ABSTRACT

Aims. We report results of an X-ray study of the supernova remnant (SNR) G344.7-0.1 and the point-like X-ray source located at the geometrical center of the SNR radio structure.

Methods. The morphology and spectral properties of the remnant and the central X-ray point-like source were studied using data from the XMM-Newton and Chandra satellites. Archival radio data and infrared Spitzer observations at 8 and 24 μm were used to compare and study its multi-band properties at different wavelengths.

Results. The XMM-Newton and Chandra observations reveal that the overall X-ray emission of G344.7-0.1 is extended and correlates very well with regions of bright radio and infrared emission. The X-ray spectrum is dominated by prominent atomic emission lines. These characteristics suggest that the X-ray emission originated in a thin thermal plasma, whose radiation is represented well by a plane-parallel shock plasma model (PSHOCK). Our study favors the scenario in which G344.7-0.1 is a 6×10^3 year old SNR expanding in a medium with a high density gradient and is most likely encountering a molecular cloud on the western side. In addition, we report the discovery of a soft point-like X-ray source located at the geometrical center of the radio SNR structure. The object presents some characteristics of the so-called compact central objects (CCO). However, its neutral hydrogen absorption column (N_{H}) is inconsistent with that of the SNR. Coincident with the position of the source, we found infrared and optical objects with typical early-K star characteristics. The X-ray source may be a foreground star or the CCO associated with the SNR. If this latter possibility were confirmed, the point-like source would be the farthest CCO detected so far and the eighth member of the new population of isolated and weakly magnetized neutron stars.

1. Introduction

The Galactic supernova remnant G344.7-0.1 was discovered in the southern sky by Caswell et al. (1975) with the Molonglo and Parkes radio telescopes at 408 MHz and 5000 MHz, respectively. High-resolution radio imaging of the source at 1465 MHz (Dubner et al. 1993) allowed to classify the object as a possible composite SNR. These radio observations revealed a clearly asymmetric and bright shell structure (stronger in the northwest direction) with an angular size of 8–10 arcmin. Values of radio flux densities at 408 MHz, 843 MHz, 1.47 GHz, and 5 GHz were measured, yielding 4.7 Jy, 2.5 Jy, 1.7 Jy, and 1.3 Jy, respectively (see, Caswell et al. 1975; Dubner et al. 1993; Whiteoak & Green 1996). As a result, a non-thermal spectral index of

-0.5 ($S \propto \nu^\alpha$) was computed for the source, which can be interpreted as the result of synchrotron radiation from high-energy electrons. The distance to the source is uncertain. However, Dubner et al. (1993) derived a linear diameter of ~ 30 pc and a distance of about 14 kpc for the SNR, applying the Huang & Thaddeus (1985) Σ -D calibration. Throughout this work, a mean distance of 14 kpc is assumed.

With the advent of the ASCA satellite, which operated in the 0.2–10 keV energy range, a large number of hard X-ray sources were discovered within the Galactic plane (Sugizaki et al. 2001). Using these ASCA data, Yamauchi et al. (2005) studied the SNR G344.7-0.1 and found that the source displays extended thermal X-ray emission with a diameter of ~ 6 arcmin and that its X-ray spectrum exhibits emission lines from highly ionized

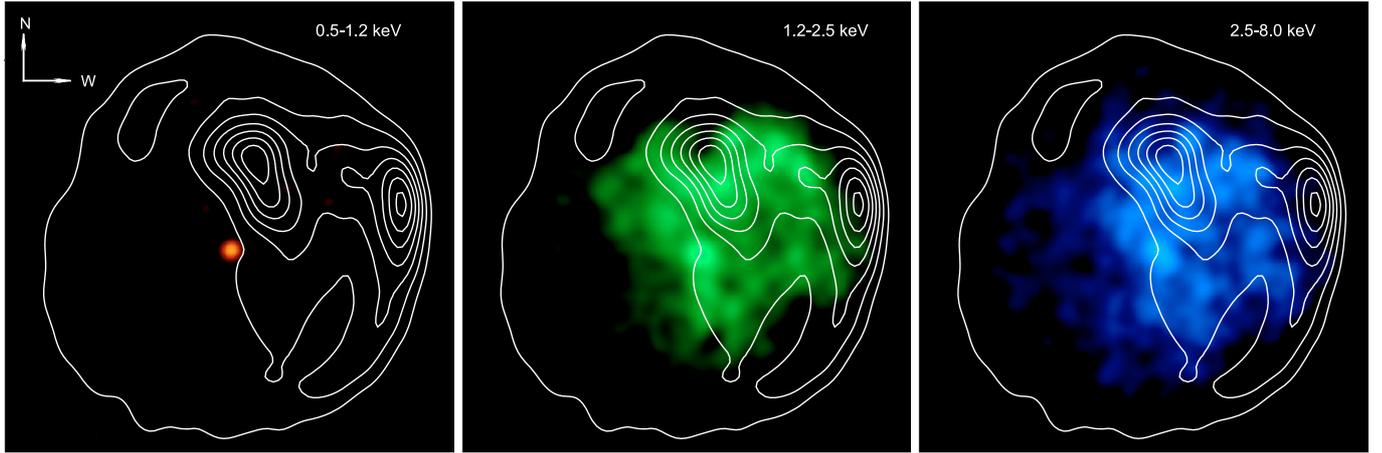

Fig. 1. Chandra ACIS images, with a size of 10.4×10.6 arcmin, of the SNR G344.7-0.1 in the three X-ray energy bands. *Left panel:* soft X-rays energies (0.5–1.2 keV) in red. *Middle:* medium X-ray energies (1.2–2.5 keV) in green. *Right:* hard X-ray energies (2.5–8 keV) in blue. Smoothed images were convolved with a two-dimensional Gaussian function using the ACONVOLVE CIAO task. Overlapping white contours are the 843 MHz radio image taken from the MOST Supernova Remnant Catalog (Whiteoak & Green 1996).

