ABSTRACT

Context. With the latest infrared surveys, the number of massive protostellar candidates has increased significantly. New studies have posed additional questions on important issues about the formation, evolution, and other phenomena related to them. Complementary to infrared data, radio observations are a good tool to study the nature of these objects, and to diagnose the formation stage.

Aims. Here we study the far-infrared source IRAS 16353–4636 with the aim of understanding its nature and origin. In particular, we search for young stellar objects (YSOs), possible outflow structure, and the presence of non-thermal emission.

Methods. Using high-resolution, multi-wavelength radio continuum data obtained with the Australia Telescope Compact Array*, we image IRAS 16353–4636 and its environment from 1.4 to 19.6 GHz, and derive the distribution of the spectral index at maximum angular resolution. We also present new JHKs photometry and spectroscopy data obtained at ESO NTT**. 13CO and archival H I line data, and infrared databases (MSX, GLIMPSE, MIPSGal) are also inspected.

Results. The radio continuum emission associated with IRAS 16353–4636 was found to be extended (∼10 arcsec), with a bow-shaped morphology above 4.8 GHz, and a strong peak persistent at all frequencies. The NIR photometry led us to identify ten near-IR sources and classify them according to their color. We used the H I line data to derive the source distance, and analyzed the kinematical information from the CO and NIR lines detected.

Conclusions. We have identified the source IRAS 16353–4636 as a new protostellar cluster. In this cluster we recognized three distinct sources: a low-mass YSO, a high-mass YSO, and a mildly confined region of intense and non-thermal radio emission. We propose the latter corresponds to the terminal part of an outflow.

Key words. stars: early-type – radio continuum: stars – radiation mechanisms: non-thermal

1. Introduction

The availability, in recent years, of infrared survey products like the MSX (Price et al. 2001) and successive catalogs have provided an extremely rich database to look for massive young stellar objects. Programs such as the Red MSX Survey (RMS; Lumsden et al. 2002; Hoare et al. 2005) have been successful in finding thousands of candidates. The goals of these surveys have been to confirm the evolutionary status of luminous, embedded sources, to perform a statistical analysis of these objects on galactic scales, and to look for efficient mechanisms for massive star formation.

Observations of star forming regions and associated outflows at radio wavelengths can be used to further our understanding of massive star formation, a topic which is still not completely understood. However, such studies require high angular resolution and sensitivity, because massive young stars are often found at kilo-parsec distances and are usually associated with densely populated clusters of intermediate and low mass stars.
Up to now, only a few massive young stellar objects (massive YSOs or MYSOs) are related to collimated jets mapped at the radio range, such as the Serpens sources (Rodríguez et al. 1989), HH 80-81 (Martí et al. 1993), and IRAS 16547–4247 (Garay et al. 2003). Garay et al. found this last object to be a triple quasi-linear radio source, that shows non-thermal indices at the lobes. The source could be associated with a molecular core. The authors have proposed that it is a MYSO ejecting a collimated wind that interacts with the surrounding interstellar medium, producing shocks and consequent radio emission. In recent years, near-IR and (sub)millimeter line studies have proved very valuable in supplying more information on (M)YSOs; see, for example, Varricatt et al. (2010) and references therein.

We have found an intense infrared source, IRAS 16353–4636 ($l, b = 337.99^\circ, 0.08^\circ$) which seems to share some characteristics with IRAS 16547–4247, the object observed by Garay et al. (2003). The source IRAS 16353–4636 has been cataloged as a star-forming region by Avedisova (2002), based on its IRAS colors, and studied for the first time by Combi et al. (2004). Although the available multi-wavelength data from radio to high-energy gamma rays suggested it could be a microquasar candidate, later X-ray observations with XMM-Newton provided a more precise position that was away from the IRAS source and its radio counterpart (Bodaghee et al. 2006). In fact, the X-ray source has been found to be an accreting X-ray pulsar.

The main goal of this study is to establish the nature of IRAS 16353–4636. Section 2 describes the already known sources in the target field, and details the observation and reduction processes we have carried out. In Sect. 3 we present the results. A discussion is given in Sect. 4 and the conclusions are stated in Sect. 5.

### 2. Observations and data reduction

#### 2.1. The field of IRAS 16353–4636

The infrared source is centered at $(\alpha, \delta) [J2000] = 16^h39^m3.52^s, −46^d42'28.28''$. The uncertainty ellipse major and minor axes and position angle are $14'' \times 4'', 97^\circ$ (Beichman et al. 1988). Mid-IR and Far-IR fluxes are given in Table 1. Sources from other catalogs are found in the neighborhood and we plotted them in Fig. 1. The MSX6C catalog (Egan et al. 2003) lists the source G337.9947+0.00770, which coincides with IRAS 16353–4636 and is detected at the four MSX bands (Table 1).

