Myr and to beyond 100 AU at $t = 0.725-0.775$ Myr, but in both cases Saturn pulls it back. This erratic motion of a_U correlates with the one of a_S. Eventually Uranus' semi-major axis stabilises at ~35 AU. Thus, Uranus and Neptune switch positions, relative to their initial configuration. This happened in all our simulations where Jupiter-Uranus encounters took place.

We now proceed to simulate the evolution of the terrestrial planets in the framework of the evolution of Jupiter, Saturn and Uranus discussed above. However, we cannot simply add the terrestrial planets into the system and redo the simulation because the dynamics is chaotic and the outcome for the giant planets would be completely different. Thus, we need to adopt the strategy introduced by Petit et al. (2001). More precisely, we have modified the code Swift-WHM (Levison & Duncan 1994), so that the positions of Jupiter, Saturn and Uranus are computed by interpolation from the output of the original simulation. Remember that the orbital elements of the outer planets had been output every 100 yr. The interpolation is done in orbital element space, and the positions and velocities are computed from the result of the interpolation. For the orbital elements a, e, i, Ω, and ω, which vary slowly, the interpolation is done linearly. For the mean anomaly M, which cycles over several periods in the 100 yr output-interval, we first compute the mean orbital frequency from the mean semi-major axis (defined as the average between the values of a at the beginning and at the end of the output-interval) and then adjust it so that M matches the value recorded at the end of the output-interval. Then, over the output-interval, we propagate M from one time-step to another, using this adjusted mean orbital frequency.
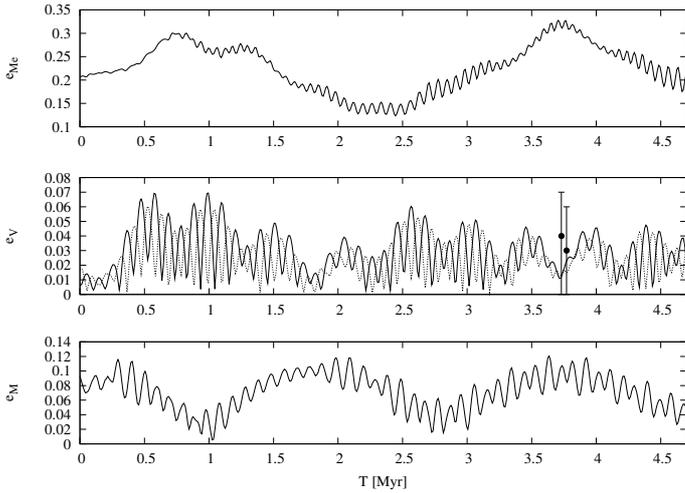

To test the performance of this code, we have done two simulations of the evolution of the 8 planets of the solar system. In the first one, the planets were started from their current configuration and were integrated for 1 Myr, using the original
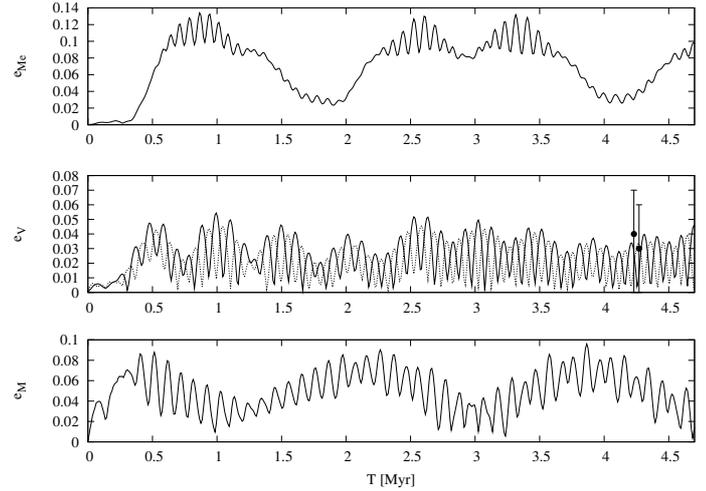

Fig. 6. The evolution of the eccentricities of Mercury (*top*), Venus and Earth (respectively solid and dashed lines) in *the middle panel*, and Mars (*bottom*), during the dynamics of Jupiter and Saturn illustrated in Fig. 4. The initial orbits of the terrestrial planets are assumed to be circular and coplanar. The solid circles and vertical bars represent the eccentricity oscillation of Earth and Venus, as in Fig. 2.