Si, S, Ar, and Ca, which indicate a thin thermal plasma origin. In addition, a strong Fe-K α line at 6.4 keV was found, which is indicative of a low-ionized Fe-rich plasma. Reach et al. (2006), using the Infrared Array Camera (IRAC) images at 3.6, 4.5, 5.8, and 8 μ m from the GLIMPSE legacy science program of the Spitzer Space Telescope, detected an area of irregularly structured infrared emission on the western side of G344.7-0.1.

With the unprecedented capabilities of the Chandra X-ray Observatory and XMM-Newton telescope, it is now possible to perform high-quality imaging and spectroscopy that are particularly well suited to the study of distant SNRs, such as G344.7-0.1. In the past decade, several new and well-known SNRs have been studied at hard X-ray energies using these instruments, with very interesting results (e.g. Senda et al. 2003; Bamba et al. 2003; Yamauchi et al. 2004; Combi et al. 2006, 2008).

In this paper, we present an X-ray study of G344.7-0.1 and the point-like X-ray source discovered at the geometrical center of the SNR, using XMM-Newton and Chandra observations. Archival Spitzer data were also used to compare the radio, infrared, and X-ray morphologies of the SNR. The structure of the paper is as follows: in Sect. 2, we describe XMM-Newton and Chandra observations and the data reduction. X-ray analysis and results are presented in Sect. 3. The results from the Spitzer observations are presented in Sect. 4 and a search for radio, infrared, and optical counterparts are presented in Sect. 5. Finally, we discuss our results in Sect. 6 and present our conclusions in Sect. 7.

2. Observations and data reduction

The field of G344.7-0.1 was observed by the Newton X-ray Multi-Mirror Mission (XMM) observatory with the European Photon Imaging Camera (EPIC) pn and MOS cameras. Furthermore, two Chandra X-ray observations conducted with the ACIS camera are available. Such a large set of observations provide us the possibility, for the first time, to perform a detailed X-ray analysis of SNR G344.7-0.1.

The XMM data were analyzed with the XMM Science Analysis System (SAS) version 9.0.0 and the latest calibrations. Chandra observation were calibrated using CIAO (version 4.1.2) and CALDB (version 3.2.2). To exclude strong background flares, which can affect the observations, we extracted light curves of photons above 10 keV from the entire field-of-view of the cameras, and excluded time intervals up to 3σ to produce a GTI file. Detailed information about the observations and the instrumental characteristics is given in Table 1.

3. X-ray study of G344.7-0.1

3.1. X-ray images

Because of the high spatial resolution and sensitivity of the data set, we were able to examine the X-ray morphology of the supernova remnant in detail. In Fig. 1, we show narrow-band images generated in the energy ranges 0.5–1.2 keV,

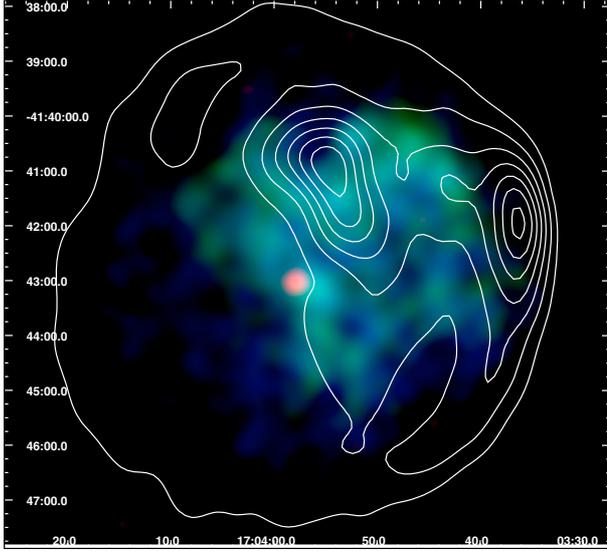

Fig. 2. Combined color-coded X-ray image of SNR G344.7-0.1 in the 0.5–8.0 keV energy band. Color coding is the same as for Fig. 1. The position of the X-ray source CXOU J170357.8-414302, at the geometrical center of the SNR, is evident in the image (see text).

1.2–2.5 keV, and 2.5–8.0 keV, with superimposed radio contours at 843 MHz (Whiteoak & Green 1996). In the soft energy range (i.e. <1.2 keV), only a point-like object is detected. Extended X-ray emission is quite prominent at medium (1.2–2.5 keV) and hard (2.5–8.0 keV) energies. As can be seen, the overall diffuse X-ray emission correlates well with the brightest radio regions and some hard X-ray emission extends towards parts of the SNR where weak or no radio emission is observed.

We combined these three images into a single false color image. Figure 2 shows an ACIS image of G344.7-0.1, where the overall structure of the diffuse X-ray emission matches the brightest regions of the radio remnant, which appears concentrated toward the northwest part of the source. Furthermore, it seems that the hard X-ray emission is more extended than the emission at medium energies. Total X-ray fluxes, for each energy range, soft (0.5–1.2 keV), medium (1.2–2.5 keV), and hard (2.5–8.0 keV) are $F_{0.5-1.2 \text{ keV}} = 7.2 \times 10^{-15} \text{ erg s}^{-1} \text{ cm}^{-2}$, $F_{1.2-2.5 \text{ keV}} = 4.7 \times 10^{-12} \text{ erg s}^{-1} \text{ cm}^{-2}$, $F_{2.5-8.0 \text{ keV}} = 5.03 \times 10^{-12} \text{ erg s}^{-1} \text{ cm}^{-2}$, which correspond to 1%, 47%, and 52% of the total observed X-ray flux ($F_{0.5-8.0 \text{ keV}} = 1.0 \times 10^{-11} \text{ erg s}^{-1} \text{ cm}^{-2}$), respectively.