In the frame of the RMS Survey, Urquhart et al. (2007) have detected $^{13}$CO ($J = 1-2$) emission lines from the MSX source, using the Mopra Telescope (angular resolution: $20''$, velocity resolution: $0.2 \text{ km s}^{-1}$, and noise temperature: $0.1 \text{ K}$). Very recently, Mottram et al. (2010) have estimated the MIPSGal $70 \mu \text{m}$ flux of the RMS source (Table 1).

In addition, there are two Spitzer-GLIMPSE point sources (SSTGLMC G337.9986+0.0758 and G337.9907+0.0733, Benjamin et al. 2003; Churchwell et al. 2009) in the vicinity of our target, though neither of them is positionally coincident with IRAS 16353–4636.

The X-ray source IGR J16393–4643 (Bodaghee et al. 2006; Chatty et al. 2008; Corbet et al. 2010), which is of X-ray pulsar origin, is also plotted in Fig. 1. The region also hosts a low-frequency radio source, J163903.9–464215.55, detected with the Giant Millimetre Radio Telescope (GMRT; Pandey et al. 2006) at 610 MHz. There is no spatial correlation between IRAS 16353–4636 and the X-ray and GMRT-radio sources.

Spitzer-GLIMPSE point sources: filled circles (Benjamin et al. 2003); MSX6C G337.9947+0.00770: square, GMRT-610 MHz J163903.9–464215.55 (Pandey et al. 2006): hollow circle; IGR J16393–4643 (Bodaghee et al. 2006): larger cross. Smaller cross: observations of $^{13}$CO line (Unqvart et al. 2007).

#### 2.2. ATCA

We have carried out radio continuum observations toward the source IRAS 16353–4636, with the Australia Telescope Compact Array (ATCA), at the frequencies 1.384, 2.368, 4.800, 8.640, 17.344, and 19.648 GHz.

Observations in the cm range. The data were taken in 2004 January 11, in the 6A configuration, at full synthesis (16:00–4:00 UT). The field was observed interleaving simultaneous observations at two frequency pairs: 1.384/2.368 GHz and 4.800/8.640 GHz. PKS 1934–638 served as the flux calibrator, and the nearby source 1646–50 was observed for phase calibration. The total bandwidth at these four frequencies was 128 MHz over 32 channels. The total time on source at each frequency resulted in 247 min at 1.384 and 2.368 GHz, and 201 min at 4.800 and 8.640 GHz.

Observations in the mm range. We observed simultaneously at 17.344 and 19.648 GHz in 2006 March 29, using ATCA in the 6C configuration (13:00–0.30 UT). The sources PKS 1934–638,

Notes. mJy/b: mJy beam\(^{-1}\), \((\text{1})\) \(R = \text{Robust, see text.}\)

1253–055 and 1646–50 were used as flux, bandpass, and phase calibrators, respectively. The total bandwidth was 128 MHz over 32 channels. The total time on source was 528 min. The high phase stability allowed us to perform 12-min target source scans.

All six data sets were reduced and analyzed with the MIRIAD package. The calibrated visibilities were Fourier-transformed using “natural”, “uniform”, and “robust” weightings. The robust weighted images combine the “natural” lower noise and the “uniform” higher angular resolution (Briggs 1995). The robustness parameter was set to \(R = 0\) for the 6A (cm) data, and to +2 for the 6C (mm) data\(^{1}\). The resulting synthesized beams and rms are given in Table 2.

2.3. VLA data

We searched for data in the VLA archives and found observations centered relatively close to IRAS 16353–4636, taken in 2001 February 1 at 20 cm in the BnA configuration. The data were taken with one IF centered at the rest frequency of the hyperfine transition of H\(\text{I}\) (1420.406 MHz), with 127 channels over a total bandwidth of 1.56 GHz, giving a width of 12.2 kHz (or 2.58 km s\(^{-1}\)) per channel. After Hanning smoothing, this resulted in a velocity resolution of 5.16 km s\(^{-1}\) per channel. The spectral observations were centered at \(\nu_{\text{LSR}} = 0\) km s\(^{-1}\). The data were edited, calibrated, and imaged using the software package Astronomical Image Processing System (AIPS) of NRAO\(^{2}\). The resulting synthesized beam was 16\("\) \times 38\("\).