Swift-WHM code. In the second one, an encounters phase was simulated, by placing Uranus initially in between the orbits of Jupiter and Saturn, while setting the terrestrial planets on circular and co-planar orbits, and integrating for 1 Myr. In both simulations the orbital elements of the planets were recorded every 100 yr. Then, we re-integrated the terrestrial planets, in both configurations, using our new code, in which the orbital evolutions of Jupiter, Saturn and Uranus were being read from the output of the previous integration. We then compared the outputs of the two simulations, for each initial planet configuration. Eccentricity differences between the two simulations of the same configuration are interpreted here as the "error" of our new code. In the first configuration (current system), which represents a quite regular evolution, we found that the root-mean-square errors in eccentricity are 1.05×10^{-4} for Mercury, 4.3×10^{-5} for Venus, 4.0×10^{-5} for the Earth and 8.9×10^{-5} for Mars. In the second simulation (repeated encounters) the evolution of the terrestrial planets, Mercury in particular, is more violently chaotic. Consequently, the error remains acceptable (~3×10^{-3}) for all planets except Mercury, for which the error grows above ~5×10^{-3} after ≈ 0.5 Myr. This is due to a shift in the secular phases of Mercury's orbit in the two simulations, which changes the outcome of the evolution. Given the chaotic character of the dynamics, both evolutions are equally likely and acceptable. Thus, we conclude that our modified integrator is accurate enough (although the effects of encounters among the giant planets are "smeared" over 100 yr intervals) to be used effectively for our purposes.

For a comparison with the case illustrated in Fig. 2, we first present a simulation where all terrestrial planets start from coplanar, circular orbits. Figure 6 shows the evolution of the eccentricity of Mercury (top), Venus and Earth (middle) and Mars (bottom). The eccentricities of the terrestrial planets increase rapidly but, unlike in the case of smooth migration of Jupiter and Saturn (Fig. 2), they remain moderate and do not exceed the values characterising their current secular evolutions (see for instance Laskar 1990). A Fourier analysis of a 4 Myr continuation of the simulation, with Jupiter and Saturn freely evolving from their final state, gives amplitudes of the g_2 and g_3 modes in Venus

Fig. 7. The same as Fig. 6, but for terrestrial planets starting from their current orbits.

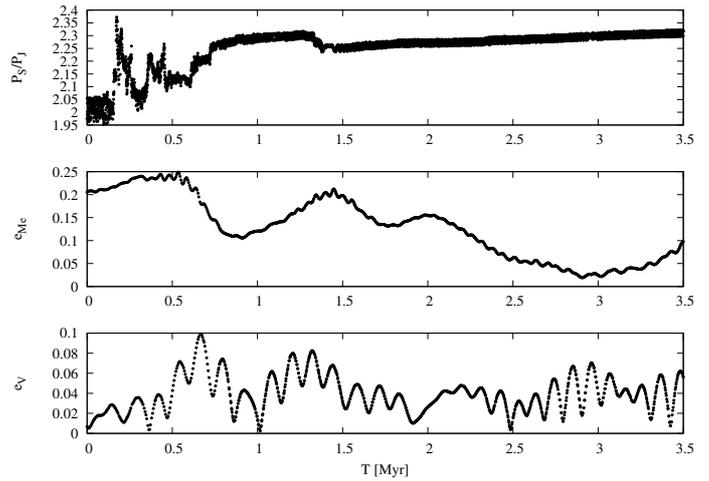

Fig. 8. *Top panel*: the evolution of the period ratio between Saturn and Jupiter in another "jumping Jupiter" evolution from the Nice model. *Middle and bottom panel*: the evolutions of the eccentricities of Mercury and Venus, respectively.

and the Earth of ~0.015, in good agreement with the real values. The amplitude of the g_4 mode in Mars is smaller than the real one. For Mercury, the analysis is not very significant because the g_1 and g_5 frequencies are closer to each other than in reality (because P_S/P_J is a bit smaller, which increases g_5 faster, and Mercury is more inclined, which decreases g_1). Nevertheless, in a 20 Myr simulation, the eccentricity of Mercury does not exceed 0.4.