The sensitivity of the Chandra observations allowed us to detect, for the first time, a soft X-ray point-like source at the geometrical center of the radio structure of the SNR. This central X-ray source is absent in the radio map, but clearly detected in the Chandra data (see Fig. 3). We used PWDetect detection code (Damiani et al. 1997a,b) to improve the quality of the detection. Since the central soft source is surrounded by non-uniform SNR emission, mostly over 1.5 keV, the detection procedure was performed onto an event list file restricted to soft energies (i.e. 0.5–1.5 keV). The source is located at $\alpha_{J2000} = 17:03:57.852$, $\delta_{J2000} = -41:43:02.03$ (hereafter we refer to this object as CXOU J170357.8-414302). A total of 49 photons were detected in a single event file in the 0.5–1.2 keV. The X-ray source has a $\sim 17\sigma$ significance above local background, being a quite robust detection.

To check whether CXOU J170357.8-414302 is a point-like object or not, we searched for extended X-ray emission (i.e. a pulsar wind nebula) that might be associated with the source. For this purpose, we applied the PWDetect detection code out to a

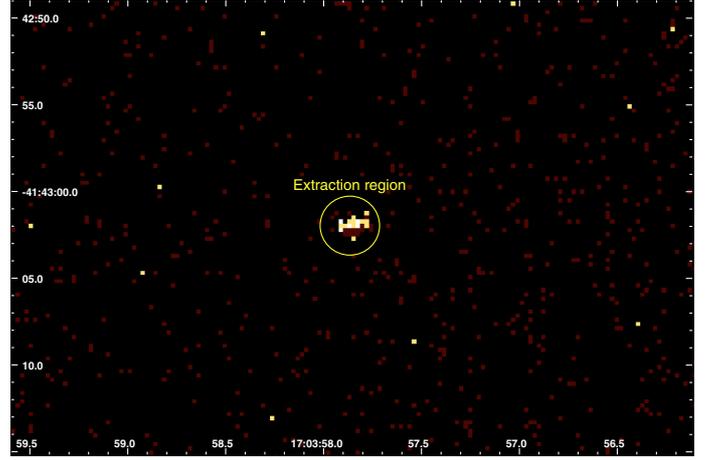

Fig. 3. Chandra ACIS image, with a size of $56'' \times 36''$, of CXOU J170357.8-414302 and its surroundings in the 0.5–1.5 keV band. The pixel size is $0.246''$ (i.e., 1/2 of the original ACIS pixel size). The yellow circle around the object shows the extraction region of $1.7''$ radius used for the spectral analysis. No pulsar wind nebula is observed in the image.

radius of 16 arcsec. As a result, the analysis shows no trace of significant extended X-ray emission around the position of the object. In Fig. 3, we show the surroundings of CXOU J170357.8-414302. The source is clearly point-like.

3.2. Spectral analysis

3.2.1. The SNR G344.7-0.1

XMM-Newton and Chandra spectra were extracted for G344.7-0.1. For the EPIC camera, we used EVSELECT SAS task with the appropriate parameters for PN and MOS 1/2 cameras. ACIS X-ray spectra was also extracted using the specific CIAO SPEXTRACT task for extended sources. The extraction radii used for the entire SNR are 2.8 and 4.3 arcmin for Chandra and XMM data, respectively. We got nine EPIC (PN 3, MOS 4) and two ACIS X-ray spectra. Background spectra were also extracted from regions in which the SNR does not emit X-rays¹.

Figure 4 shows the background-subtracted spectra obtained from the XMM-Newton and Chandra observations. We grouped the extracted EPIC and ACIS spectra with a minimum of 36 and 16 counts per spectral bin, respectively. The spectral analysis was performed using the XSPEC package (Arnaud 1996). The overall X-ray spectrum of G344.7-0.1 exhibits several strong emission lines at the energies of 1.34, 1.85, 2.00, 2.18, 2.44, 2.86, 3.12, 3.87, and 6.4 keV. Following the interactive guide for ATOMDB², we were able to identify the most prominent emission lines according to their transition intensities. Observed features in the spectra correspond to atomic transitions of Mg XI, Si XIII, Si XIV, S XV, Ar XVII, Ca XIX, and Fe XXV. However, because of the moderate spectral resolution of the EPIC and ACIS cameras, most of them are strongly affected by line blending, biasing the identification and abundance determination of single chemical elements.

X-rays from most SNRs come from a hot thin plasma consisting of ejecta and swept-up interstellar medium. The X-ray

¹ We examined the effects of the background aperture size on the spectral fitting. The parameters obtained from EPIC and ACIS spectral fit are consistent, with differences within 1σ uncertainties.