2.4. NTT NIR

We conducted photometric (\(J, H\) and \(K\), filters) and spectroscopic (0.9–2.5 \(\mu\)m) NIR observations of IRAS 16353–4636 on 2004 July 10 with the spectro-imager SofI, installed on the ESO New Technology Telescope (NTT). The large field imaging of SofI’s detector was used, giving an image scale of 0.15\("\) per channel. The data were edited, calibrated, and imaged using the software package Astronomical Image Processing System (AIPS) of NRAO\(^{3}\). The resulting synthesized beam was 10\("\) \times 38\("\).

Notes.

---

1. “Robust” weights are a function of local \(u−v\) weight density: in regions where the weight is low [high], the effective weighting is natural [uniform]. The optimal value thus depends strongly on the configuration. Larger values of \(R\) can produce beams that have nearly the same point source sensitivity as the naturally weighted beam, but with enhanced resolution.

2. The National Radio Astronomy Observatory is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc.
Fig. 2. ATCA radio continuum images of IRAS 16353−4636. A: image at 1.4 GHz; contour levels of −3, 3, 5, 10, 18, 30, and 45 times the rms noise of 1.0 mJy beam$^{-1}$. B: image at 2.4 GHz; contour levels of −3, 3, 5, 10, 18, 30, and 45 times the rms noise of 0.5 mJy beam$^{-1}$. C: image at 4.8 GHz; contour levels of −3, 3, 6, 9, 12, 20, 30, 45 and 60 times the rms noise of 0.14 mJy beam$^{-1}$. D: image at 8.64 GHz; contour levels of −3, 3, 6, 9, 12, 20, 24 and 28 times the rms noise of 0.09 mJy beam$^{-1}$. E: image at 17.344 GHz; contour levels of −3, 3, 5, 8, 11, 14, 17, 19, and 20 times the rms noise of 0.10 mJy beam$^{-1}$. F: image at 19.648 GHz; contour levels of −3, 3, 5, 8, 11, 14, 17, 19, and 20 times the rms noise of 0.09 mJy beam$^{-1}$. Synthesized beams are plotted at bottom left corners. North is up and east is to the left.

Page 4 of 9
strongest of the southern sources (here called #5, see below) is

the position of the strongest of the eastern sources (#8, see below),
\( \alpha > 0 \); and (iii) a negative spectral index corresponds to the PPP
radio maximum.

3.2. VLA

We produce a continuum image at 1.42 GHz using the line-free
channels in the +5 to +152 km s\(^{-1}\) range. It basically matches the
ATCA image obtained at 1.354 GHz, thus confirming the results of
the ATCA observations albeit with pointing differences. These are
probably due to poor phase referencing at low elevations for the VLA.

From the VLA data set, we also obtain \(^1\)H\(^\alpha\) spectra toward the
peak in these radio data. The center of the box region over which the \(^1\)H\(^\alpha\) emission was averaged coincides with star #5 in
our near-IR observations (see below). However, due to the larger angular resolution of the VLA data, the region encompassed all
the near-IR sources relevant here. The \(^1\)H\(^\alpha\) spectrum of the target is presented in Fig. 4, Hanning-smoothed to a resolution of
5.2 km s\(^{-1}\). At negative velocities there is broad absorption down to
\(-100 \) km s\(^{-1}\), followed by a detached feature spread over 4 channels, centered at a velocity of approximately \(-120 \) km s\(^{-1}\).

3.3. NTT NIR

We show the final \( J, H \) and \( K_s \) band images in Fig. 5; we also compare our 17.3 GHz radio map with the \( K_s \) band image in
this figure. Besides diffuse NIR emission, there are several point-
like objects. We have identified the brightest ones, and numbered them from 1 to 9 at increasing right ascension (labeled in Fig. 5, bottom left panel).

The \texttt{daophot} package in the IRAF suite has been used to extract all the sources in the crowded field through PSF fitting. The aperture has been adapted from 4 to 10 pixels, up to the Airy’s ray if possible, to each source, only to take into account the stellar flux, subtracting the nebula flux. At the end of the extraction process, we apply an aperture correction so as to finally use the same aperture photometry for all of the sources. An adjacent annulus of 1 pixel outer radius is used to estimate the sky background. The results are quoted in Table 3. The magnitudes of the whole extended emission (point-like sources and diffuse emission) are \( J = 13.1 \pm 0.5, H = 11.9 \pm 0.2 \) and \( K_s = 10.7 \pm 0.2 \).