Since it is unlikely that the terrestrial planets formed on circular orbits, but from the beginning should have had some orbital excitation, remnant of their violent formation process, we have re-enacted the evolution of the terrestrial planets, but starting from their current orbits. In this case we assume that their current orbital excitation is an approximation to their primordial excitation. Again, Jupiter and Saturn evolve as in Fig. 4. The results are illustrated in Fig. 7. We find that the eccentricities of the terrestrial planets remain moderate and comparable to the current values. A Fourier analysis of the continuation of this simulation shows again that amplitudes of the g_2 and g_3 terms in Venus and the Earth are ~0.015. The final amplitude of the g_4 term in Mars has preserved the initial value of ~0.04. The maximal eccentricity of Mercury does not exceed 0.35.

Taken together, these two simulations are a successful demonstration that the rapid evolution of P_S/P_J over the 2.1−2.4 range allows the excitation of the terrestrial planets to remain comparable to their current values, because the sweeping of the g_5 secular resonance is too fast to have a noticeable effect.

We have to stress, though, that not all "jumping-Jupiter" evolutions are favourable for the terrestrial planets. In some cases the rapid evolution of P_S/P_J ends when the orbital period ratio is ~2.2 or less, which is close to the $g_5 = g_1$ and $g_5 = g_2$ resonance. In other cases, after having increased to above 2.3, P_S/P_J decreases again and for a long time remains in the range of values for which these secular resonances occur. In these cases, the destiny of the terrestrial planets is set: Mercury typically becomes unstable, and the Earth and Venus become much more eccentric than they are in reality, due to the excitation of the g_2 mode.

Nevertheless, the evolution of P_S/P_J does not need to be as fast as in Fig. 4 to lead to "good" terrestrial planets. Figure 8 gives another example from a different realisation of the Nice model: the top panel shows the evolution of P_S/P_J, the middle and the bottom panel show the evolutions of the eccentricities of Mercury and Venus, respectively, for a system of terrestrial

planets starting from current orbits. In this case P_S/P_J evolves rapidly to ~2.35, but then it returns in the 2.10−2.25 range, where it spends a good half-a-million years. Subsequently, after evolving again to 2.3, it returns to 2.25 and starts to increase again, slowly. In this case the effect of secular resonances is no longer negligible as in the case illustrated above. But in our terrestrial planet simulation the eccentricity of Mercury is effectively damped, enacting the principle formulated in Sect. 3.3. The eccentricity of Venus, via the amplitude of the g_2 mode, is excited during the time when $P_S/P_J \sim 2.15$ and reaches 0.1. However, it is damped back when P_S/P_J decreases again to 2.5 at $t \sim 1.5$ Myr. At the end, the orbits of the terrestrial planets are again comparable to their observed orbits, in terms of eccentricity excitation and amplitude of oscillation.

At this point, one might wonder what is the fraction of giant planets' evolutions in the Nice model that are favourable for the terrestrial planets. This is difficult to evaluate, because we only performed a limited number of simulations and then cloned the simulations that seemed to be the most promising. We try, nevertheless, to give a rough estimate. As we said at the beginning of this section, the jumping Jupiter evolutions are about 15−20% of the successful Nice model runs. By successful we mean those runs that, at the end, yielded giant planets on orbits resembling their observed ones, without considering terrestrial planets constraints. The successful runs are about 50−70% of the total runs (Gomes et al. 2005; Tsiganis et al. 2005). Most of the unsuccessful runs were of the jumping Jupiter category, but led to the ejection of Uranus. It is possible that, if the planetesimal disc had been more massive than the one used in the simulation, or represented by a larger number of smaller particles, so as to better resolve the process of dynamical friction, Uranus would have been saved more often, thus leading to a larger fraction of successful jumping Jupiter cases. Then, by cloning jumping Jupiter simulations after the time of the first encounter with Uranus, we find that about 1/3 of the "successful" jumping Jupiter cases are also successful for the terrestrial planets, like the cases presented in Figs. 6−8; P_S/P_J evolves very quickly beyond 2.3, and does not exceed 2.5 in the end. This brings the total probability of having in the Nice model a giant planet evolution compatible with the current orbits of the terrestrial planets to about 6%.

## 4. The $g_5 = g_3$ and $g_5 = g_4$ resonance crossings

The study described in this section is very similar to that presented at two DPS conferences by Agnor (2005) and Agnor & Lin (2007) and therefore its results are not new. However, Agnor and collaborators never presented their work in a formal publication so, for completeness, we do it here.