Flux [cgs]	7.25×10^{-10}	1.14×10^{-10}	6.12×10^{-11}	10.79×10^{-11}	4.74×10^{-11}	7.56×10^{-11}
χ^2_{ν} /d.o.f.	1.5/4037	1.1/70	1.4/245	1.12/142	1.1/101	1.0/64

Notes. N_{H} is in units of cm^{-2} . τ is in units of s cm^{-3} . Fe-abund is relative to solar values of Anders & Grevesse (1989). Normalization is defined as $10^{-14}/4\pi D^2 \times \int n_{\text{H}} n_{\text{e}} dV$, where D is the distance in units of cm, n_{H} is the hydrogen density [cm^{-3}], n_{e} is the electron density [cm^{-3}], and V is the volume [cm^3] in units of 10^{-3} . τ_{ll} lower limit was fix to zero while τ_{ul} upper limits, ionization time-scales was left as free parameter and is expressed in units of s cm^{-3} . EM is the emission measure of the X-ray emitting plasma in units of cm^3 . Values in parentheses are single parameter 90% confidence interval.

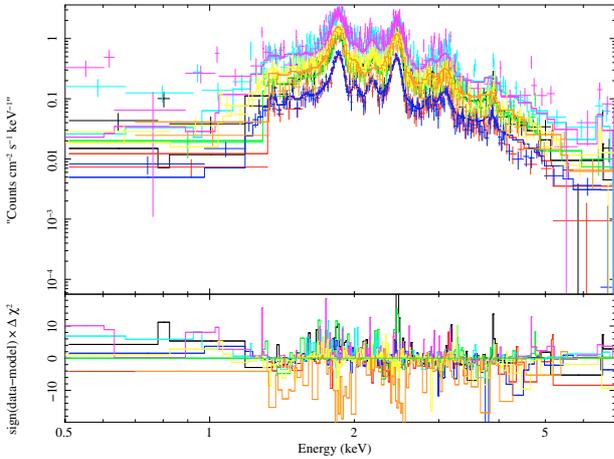

Fig. 4. Upper panel: EPIC pn (in magenta, cyan and yellow colors) and MOS1/2 (in black, red, green and blue colors) spectra of the SNR G344.7-0.1, for the distinct observations. ACIS-I X-ray spectra of the SNR is indicated in orange. Solid lines indicate the best-fit (PSHOCK) model (see Table 2). Lower panel: Chi-squared residual of the best-fit model.

spectrum of this hot plasma is usually fitted by a non-equilibrium ionization (NEI) model, with different abundances for each chemical element. In this case, the X-ray spectrum was fitted with a PSHOCK model (Borkowski et al. 2001) modified by a low-energy absorption model WABS (Morrison & McCammon 1983). To evaluate systematics, we fitted XMM and Chandra data separately, and compared results with those obtained from a simultaneous EPIC+ACIS fit (see Table 2). We decided to avoid energy channels that are not well calibrated, ignoring energies below 0.5 keV and above 8.0 keV in the X-ray spectral analysis.

In the fitting procedure, we initially froze the individual abundances to solar, and just varied the absorption (N_{H}), temperature (kT), ionization timescale upper limit (τ_{ul}), and model normalization. The ionization timescale lower limit (τ_{ll}) was fixed to zero, because the PSHOCK model describes a plasma with a linear distribution of timescales, ranging from the immediately post-shock region (where $\tau = \tau_{\text{ll}}$) to the plasma at the largest distance from the shock front (at τ_{ul}). Once we obtained the main parameters of PSHOCK, we treated the abundance as a free parameter. We note that as previously reported by Yamauchi et al. (2005), the Fe line at 6.4 keV is likely also present in our

spectra, although marginally detected. All results from our spectral analysis are shown in Table 2.

Finally, we compared the best-fit parameters obtained using a PSHOCK model, with those reported by Yamaguchi et al. (2005), obtained with the ASCA data, using a thin thermal plasma model (NEI) with an extra component for producing the Fe-K line. The higher quality photon statistics and spatial resolution of the XMM-Newton and Chandra data have obviously improved the quality of the spectral fit. The PSHOCK model naturally reproduces the observed spectrum (no extra component is required), and provides a good first approximation to the physical state of the plasma. Compared to the (NEI+Fe K line) model used by Yamaguchi et al. (2005), in the PSHOCK model every fitted parameter is more tightly constrained.

3.2.2. The source CXOU J170357.8-414302

The point-like source CXOU J170357.8-414302, detected at the geometric center of the radio SNR, is marginally detected in the XMM-Newton images. There are three available XMM-Newton observations of the region. The object is located ~ 2 arcmin offset from the aim-point and the extraction radius enclosing 90% of the energy is 9 arcsec. Unfortunately, the source is at a position where the X-ray emission from the diffuse SNR gas is intense, thus veiling the intrinsic spectrum of the source. Out of the expected 60 photons from the PN spectrum, we obtained a total of 135 photons for the background corrected spectrum, i.e. more than 50% of the photons come from the diffuse SNR X-ray emission. This situation is strongly improved in the Chandra observation.

Since the point-like source CXOU J170357.8-414302 is embedded in the diffuse X-ray emission of the SNR (see Fig. 1), the source extraction region should avoid including SNR photons. Chandra data were used for the analysis because of its high spatial resolution (see Sect. 2). Following the analysis in Pavlov & Luna (2009), we chose a $1.7''$ radius and used the CIAO PSEXTRACT script to extract a spectrum. The $1.7''$ radius aperture contains 57 photons in the 0.2–3.0 keV range. This corresponds to a source count-rate of 1.8×10^{-3} count/s. Background was extracted from the same region used for the SNR spectral analysis. The spectrum shown in Fig. 5 is background corrected. We group the spectra with a minimum of 2 photons per bin because of the low count-rate.