The NTT photometry is used to build a color–color (C–C) plot, \((J–H)\) versus \((H–K_s)\) colors are plotted in Fig. 6. As a reference, we have included the loci of dwarf, giant and supergiant stars, following the intrinsic colors listed by Tokunaga (2000). Straight dotted lines show the reddening vectors for these stars, and define a band where stars with normal colors, only affected by reddening, are expected to be found in the diagram. All the objects lying to the right of this band show an infrared excess in their \( H – K_s \) colors and are presumably young stars still undergoing some form of accretion.

From a global point of view, all the objects in Fig. 6 seem to share a common amount of reddening, equivalent to 8 to 10 mag of extinction in the visual band. The colors of objects #1, 2, 3, and 4 are characteristic of reddened normal stars like foreground objects. The rest of the sources shows an infrared excess at \( K_s \)-band; they could represent an embedded cluster of YSOs. We have examined in particular the two brightest \( K_s \) sources with colors of protostellar objects (stars #5 and #8). We use NTT spectroscopy, and SED fitting to study #5 and #8, respectively. Notably, source 8 lies close to the IRAS and MSX peak in this region, and is the most extreme outlier in the C–C diagram. Source 8 also coincides with a region of positive spectral index in our radio data (Fig. 3). This is consistent with thermal radio emission which could be associated with a thermal radio jet or optically thick HII region (Martí et al. 1993). Source 8 is therefore potentially the best candidate for an intermediate or even high-mass YSO in the cluster. Source 5, on the other hand, coincides with non-thermal radio emission, as one might expect if this source was also a YSO associated with an outflow (see for example Bosch-Ramon et al. 2010 for theoretical considerations).

It is unlikely, however, that source 5 is a UCHII region, since UCHII regions are usually associated with thermal emission (Wood & Churchwell 1989).
Fig. 5. Upper left panel: $J$-band image of the region toward IRAS 16353$-4636$, obtained with the NTT on 2004 July 10. Levels: 1, 3, 5, 10, ..., 100, 120, 150, 190, 250, 320, and 400 Jy. The uncertainty in the position of the IRAS source is indicated by an ellipse. Upper right panel: the same as the upper left panel but in the $H$ band. Levels: 5, 10, 20, ..., 400 Jy. We show the position and size of the slit used for spectroscopic purposes. Lower left panel: the same as the upper left panel but in the $K_s$ band. Levels: 20, 30, ..., 400 Jy. The extended emission appears more clearly than in the $J$- and $H$-band images. Several point-like sources are visible, and labeled with numbers as in Table 3, at increasing right ascension. Lower right panel: continuum emission at 17.344 GHz in greyscale and grey contours, superimposed on to black contours corresponding to strongest near-IR $K_s$ sources. North is up and east is to the left.

Figure 5, bottom right panel, shows the correlation of near-IR emission ($K_s$ band) with radio emission at 17.3 GHz. The radio peak has no near-IR counterpart. The comparison tells us that the spectral index/NTT sources coincidences evident in Fig. 3 must be taken with caution, since the radio emission associated with NIR sources 5 and 8 appears to be swamped by extended emission associated with the radio peak itself. Sources 5 and 8 are not discretely resolved in the radio data. So its not entirely clear that the negative and positive spectral indices observed around sources 5 and 8 are really linked to these NIR point sources. The bulk of the radio emission may be unrelated to the NIR sources.

3.4. Individual sources

Source #5. Our NTT spectrum of source 5 reveals the presence of $H$ I emission lines and absorption in the CO vibrational bands ($^{12}$CO and $^{13}$CO, $\Delta v = 2$ and 3), typical of pre-main sequence stars (see Nisini et al. 2005, and references therein). Figure 7 shows the spectrum with individual lines identified in the $J$, $H$, and $K_s$ bands.\(^3\)

\(^3\) We checked the lines at http://www.jach.hawaii.edu/UKIRT/astronomy/calib/spec_cal/lines.html

Fig. 6. Near-infrared color–color plot ($J-H$) vs. ($H-K_s$) derived using the magnitudes measured by us with the NTT, listed in Table 3. The dotted curves show the loci of dwarf, giant and supergiant stars, based on the intrinsic colors by Tokunaga (2000). The straight dotted lines represent the reddening vectors for these stars (see text).