As discussed in Sect. 2, when Jupiter and Saturn are close enough to their mutual 2:1 mean motion resonance, the g_5 frequency can be of the order of $17-18''$/yr (see Fig. 1), and therefore resonances with the proper frequencies of Mars and the Earth (g_4 and g_3) have to occur. If the migration of Jupiter and Saturn from the 2:1 resonance is sufficiently fast, as shown in Fig. 2, the sweeping of the $g_5 = g_4$ and $g_5 = g_3$ does not cause an excessive excitation of the amplitudes of the g_4 and g_3 mode.

However, while a fast departure from the 2:1 resonance is likely, in the original version of the Nice model (Gomes et al. 2005) Jupiter and Saturn have to *approach* the 2:1 resonance very slowly, in order to cross the resonance with sufficient delay to explain the timing of the LHB. During the approach phase the eccentricities of Jupiter and Saturn (and, therefore, also the amplitude of the g_5 term) were very small but, nevertheless, the long timescales involved could allow the secular resonances to have a destabilising effect on the terrestrial planets.

To illustrate this point, we repeated the last part of the simulation presented in Gomes et al. (2005), during which Jupiter and Saturn slowly approach the 2:1 resonance, and we added the terrestrial planets, Venus to Mars, initially on circular orbits. The top panel of Fig. 9 shows the evolution of the eccentricities of the terrestrial planets, while on the bottom panel the evolution of the period ratio between Saturn and Jupiter over the integrated time-span is depicted. The initial configuration is very close to the $g_5 = g_4$ resonance. At this time, Jupiter's eccentricity is oscillating from ~0 to ~0.015, but with a high frequency related to the 2:1 resonance with Saturn. The amplitude of the g_5 mode in Jupiter is only 3×10^{-4}. Eventually, the secular resonance (i.e. at $t \sim 0.045$ Gyr) excites the amplitude of the g_4 term in Mars to approximately 0.15, in Earth and Venus to 0.033 and 0.023 respectively, as well as the amplitude of the g_5 mode in Jupiter to 2×10^{-3}. At the same time, the g_4 frequency increases abruptly because of the increase in Mars' eccentricity and becomes approximately $0.2''$/y faster than g_5. The long periodic oscillations of the eccentricity of Mars after 0.05 Gyr are precisely related to the $g_4 - g_5$ beat. As migration proceeds, the g_5 frequency increases. Surprisingly, the g_4 frequency increases accordingly, which causes the mean eccentricities of Mars, Earth and Venus to also increase accordingly. We interpret this behaviour as if the dynamical evolution is sticking to the outer separatrix of the $g_5 = g_4$ resonance, in apparent violation of adiabatic theory. Therefore the $g_5 = g_4$ resonance is not crossed again. At the end, the eccentricity of Mars becomes large enough to drive the terrestrial planets into a global instability. This is a very serious problem, which seems to invalidate the original version of the Nice model.

Fortunately, the new version of the Nice model, presented in Morbidelli et al. (2007) solves this problem. This version was built to remove the arbitrary character of the initial conditions of the giant planets that characterised the original version of the model. In Morbidelli et al. (2007), the initial conditions of the *N*-body simulations are taken from the output of a hydrodynamical simulation in which the four giant planets, evolving in the gaseous proto-planetary disc, eventually reach a non-migrating, fully resonant, stable configuration. More precisely, Jupiter and Saturn are trapped in their mutual 3:2 resonance