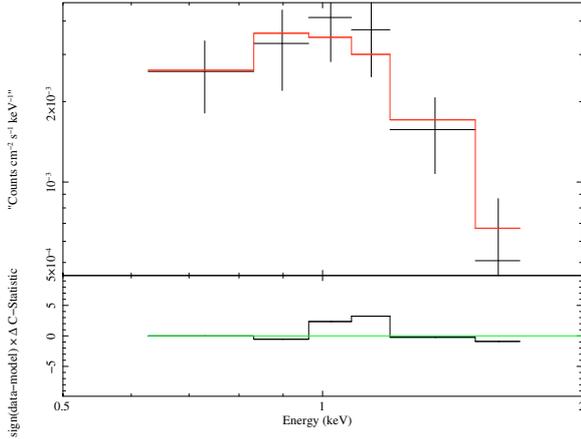

Fig. 5. Fit of the CXOU J170357.8-414302 spectrum extracted from the 1.7'' aperture with an absorbed power-law model (see text).

The CXOU J170357.8-414302 spectrum was initially fitted by a single power-law (PL) model that yields an index $\Gamma = 9.5(\pm 2)$ and a normalization of $2.4(\pm 0.4) \times 10^{-4} \text{ cm}^{-2}$. The absorption-corrected X-ray flux is $F_x = 7.8 \times 10^{-14} \text{ erg s}^{-1} \text{ cm}^{-2}$ in the 0.7–2.0 keV band. The fit is acceptable in terms of the minimum χ^2 ($\chi^2_\nu = 0.43$ for 41 d.o.f.). We also fitted an absorbed thermal APEC model, which yields a neutral hydrogen absorption column $N_H = 1.2(\pm 0.9) \times 10^{22} \text{ cm}^{-2}$ and a temperature $kT = 0.36 \pm 0.1 \text{ keV}$ with sub-solar abundance of 0.66 ± 0.8 . In this case, the absorption-corrected X-ray flux is $F_x = 6.9 \times 10^{-14} \text{ erg s}^{-1} \text{ cm}^{-2}$. The fit is acceptable in terms of the minimum χ^2 ($\chi^2_\nu = 0.51$ for 39 d.o.f.).

Finally, to search for variability in our ACIS-I observation, we used the photon arrival times in the 0.5–2.0 keV band. With the frame readout time ($t_{\text{frame}} = 3.24 \text{ s}$), we can search for variability on timescales longer than $2 t_{\text{frame}} = 6.48 \text{ s}$. No hints of variability were detected during the observation, indicating that the pulsar period, if any, should probably be shorter than 1 s. The source has not been detected in the XMM-Newton data because of the high background of the EPIC camera. Therefore, no variability study could be performed on EPIC observations.

3.2.3. Spatially resolved spectral analysis

If CXOU J170357.8-414302 and the SNR were physically related, both sources should have similar neutral hydrogen absorption column. To check for possible N_H spatial variations across the SNR region (possibly due to an extremely inhomogeneous foreground medium), we extracted spatially resolved X-ray spectra at different regions (defined in Fig. 6) of the SNR. For this purpose, we used the same model to describe the global properties of the diffuse X-ray emission. As a result, we found that the neutral hydrogen absorption column of different regions have similar values to those obtained by analyzing the global spectrum of the remnant. The X-ray spectral parameters of different regions of G344.7-0.1 are shown in Table 3. This picture is consistent with the results obtained from the infrared analysis presented in Sect. 4.

As shown in Table 2, there are small variations in the temperature of the different regions, probably due to the efficiency of the heating processes, changes in the ISM density, or the shock wave interactions. However, the global temperature ($kT \sim 1.2 \text{ keV}$) agrees with that expected from middle-aged SNRs (e.g. Williams & Chu 2005). We also studied the spatial-abundance

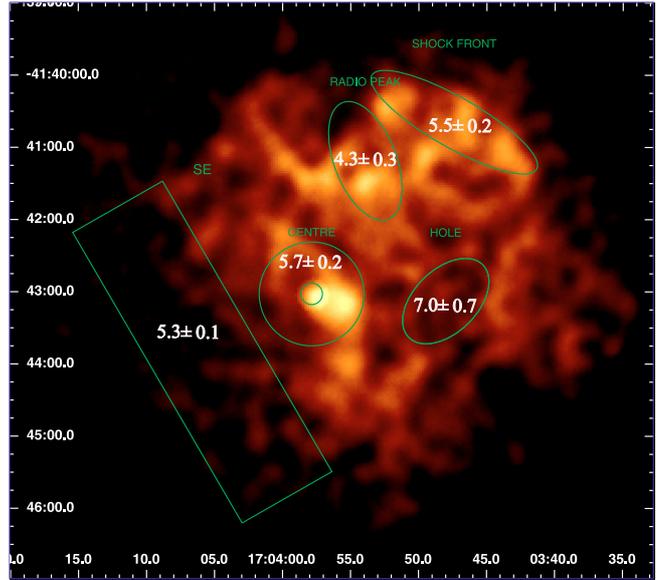

Fig. 6. Distribution of the column density N_H for different regions (i.e., centre, hole, radio peak, shock front and southeast:SE) expressed in units of 10^{22} cm^{-2} . N_H was derived using the model summarized in Table 2. Note that the central point-like source was excluded from the center region.

Notes. ^(a) U SNO-B1 (United States Naval Observatory B1.0 Catalog); ^(b) 2 MASS All-Sky Point Source Catalog (PSC).

variations, which become higher (by a factor two or even three) at the region named FRONT-SHOCK. It suggests that chemical inhomogeneities are detected in the ejecta. The other fitted parameters can be considered unchanged within the expected errors. Deep X-ray and radio observations are needed to determine changes in the spectrum along the different parts of the radio-emission, but this point is beyond the scope of this paper.