We find the following spectral lines: Pa$\beta$, Pa$\delta$, $^{12}$CO lines and bands, $^{13}$CO bands, Br$\gamma$, and possibly Br10, Br11. All
of them are characteristic of star-forming regions. Many lines peak at velocities close to or more negative than the H1 absorption feature at $-120$ km s$^{-1}$. Table 4 lists the suggested line identifications, measured wavelengths, rest wavelengths, and measured LSR central velocities. A standard Galactic rotation circular model, such as Brand & Blitz (1993), assigns a minimum velocity of about $-125$ km s$^{-1}$ to the gas at the tangent point. Table 4 indicates that the velocity shifts are extremely widespread.

Errors in the determination of radial velocities are strongly dependent on the signal of the individual lines measured and the wavelength resolution of the spectrum. For relatively strong emission lines, such as Br$\gamma$, the uncertainty in the estimation of the centroid of the Gaussian profile is expected to be about 1 pixel, which is equivalent to about 14 km s$^{-1}$. The uncertainty grows for less intense profiles and largely increases for the CO lines, for which no profile fitting is possible as we are dealing with unresolved absorption bands.

Besides identifying hydrogen emission and CO absorption features that are typical of pre-main-sequence (PMS) interaction, we were also able to identify a few absorption lines, which can be attributed to the PMS star itself. As shown in Fig. 7, Mg I (1.71 $\mu$m) and Na I (2.20 $\mu$m) seem to be present in our NIR spectrum, although somewhat noisy, with equivalent widths of $\sim$ 3 Å and $\geq$ 2 Å, respectively. Notwithstanding the presence of spectral veiling from the circumstellar disk, we can perform a first-order approximation of the stellar spectral type, making use of the atlas of Rayner et al. (2009) and its discussion in Bik et al. (2010). From the cool star atlas, we find that the present combination of equivalent widths can only be found in a late (K5-M0) dwarf star.

Source #8. The position of the MSX source G337.9947+0.0770 (Sect. 2) corresponds to NTT source #8. Mottram and co-workers (2010) have measured the 70-$\mu$m flux toward this MSX source, from the Spitzer-MIPSGal data, also noting that IRAS 60 and 100-$\mu$m fluxes can be considered upper limit fluxes of the same source. We use these mid-infrared fluxes, together with our near-infrared photometry, as inputs for the SED builder and fitting tool by Robitaille et al. (2007)$^4$. The authors have built a grid of precomputed radiative transfer models that use a fast $\chi^2$ minimization algorithm. If $N$ is the number of data points (excluding the upper limits), we select the two models for which $\chi^2 - \chi^2_{\text{min}} < 2N$. In Fig. 8 we plot the best model that fulfills the last condition. The SED has been built with the NTT $JHK_s$ fluxes, the MSX fluxes, the 70-$\mu$m-Spitzer-MIPS flux, and the IRAS 60 and 100-$\mu$m fluxes as upper limits. We have set a distance range from 6 to 10 kpc (see Sect. 4), and an interstellar visual absorption range from 5 to 12 (Sect. 3.3).

Table 3. NIR coordinates, the band at which they are measured (J-band: 1.25 $\mu$m, H-band: 1.65 $\mu$m, K$_s$-band: 2.17 $\mu$m), and magnitudes of the 9 objects, ordered by increasing right ascension and marked in Fig. 5, lower left panel.

Notes. Astrometric errors are: $\Delta\alpha < 0.01^\circ$, $\Delta\delta < 0.1^\prime$.

4. Discussion

The H1-line self-absorption technique is a useful tool when deriving distances (see, for instance, Busfield et al. 2006). In this way, we measure the most negative absorption feature of the VLA-data spectrum on IRAS 16353$-$4636 (Fig. 4) at $v_{\text{neg}} \sim -120$ km s$^{-1}$. The Galactic rotation model of Brand & Blitz (1993) provides two kinematical distances: 6.8 and 9 kpc. The presence of absorption at $-120$ km s$^{-1}$ indicates that the source is located at or beyond the sub-central point at a distance of $\sim$8 kpc. At such a distance, 1$''$ corresponds to 0.04 pc, and the $\sim$10$''$ size of the radio source, to 0.4 pc. These are typical values for the size of a molecular cloud in the process of contraction to form stars (e.g. Garay et al. 2003). The lack of H1 absorption at positive velocities implies that the source is not beyond the solar circle, which sets an upper limit of $\leq$15 kpc to its distance.