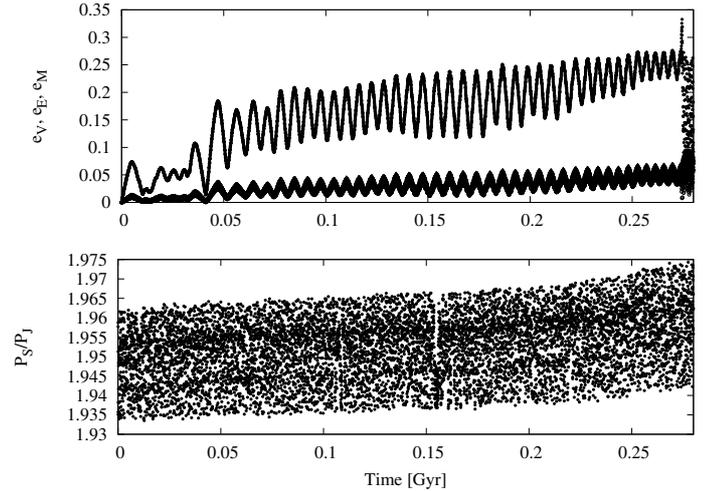

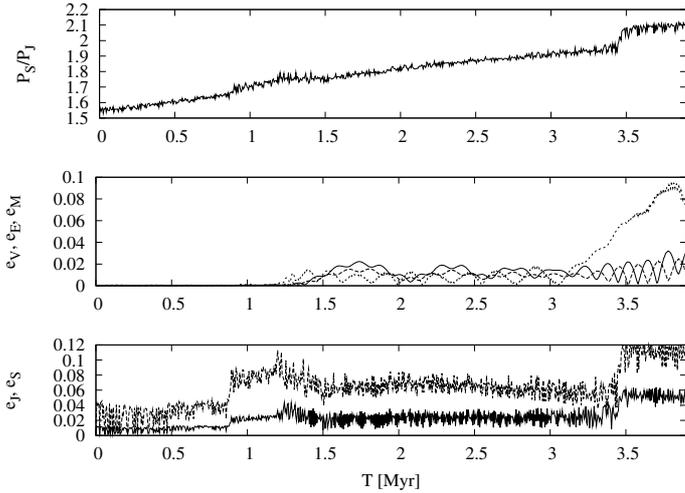

Fig. 9. The evolution of eccentricities of Venus, Earth and Mars in a simulation where Jupiter and Saturn approach slowly their 2:1 resonance. *The top panel* shows the evolution of the eccentricities of Mars (upper curve) and of Earth and Venus (overlapping almost perfectly in a unique lower curve). *The bottom panel* shows P_S/P_J vs. time.

(see also Masset & Snellgrove 2001; Morbidelli & Crida 2007; Pierens & Nelson 2008); Uranus is in the 3:2 resonance with Saturn and Neptune is caught in the 4:3 resonance with Uranus. Morbidelli et al. (2007) showed that, from this configuration, the evolution is similar to that of the original version of the Nice model (e.g. Tsiganis et al. 2005; Gomes et al. 2005), but the instability is triggered when Jupiter and Saturn cross their mutual 5:3 resonance (instead of the 2:1 resonance as in the original version of the model). Additional simulations done by our group (Levison et al., in preparation) show that, if the planetesimal disc is assumed as in Gomes et al. (2005), the instability of the giant planets is triggered as soon as a pair of planets leaves their original resonance, and this can happen as late as the LHB chronology seems to suggest.

For our purposes in this paper, the crucial difference between the new and the original version of the Nice model is that Jupiter and Saturn approach their mutual 2:1 resonance fast, because the instability has been triggered before, when Jupiter and Saturn were still close (or more likely locked in) their 3:2 resonance.

To test what this implies for the terrestrial planets, we have run several simulations, in which Jupiter and Saturn, initially on quasi-circular orbits, migrate all the way from within the 5:3 resonance to the 2:1 resonance on timescales of a several million years (corresponding to $\tau = 5-25$ Myr). We stress that we enact a smooth migration of the giant planets (evolutions of the jumping Jupiter case would be a priori more favourable) and that the migration time to the 2:1 resonance could easily be much shorter than we assume (see for instance the bottom panel of Fig. 8 in Morbidelli et al. 2007). On the other hand, in these simulations the amplitude of the g_5 term in Jupiter is excited through the multiple mean motion resonance crossings between Jupiter and Saturn, and therefore is about 1/3 of the current value (see Paper I).

We present two simulations here. Both have been obtained with $\tau = 5$ Myr; the first one investigates the outcome of initially circular terrestrial planets while the other uses the current orbits of the terrestrial planets. The results are presented in Figs. 10 and 11, respectively. In both figures, the top panel shows the evolution of the orbital period ratio between Saturn and Jupiter; the middle panel shows the eccentricities of the terrestrial