4. Infrared emission from G344.7-0.1

Using Infrared Array Camera (IRAC) images at 3.6, 4.5, 5.8, and 8 μm from the GLIMPSE science program with the Spitzer Space Telescope, Reach et al. (2006) detected an area of irregularly structured infrared emission on the western part of G344.7-0.1. Although part of the infrared emission in the IRAC channels is coincident with the brightness regions of radio emission, no SNR structure was detected with IRAC by these authors, who suggest that the infrared colors of the structure observed with IRAC are compatible with ionized shocked gas and molecular shocks (see Fig. 22, Reach et al. 2006).

It has been demonstrated that most SNR emit conspicuously at 24 μm (e.g. Borkowski et al. 2006; Williams et al. 2006; Morton et al. 2007). This emission traces warm dust (very small grains, VSG) stochastically heated to temperatures of around

Fig. 7. *Left panel:* MIPS 24 μm mosaic of G344.7-0.1. Radio contours are overplotted. The square marks the position of the punctual X-ray source observed with Chandra (small window in the left-bottom corner). Scale was determined assuming a distance of 14 kpc for the SNR. *Central panel:* three-color image of G344.7-0.1 (red is MIPS 24 μm , green is IRAC 8 μm , and blue is optical R band). *Right panel:* RGB composition of MIPS (24 μm ; red), IRAC (8 μm ; green), and Chandra (0.58.0 keV energy band; blue).

30–100 K (Li & Draine 2001). In SNRs, this dust component is heated by electrons and X-ray photons within the hot thermal gas (Dwek & Werner 1981; Hines et al. 2004). Therefore, a correlation between X-ray and 24 μm emission is expected.

To investigate the 24 μm emission from hot grains in G344.7-0.1, we used a Spitzer-MIPS (Rieke et al. 2004) observation of the region performed in October 2006 (AORs. #20496896, #20497152, and #20497408). The MIPS basic calibrated data (BCD) were downloaded from the Spitzer archive. These images were processed with the regular MIPS pipeline (version S18.7.0), and then mosaicked using MOPEX (version 18.3.1) and the standard MIPS 24 μm mosaic pipeline. In Fig. 7, left, central and right panels we show the MIPS image with superimposed radio contours, without the radio contours, and a composite of the infrared, optical, and X-ray images, respectively. In contrast to what is observed in the IRAC bands by Reach et al. (2006), the 24 μm emission fills the radio contours and exhibits a good correlation with the diffuse X-ray emission.

In general, the 24 μm emission exhibits a filamentary morphology that is strongly correlated with regions of radio emission. In addition, two external infrared filaments seen at 24 μm are not observed in X-rays. They coincide in location with the southwest and northeast filaments observed at radio wavelengths. In Fig. 7 (right panel), we show an RGB color-coded image of the SNR. We used red for the 24 μm emission, green for the IRAC 8 μm emission (AOR #11957248), and blue for an DSS optical image in the R band. Emission from interstellar medium at 8 μm is dominated by polycyclic aromatic hydrocarbon (PAH) bands.

5. Search for radio, infrared, and optical counterparts to CXOU J170357.8-414302

To identify possible radio, infrared or optical counterparts within the location error box of the central X-ray source, we used VLA data, inspected the 2 Micron All Sky Survey (2MASS, Cutri et al. 2003), and searched the USNO B1.0 optical catalog (Monet et al. 2003).

To find evidence of radio emission from the CXOU J170357.8-414302 source, we explored the radio data in the National Radio Astronomy Observatory (NRAO) archive. The region has been barely observed and therefore data from

only three projects were retrieved. Among them only the AD260, conducted on 1991 February 23 with the Very Large Array (VLA), is available in continuum. This observation was carried out in CD-configuration at 20 cm wavelength, amounting to a total on-source time of 40 min. The instrumental setup included two intermediate frequency (IF) pairs with 50 MHz bandwidth each. The data set was processed using the AIPS software package of NRAO following the standard procedures for continuum calibration of interferometers. The flux density scale was set using the primary amplitude calibrator 3C 286, whereas the phase calibration was performed by repeated observations of the nearby phase calibrator 1730–130. At the end of a self-calibration deconvolution iteration scheme, we produced several versions of the radio map using different values for the ROBUST and UVRANGE parameters to enhance the point-like sources. A close inspection indicates no source detection inside or in the vicinity of the Chandra error circle. The resulting radio flux upper limit ($3\text{-}\sigma$) at 20 cm is estimated to be 0.9 mJy/beam.

At the infrared and optical part of the spectrum, we found the sources USNO B1.0 0482-0503281 and 2MASS J17035785-4143020 to be consistent with the Chandra position of the putative point-like X-ray source. Figure 8 displays the probable USNO R -band counterpart of CXOU J170357.8-414302. Table 3 displays the photometric properties of the infrared and optical counterparts of the central source.

6. Discussion

6.1. The origin of the diffuse X-ray emission in G344.7-0.1

The X-ray analysis presented above has detected centrally bright X-ray emission from SNR G344.7-0.1 that is apparently thermal. Its spectrum is dominated by prominent atomic emission lines such as Mg XII, Si XIII, Si XIV, S XV, Ar XVII, Ca XIX, and Fe XXV, and is represented well by a plane-parallel shock plasma model with variable abundances. The most intense region of radio emission and the diffuse X-ray emission of G344.7-0.1 correlate spatially well with an area of irregularly structured infrared emission detected with the Spitzer Space Telescope (see Fig. 7 in Reach et al. 2006). These results indicate that the irregular morphology of the remnant is caused by the expansion through a dense interstellar medium with a density gradient towards the west of the remnant.