The $^{12}$CO line results from Urquhart et al. (2007) confirm that there is molecular gas with $v = v_{\text{lsr}}$ at least related to NTT source #8. The Mopra profile shows five emission lines, with LSR-velocities from $-122.7$ to $-38.6$ km s$^{-1}$. Table 5 lists the components, widths, and kinematic distances derived from them (Urquhart et al. 2007). The central velocity of the strongest line is in very good agreement with the extreme H1 absorption feature at $-120$ km s$^{-1}$. The rest of the detected $^{12}$CO lines can be explained, for example, if additional gas clouds are present in the direction of IRAS 16353$-$4636. Observations with better angular resolution can help to clarify this issue.

The velocities measured from the near-IR emission and absorption lines in Table 4 are generally consistent with the large negative velocities measured in $^{13}$CO. Note in particular that the strongest emission line, Bry, peaks at an LSR velocity of $-137$ km s$^{-1}$ (i.e. within 15 km s$^{-1}$ the most negative $^{13}$CO component).

The bolometric luminosity of IRAS 16353$-$4636, derived using the IRAS flux values, is

$$L_{\text{IRAS}} = \left( \frac{D}{8 \text{ kpc}} \right)^2 6.1 \times 10^3 L_\odot,$$

which is a typical value for massive YSOs (Garay et al. 2003).
On the other hand, if we assume that the continuum emission from NTT source #8 has an optically-thin free-free component with flux in the cm wavelengths of the order of 10 mJy (the total flux of the entire radio source at 6 cm is \( \sim 80 \) mJy), and an electron temperature of \( 10^4 \) K for the ionized gas, we find that an ionizing photon flux of \( N_i \sim 5 \times 10^{47} \) s\(^{-1}\) (Carpenter et al. 1990) is required to maintain the ionization. This ionizing photon flux can be provided by an O9.5 ZAMS star (Panagia 1973). The luminosity of such a star is \( 3.8 \times 10^4 L_\odot \), within a factor of two of the bolometric luminosity estimated from the IRAS fluxes. Although the FIR colors could be compatible with an ultracompact H II region, the source does not appear in the CS survey by Bronfman et al. (1996).

The good fit of the SED model (Fig. 8) of the infrared spectrum of source #8, together with its location in the NIR C–C diagram (Fig. 6), and the agreement with the coordinates of the IRAS and MSX sources in the region, make it the most promising candidate for a MYSO in this cluster. The best fit for an object at \( \sim 8 \) kpc, with \( A_V \sim 10 \), is achieved for a model source of \( \sim 23 \) solar masses, \( \sim 90 \) solar radius, \( \sim 9000 \) K effective temperature, and 5000 yr of age.

**Notes.** Measured and laboratory wavelengths are listed in angstroms in Cols. 2 and 3, and their measured radial velocities (\( v_{\text{LSR}} \)), are shown in Col. 4. Radial velocities derived for CO lines are indicated in brackets as our spectral resolution does not allow us to identify individual lines that constitute the absorption band. We have therefore manually measured the wavelength of the edge of the absorption profile and used it as a reference value for the band head.

5. Conclusions

From the multi-frequency study presented here on IRAS 16353–4636, we have found strong evidence that supports its nature as a star-forming region. The H I absorption spectrum indicates that the source is located at or beyond the sub-central point at a distance of $\sim$8 kpc. At such a distance, the size of the radio source agrees with typical values for the size of a molecular cloud in the process of contraction to form stars. The region harbors, at least, two pre-main sequence stars or YSOs (NTT sources #5 and #8), plus three YSO candidates (NTT sources #6, #7, and #9). Our photometry shows that these five point sources have infrared excess. NIR spectra obtained from one of these (#5) indicate that it is a low-mass pre-main sequence star, whilst the combination of near- and mid-infrared data suggests that another one (#8) is a massive young stellar object.

The broad H I absorption feature and multiple CO emission lines seen at various velocities along the line of sight towards the region studied here suggest the presence of multiple cloud components.

The radio results reveal that the region is complex, with fine-scale structure seen at the highest frequencies. The results of a spectral index analysis at mm wavelengths are indicative of different physical conditions varying according to position. From 1.4 to 19.6 GHz, the radio emission presents a peak, characterized with a negative spectral index. This can be explained if the peak represents the terminal point of an outflow.

Obtaining NIR spectra for the remaining sources in this region will allow us to improve our knowledge of the whole star forming region, as high-quality spectra provide both physical insight into their sources and kinematical information necessary to disentangle projection effects. Higher angular resolution and better sensitivity observations at low radio frequencies to search for polarized emission, combined with molecular line and continuum studies, are needed to deepen our investigation of this interesting source.