Fig. 10. The evolution of eccentricities of Venus, Earth and Mars, starting from circular orbits, in a simulation where Jupiter and Saturn migrate from within the 5:3 resonance to the 2:1 resonance. *The top panel* shows ratio of orbital periods between Saturn and Jupiter. *The middle panel* shows the evolution of the eccentricities of Mars (short dashed), Earth (long dashed) and Venus (solid). *The bottom panel* shows the eccentricities of Jupiter (solid) and Saturn (dashed).
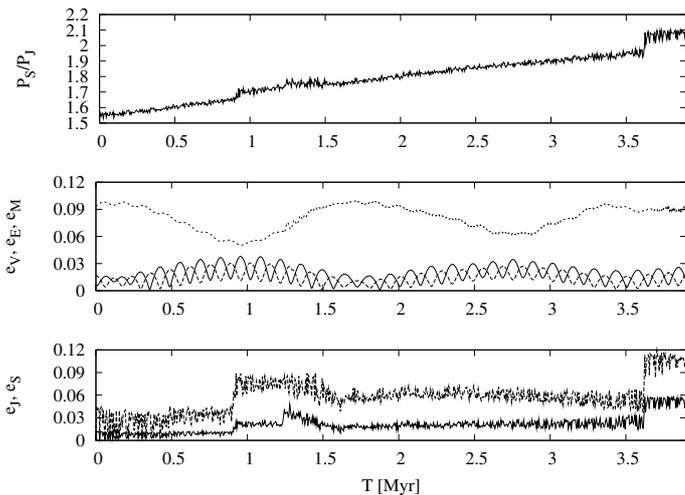

Fig. 11. The same as Fig. 10, but for terrestrial planets starting from their current orbits. Notice that the evolution for Jupiter and Saturn is not exactly the same as that of the previous simulation, despite the initial conditions and τ are the same. This is a result of the effects of resonance crossings, which are chaotic and thus give effects that are different, from run to run.

planets except Mercury, and the bottom panel the eccentricities of Jupiter and Saturn.

Notice the little jumps of the P_S/P_J curve and of e_J and e_S when Jupiter and Saturn cross mean motion resonances. Also notice that in the interim between resonances, the eccentricities of Jupiter and Saturn decay, as a consequence of a damping term that we introduced on Saturn to mimic the effect of dynamical friction, and to ensure that they do not become unstable (see Paper I). In the case where the terrestrial planets have initially circular orbits (Fig. 10) we see that they start to be excited after 1.5 Myr, when Jupiter and Saturn cross their mutual 9:5 resonance and become more eccentric themselves. The simultaneous increase in the eccentricities of Venus and Earth is mostly caused by an increase in their g_2 terms because of the

near-resonance $g_5 = g_2$ when $P_S/P_J \sim 1.7$ (see Fig. 1); the amplitude of their g_2 terms becomes approximately 0.02. The effect of the $g_5 = g_4$ resonance is visible towards the end of the simulation, when Mars becomes suddenly more eccentric (dashed line; middle panel) and has its g_4 term increased to about 0.08. However, its eccentricity does not exceed 0.09, and decreases again in response to the giant planets crossing the 2:1 resonance. In the next figure, the case where the terrestrial planets are initially on their current orbits (Fig. 11), we see almost no changes in the eccentricity evolution of the terrestrial planets, which remain of the same order as the initial ones. The most likely reason for this behaviour is that the chaotic nature of the migration causes the behaviour of Jupiter and Saturn to be slightly different from one simulation to the next. Indeed, the value of P_S/P_J has a longer plateau in Figs. 10 than in 11. In addition, in the first simulation the value of $M_{5,5}$ is slightly larger than in the second, which can be seen from the slightly larger excursions of Jupiter's eccentricity from its mean. In addition, the little changes in the eccentricities of the terrestrial planets in Fig. 10 become nearly invisible if the eccentricities are already quite large.

Thus, we conclude that the $g_5 = g_4$ and $g_5 = g_3$ secular resonances are not a hazard for the terrestrial planets, at least in the new version of the Nice model.

5. Note on the inclinations of the terrestrial planets

The dynamical excitation of the terrestrial planets at the end of the process of formation is still not known. Simulations (e.g. O'Brien et al. 2006) show that the planets had an orbital excitation comparable to the current one, but this could be an artifact of the poor modelling of dynamical friction. Therefore, any indirect indication of what had to be the real dynamical state of the orbits of the terrestrial planets would be welcome.

In the two previous sections we have seen that original circular orbits cannot be excluded. In fact, if the terrestrial planets had circular orbits after their formation, the current eccentricities and amplitudes of the secular modes could have been acquired during the evolution of the giant planets through secular resonance crossings and reactions to the jumps in eccentricity of Jupiter's orbit. It is interesting to see if the same is true for the inclinations, which are between 2 and 10 degrees for the real terrestrial planets. In fact, if the terrestrial planets had originally quasi-circular orbits (probably as a result of strong dynamical friction with the planetesimals remaining in the inner solar system at the end of the giant collisions phase), presumably they had also inclinations close to zero. If the evolution of the giant planets could not excite the inclinations of the terrestrial planets, then the orbits of these planets had to be excited from the very beginning. In the opposite case, co-planar (and circular) initial orbits cannot be excluded.