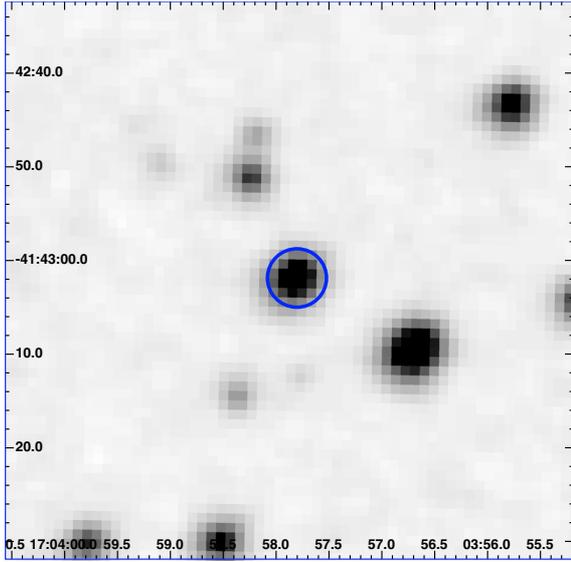

Fig. 8. USNO *R*-band counterpart of the central X-ray source CXOU J170357.8-414302. The position error circle (in blue) is shown in the image.

It is widely accepted that the soft X-ray emission from middle-aged SNRs is produced by their expansion against a dense medium, while the hard component originates in the interior heated by a fast shock in the early stage of the SNR evolution. In the case that we have studied, the soft X-ray emission arises mainly from the compact central source CXOU J170357.8-414302, and the thermal medium/hard X-ray emission, which correlates with regions of enhancement radio and infrared emission along the western edge of the SNR, seems to be associated with hot gas in the remnant interior, heated by the passage of the shock wave.

On the basis of information gathered at radio and X-ray wavelengths, it has been possible to delineate the evolution of G344.7-0.1. We first estimated the volume V of the X-ray emitting plasma. Assuming that the plasma fills a sphere with a diameter of 6 arcmin, we obtained a volume of $4.9 \times 10^{58} \text{ cm}^3$ at a mean distance of 14 kpc. Using the emission measure (EM) determined from the spectral fitting, we estimated the electron density of the plasma $n_e = \sqrt{EM/V}$ to be 1.26 cm^{-3} . In this case, the density of the nucleons was simply assumed to be the same as that of electrons. The age t was then determined using the upper limit ionization timescale, τ_{ul} , by $t = \tau_{\text{ul}}/n_e$. As a result, the elapsed time after the plasma was heated is $\sim 6 \times 10^3 \text{ yr}$. The total mass of the plasma M_{total} was estimated to be $M_{\text{total}} = n_e V m_{\text{H}} \sim 54 M_{\odot}$, where m_{H} is the mass of a hydrogen atom.

On the other hand, we can independently estimate the age of the SNR using standard arguments based on the Sedov dynamics (Sedov 1959). Assuming that the SNR expansion is adiabatic and adopting a mean distance of 14 kpc for G344.7-0.1, we found that the SNR radius should be $R \sim 16 \text{ pc}$. If the SNR expansion occurs in a medium with density $n \sim 0.2 \text{ cm}^{-3}$, and the released SN total energy is $E \sim 1.0 \times 10^{51} \text{ erg}$ (Spitzer 1998), then the SNR age is $t \sim 6.5 \times 10^3 \text{ yr}$. This value is consistent with that obtained from the X-ray emitting plasma.

6.2. The nature of CXOU J170357.8-414302

The point-like X-ray source located at the geometrical center of the SNR, exhibits steady X-ray flux emission that appears to

exclude an accreting binary origin and soft thermal spectra that rules out a background active nucleus, lacks a radio counterpart, and contains no surrounding pulsar wind nebula. Therefore, the source displays some characteristics in common with the so-called CCO (see Pavlov et al. 2004, for a review), a new population of isolated neutron stars (NSs) with clear differences from isolated rotation-powered pulsars, and accretion-powered X-ray pulsars in close binary systems.

At present, only seven confirmed examples of CCOs are known (Gotthelf et al. 2005; Halpern & Gotthelf 2010). The nature of these CCOs is still unclear. It is thought that the X-ray emission from CCOs is generally caused by the thermal cooling of the NS (e.g., Zavlin et al. 1999), with typical temperatures of a few 10^6 K , as inferred from their thermal-like spectra. They have X-ray luminosities (L_X) in the range of 10^{33} – $10^{34} \text{ erg s}^{-1}$ and display X-ray spectra characterized by a black-body model with temperatures (kT) in the range of 0.2–0.5 keV or a power-law model with very steep index Γ (see Pavlov et al. 2003). Halpern & Gotthelf (2010) suggested that these objects could be weakly magnetized NSs ($B \sim 10^{10} \text{ G}$), i.e., a kind of “anti-magnetars”.

To verify the other physical parameters of CXOU J170357.8-414302, we computed its L_X and spin-down luminosity \dot{E} , to compare with well-known CCOs objects (Pavlov et al. 2003). Adopting again a mean distance of 14 kpc, we determined a total unabsorbed X-ray flux of $F_{0.7-2.0} = 6.9 \times 10^{-14} \text{ ergs cm}^{-2} \text{ s}^{-1}$, which corresponds to an unabsorbed luminosity $L_X = 1.6 \times 10^{33} \text{ erg s}^{-1}$. A rough estimate of the spin-down luminosity can be derived using the empirical formula by Seward & Wang (1988), $\log L_X (\text{erg s}^{-1}) = 1.39 \log \dot{E} - 16.6$, which implies that $\dot{E} = 6.7 \times 10^{35} \text{ erg s}^{-1}$. This value of L_X agrees with those in the range listed by Pavlov et al. (2004) and Halpern & Gotthelf (2010) for CCO objects. The second quantity, \dot{E} , falls below the empirical threshold for generating bright wind nebulae of $\dot{E}_c \approx 4 \times 10^{36} \text{ erg s}^{-1}$. All the results obtained are typical of CCO found in other supernova remnants (e.g. Pavlov et al. 2004; Gotthelf et al. 2008).