Unlike the eccentricity case, there are no first-order secular resonances affecting the evolution of the inclinations of the terrestrial planets during the migration of Jupiter and Saturn. In fact, neglecting Uranus and Neptune, the secular motion of Jupiter and Saturn in the Lagrange-Laplace theory is characterised by a unique frequency (s_6). Its value is now approximately $-26''/yr$ and should have been faster in the past, when the two planets were closer to each other. The frequencies of the longitudes of the node of the terrestrial planets are all smaller in absolute value than s_6: the frequencies s_1 and s_2 are about -6 to $-7''/yr$; the s_3 and s_4 frequencies are -18 to $-19''/yr$ (Laskar 1990). So, no resonances of the kind $s_6 = s_k$, with $k = 1$ to 4 were possible.
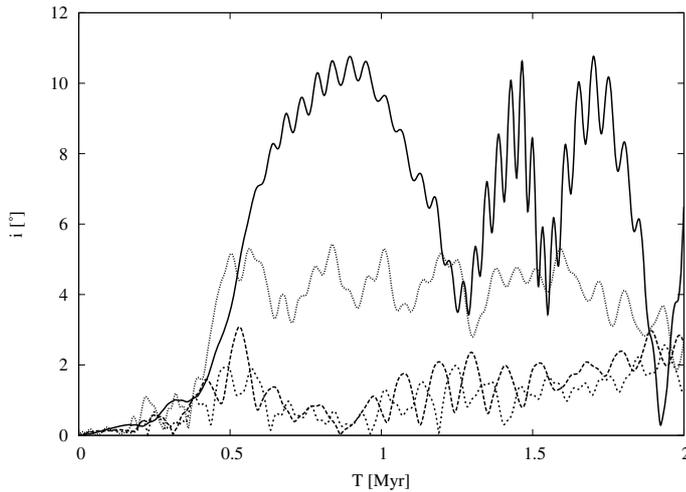

Fig. 12. Evolution of the inclinations of Mercury (solid), Venus (dark dashed) Earth (light dashed) and Mars (dotted), all starting from 0, in the "jumping Jupiter" evolution shown in *the top panel* of Fig. 8.

Nevertheless, in our simulations with terrestrial planets starting with circular and co-planar orbits in Sect. 3.4 we find (see Fig. 12) that the inclinations are excited and the current values can be reproduced, including that of the Mercury (whose mean real inclination is ~8°; Laskar 1988) and Mars (4°). This is because there are a number of non-linear secular resonances that can occur, which also involve Uranus or Neptune. The frequencies s_1 and s_2 could resonate with s_7 or s_8, whenever the latter were larger in absolute value than the current values (respectively −2.99 and −0.67″/yr now), which is likely when the ice giants had much stronger interactions with Jupiter and Saturn. The frequencies s_3 and s_4 were close to the 1:2 resonance with s_6, when the latter was larger than now due to the smaller orbital spacing between the giant planets. As is well known, a resonance $s_6 = 2s_4$ cannot have dynamical effects, because the corresponding combination of the angles does not fulfil the D'Alembert rule (see for instance Morbidelli 2002). However, a resonance like $2s_4 = s_6 + s_7$ does satisfy the D'Alembert rule and is close to the previous one, due to the current small value of s_7. The variety of dynamical evolutions of Uranus and Neptune that are possible in the Nice model (even within the subset of jumping-Jupiter evolutions) precludes us to say deterministically which resonances really occurred, when and with which effects. But the possibility of exciting the current inclinations starting from $i \sim 0$ is not remote and therefore, unfortunately, we cannot conclude on what had to be the initial dynamical state of the orbits of the terrestrial planets.

6. Discussion and conclusions

In this work we have shown that the radial smooth migration of Jupiter and Saturn tends to excite the eccentricities of the orbits of Mercury, Venus and the Earth well above the values achievable during their current evolution. This happens because the g_5 frequency decreases during the migration; consequently it enters temporarily in resonance with g_2 and g_1 when $P_S/P_J \sim 2.1-2.3$, which excites the amplitudes associated with these two frequencies in the Fourier spectrum of the terrestrial planets. Conversely, the amplitude of the g_4 frequency in Mars is not excited too much, provided that Jupiter and Saturn approached and departed rapidly to/from their mutual 2:1 mean

motion resonance, as in the new version of the Nice model (Morbidelli et al. 2007).

We have found two possible, but low-probability mechanisms that may make giant planet migration compatible with the current orbital architecture of the terrestrial planets. One requires that the original structure of the terrestrial planets was quite strange, with an amplitude of the g_2 mode significantly larger than that of the g_3 mode. In this case, the $g_5 = g_2$ resonance could have damped the amplitude of the g_2 mode (and to some extent also of the g_1 mode), for some lucky combination of secular phases. The other requires that P_S/P_J "jumped" (or evolved very rapidly across) the 2.1−2.3 interval, as a result of encounters between *both* Jupiter and Saturn with either Uranus or Neptune. Some evolutions of this kind occur in the Nice model, but they are rare (successful probability approximately 5%).

We are aware that most readers will consider this a first serious drawback of the Nice model. But, before leaving way to critics, we would like to advocate some relevant points.

First, this apparent problem is not confined to the Nice model, but concerns any model which associates the origin of the LHB to a delayed migration of Jupiter and Saturn (e.g. Levison et al. 2001, 2004; Strom et al. 2005; Thommes et al. 2007).

Second, an easy way out of this problem is to deny that the LHB occurred as an impact spike. In this case, giant planet migration might have occurred as soon as the gas disc disappeared, without consequences on the terrestrial planets, which had not formed yet. We warn against this superficial position. It seems to us that there are at least four strong pieces of evidence in favour of the cataclysmic spike of the LHB: (i) basins on the Moon as big as Imbrium and Orientale could not have formed as late as 3.8 Gyr ago if the bombardment rate had been declining monotonically since the time of planet formation at the rate indicated by dynamical models without giant planet migration (Bottke et al. 2007); (ii) old zircons on Earth demonstrate that the climate on Earth 4.3−3.9 Gyr ago was relatively cool (i.e. the impact rate was low; Mojzsis et al. 2001), and that strong heating events, probably associated with impacts, happened approximately 3.8 Gyr ago (Trail et al. 2007); (iii) the most prominent impact basins on Mars occurred after the disappearance of Martian magnetic field (Lillis et al. 2006, 2007); (iv) impact basins on Iapetus occurred after the formation of its equatorial ridge, which is estimated to have formed between $t = 200-800$ Myr (Castillo-Rogez et al. 2007). Anybody seriously arguing against the cataclysmic nature of the LHB should find an explanation for each of these issues.

Third, one may argue that the origin of the LHB was not determined by a delayed migration of the giant planets, but that it was caused instead by dynamical events that concerned only the inner solar system. The model by Chambers (2007) does precisely this and, in our opinion, it is the most serious alternative to the Nice model, for the origin of the LHB. In Chambers' scenario, the system of terrestrial planets originally contained five planets. The fifth rogue planet, of sub-martian mass, was in between the current orbit of Mars and the inner edge of the asteroid belt. The orbit of this planet became unstable at a late epoch: after crossing the asteroid belt for some time and dislodging most of the asteroids originally resident in that region (which caused the LHB) the rogue planet was eventually removed by a collision with another planet, a collision with the Sun, or ejection from the solar system. Although appealing, this model has never been given much consideration and has never been tested in detail, for instance against the current structure of the asteroid belt and the magnitude of the LHB. We stress that Chambers' model

cannot by any means explain the bombardment of Iapetus. Thus, to accept this model one has to find an alternative explanation of the late bombardent of this satellite of Saturn that does not involve or imply a migration of the giant planets or, alternatively, to prove that its ridge formed much earlier than estimated by Castillo-Rogez et al. (2007), so that the heavy bombardment of Iapetus could have occurred early.

As a final note, we remark that it is very dangerous to exclude or adopt a model based on probabilistic arguments on events that concern the habitability of the Earth, such as its orbital excitation. The fact that we are here to study these problems introduces an obvious observational bias: of all possible solar systems, we can be only in one that allows our existence, however improbable was the chain of events that led to its formation. The solar system is full of low-probability properties related to habitability: the presence of the Moon (necessary to stabilise the obliquity of the Earth; Laskar et al. 1993), the quasi-circular orbits of the giant planets (as opposed to the extra-solar planets), the absence of giant planets in the temperate zone, to quote only a few. Therefore, we think that the low probability to preserve a moderately excited orbit of the Earth cannot be used to disqualify the Nice model.