Nevertheless, we found an infrared and optical source that is positionally coincident with the point-like X-ray source, whose near-infrared colors ($J - H \approx 0.08$ and $H - K \approx 0.45$) are typical of an early-K star (giant or dwarf). If this source were the counterpart of the X-ray source, then the X-ray-to-optical flux ratio would be $F_X/F_H \sim 7.9 \times 10^{-3}$, which may exclude a neutron star origin of the central source (Fesen et al. 2006). However, the stellar density in the direction of G344.7-0.1 ($l = 344.7$, $b = -0.2 \text{ deg}$) is very high. The 2MASS catalog contains 4638 point-like sources in a radius of 3 arcmin from the center of G344.7-0.1, 1318 of them with $J \leq 14.5 \text{ mag}$. Thus, a chance near-alignment between a foreground star and the central object found inside the SNR seems probable.

To evaluate probability of the chance alignment between the central X-ray object and the central position of G344.7-0.1, we computed the probability that the distance between the geometrical center of the SNR and the position of the point-like source is smaller than the observed one. This is expressed by

$$P(d < d_{\text{obs}}) = 1 - e^{-n\pi d^2} \approx n\pi d^2, \quad (1)$$

where n is the density of X-ray sources (in arcsec^{-2}), inside the radio SNR contours ($n \sim 0.00478 \text{ arcsec}^{-2}$). The distance from the X-ray source to the SNR center exhibits an offset of $d \sim 14.2''$. We obtained a probability $P(d < d_{\text{obs}}) = 0.0035$, i.e. just a 0.35% chance alignment probability.

We also calculated the chance association of the observed 2MASS source with the CCO candidate. The total number of

IR sources in the SNR is 4670, thus the source density n is 0.0083325. Therefore, according to the previous relation, the probability that the X-ray to 2MASS PSFs are mismatched at a distance d is $P(\sigma_X - \sigma_{\text{spitzer}}) = 0.16$, i.e., a chance association probability of $\sim 16\%$.

Although no robust value of the distance to CXOU J170357.8-414302 can be determined, one may attempt to determine it from its visible and near-infrared colours. Assuming a spectral type K0 for a dwarf star, the source may be placed at a distance of between 450 and 800 pc. If the star were a giant, the distance would increase to 10 kpc, still far from the location of the SNR (at ~ 14 kpc). Nevertheless, we note that only giants in close binary systems emit in X-rays.

If the infrared and optical sources were physically unrelated to the X-ray source, then CXOU J170357.8-414302 might be a CCO. However, this latter possibility seems improbable since the N_{H} value of the object is inconsistent with that for G344.7-0.1. If the point-like object and the SNR are physically associated then the foreground medium (between the observer and the source) must be extremely inhomogeneous. In this case, it may have been produced by a foreground molecular cloud with a density of 1000 particles cm^{-3} extending 10 pc along the line of sight. This enormous cloud should be “in front” of the northwest region, but not in front of the “center” region, where a kind of “hole” in the interstellar absorption must be invoked. This dense and huge molecular cloud, if present, should be detectable by carbon monoxide (CO) observations. Unfortunately, at present high-resolution CO observations of this region do not exist.

7. Conclusions

We have presented an X-ray study of the SNR G344.7-0.1, using new XMM-Newton and Chandra observations. In addition, Spitzer \check{U} -MIPS observations at 24 μm have been used to study the infrared morphology of the source. A clear correlation between X-ray and infrared emission indicates that radiation in both wavebands originated in the SNR. The IR flux has allowed us to characterize the medium in which the remnant is expanding. The detected diffuse X-ray emission correlates well with the brightest radio regions of the SNR. At both radio and X-ray wavelengths, the western half of the remnant is substantially brighter than the eastern half, where irregular infrared emission is also concentrated. The X-ray spectrum exhibits emission lines from Mg, Si, S, Ar, and marginally Fe. Lines of Mg XI (1.34 keV), Si XIV (2.0 keV), and S XV (2.86 keV) were detected for the first time in this object. The X-ray characteristics suggest that the radiation has a thin thermal plasma origin, which is represented well by a plane-parallel shock plasma model. This provides a good first approximation to the physical state of the plasma. The overall imaging and spectral properties of G344.7-0.1 favor the interpretation of a middle-aged SNR ($\sim 6 \times 10^3$ yr old), propagating in a dense medium and likely encountering a molecular cloud on its west side. G344.7-0.1 provides an excellent laboratory to study the evolution and interaction of a SNR with its surrounding medium.

In addition, we have reported the discovery of a soft point-like object at the geometrical center of the G344.7-0.1 radio structure with some CCO characteristics. A broadband study from radio to the X-ray domain has shown that it might have infrared and optical counterparts. If the infrared and optical sources were physically unrelated to the X-ray source, then CXOU J170357.8-414302 might be a CCO. However, this latter possibility seems unlikely since the N_{H} value of the object is inconsistent with that of G344.7-0.1.

In summary, taking into account all gathered information we cannot confirm the nature of the object, and therefore its origin remains uncertain. Optical spectroscopic observations of the infrared/optical source are necessary to fix the distance. New Chandra observations, with a longer exposure time, will be important to improve our knowledge of this source.
