ABSTRACT

Context. Supernova remnants (SNRs) were often discovered in radio surveys of the Galactic plane. Because of the surface-brightness limit of previous surveys, more faint or confused SNRs await discovery. The Sino-German $\lambda$6 cm Galactic plane survey is a sensitive survey with the potential to detect new low-surface-brightness SNRs.

Aims. We aim to identify new SNRs from the $\lambda$6 cm survey map of the Galactic plane.

Methods. We searched for new shell-like objects in the $\lambda$6 cm survey maps and studied their radio emission, polarization, and spectra using the $\lambda$6 cm maps together with the $\lambda$111 cm and $\lambda$21 cm Effelsberg observations. Extended polarized objects with non-thermal spectra can be identified as SNRs.

Results. We have discovered two new, large, faint SNRs, G178.2–4.2 and G25.1–2.3, both of which show shell structure. G178.2–4.2 has a size of 72′ × 62′ with strongly polarized emission being detected along its northern shell. The spectrum of G178.2–4.2 is non-thermal, with an integrated spectral index of $\alpha = -0.48 \pm 0.13$. Its surface brightness is $\Sigma_\text{GHz} = 7.2 \times 10^{-3}$ W m$^{-2}$ Hz$^{-1}$ sr$^{-1}$, which makes G178.2–4.2 the second faintest known Galactic SNR. G25.1–2.3 is revealed by its strong southern shell, which has a size of 80′ × 30′. It has a non-thermal radio spectrum with a spectral index of $\alpha = -0.49 \pm 0.13$.

Conclusions. Two new large shell-type SNRs have been detected at $\lambda$6 cm in an area of 2200 deg$^2$ along the Galactic plane. This demonstrates that more large and faint SNRs exist, but are very difficult to detect.

Key words. ISM: supernova remnants – ISM: individual objects: G178.2–4.2 – ISM: individual objects: G25.1–2.3 – radio continuum: ISM

1. Introduction

Supernova remnants (SNRs) are the post-explosion relics of massive stars that have reached the end of their evolutionary life times. It has been predicted that the total number of Galactic SNRs is between 1000 and 10 000 (Berkhuijsen 1984; Li et al. 1991; Tammann et al. 1994). However, up to now just 274 SNRs have been identified (Green 2009). Among these, G192.8–1.1 has recently been disproved from being an SNR (Gao et al. 2011). This low SNR detection rate results from the insufficient sensitivity and resolution of available observations. Diffuse radio emission and discrete source complexes are not uniformly distributed along the Galactic disk, whose own emission confuses that from faint SNRs and hinders their identification.

A large number of SNRs have been identified from radio survey maps (e.g. Reich et al. 1988; Brogan et al. 2006). Shell-type SNRs can be recognized by their morphology, non-thermal spectra, and ordered polarization. Most known Galactic SNRs have a bright shell, with intrinsic magnetic fields running along the shell. The radio spectrum of an SNR is often described by a single power law, $S_\nu \sim \nu^\alpha$. Here $S_\nu$ represents the integrated flux density of an SNR at the observing frequency $\nu$. In general, SNRs have a spectral index of $\alpha \approx -0.5$, which is expected for SNRs in the adiabatic expansion phase with a compression factor of four (e.g. Reich 2002). Young SNRs can have steeper spectra ($\alpha \approx -0.6$ to $-0.8$) and show radial magnetic fields (e.g. Reich 2002).

To discover new SNRs, observations of high sensitivity are needed, which resolve confusing structures. We have conducted the Sino-German $\lambda$6 cm polarization survey of the Galactic plane (Sun et al. 2007; Gao et al. 2010; Sun et al. 2011; Xiao et al. 2011) in the region of Galactic longitude $10^\circ \leq \ell \leq 230^\circ$ and latitude $|b| \leq 5^\circ$, with an angular resolution of 9.5′. The sensitivity of the Urumqi survey, if extrapolated from 4.8 GHz to 1 GHz with a typical spectral index of $\alpha = -0.5$, is on average $\Sigma_\text{GHz} = 4.9 \times 10^{-23}$ W m$^{-2}$ Hz$^{-1}$ sr$^{-1}$, lower than the surface brightness of the faintest Galactic SNR known to date, which is $\Sigma_\text{GHz} = 5.8 \times 10^{-23}$ W m$^{-2}$ Hz$^{-1}$ sr$^{-1}$ for G156.2+5.7 (Reich et al. 1992; Xu et al. 2007). Therefore, it should be possible to detect new faint SNRs in the $\lambda$6 cm survey. Here, we report the discovery of two new SNRs, G178.2–4.2 and G25.1–2.3, and study their radio properties.

2. The $\lambda$6 cm maps of the two new SNRs

The Sino-German $\lambda$6 cm polarization survey of the Galactic plane was conducted with the Urumqi 25-m radio telescope. The $\lambda$6 cm maps are not only important for studies of the diffuse Galactic emission (Sun et al. 2011; Xiao et al. 2011), but also for studies of Galactic sources like SNRs (e.g. Sun et al. 2006; Xu et al. 2007; Shi et al. 2008; Xiao et al. 2008, 2009; Gao et al. 2011).

We have identified two extended shell-like sources, G178.2–4.2 and G25.1–2.3, in the survey maps. We used the “background filtering” technique (Sofue & Reich 1979) with a
Fig. 1. Radio images of G178.2−4.2 at λ6 cm from the Sino-German λ6 cm polarization survey in the top panels, at λ11 cm that we newly observed in the middle panels, and at λ21 cm from the Effelsberg Medium Latitude Survey (EMLS) (Reich et al. 2004) in the bottom panels. The angular resolutions of the λ6 cm, λ11 cm, and λ21 cm maps are 9.5′, 4.4′, and 9.4′, respectively. The left panels show the total-intensity (I) maps in color and in contours, with observed B-vectors overlaid (i.e. the observed E-vectors plus 90°) for polarization intensities $PI > 2.4 \text{ mK} T_B$ at λ6 cm and 32.0 mK $T_B$ at λ11 cm. Vectors are not shown at λ21 cm. The vector length is proportional to $PI$. The I contours in the λ6 cm maps are $2^n \times 1.6 (4\sigma) mK T_B$, ($n = 1, 2, 3 ...$), in the λ11 cm maps are $2^n \times 12.8 (4\sigma) mK T_B$ ($n = 1, 2, 3 ...$), and in the λ21 cm maps are $2^n \times 44.0 (4\sigma) mK T_B$ ($n = 1, 2, 3 ...$). The central panels also display the total-intensity maps, where strong point-like sources have been subtracted, to show the extended emission from the SNR more clearly. The right panels are the polarization intensity images with the contours for the total intensity maps with point-like sources subtracted. The rectangle in the λ6 cm image in the top central panel outlines the area used for the TT-plot spectral analysis displayed in Fig. 5.

filter beam size larger than that of the objects to remove the diffuse large-scale Galactic radio emission. G178.2−4.2 has a size of 72′×62′, and G25.1−2.3 has a size of 80′×30′. Following Gao et al. (2011), we measured the mean values at the corners of the Stokes $I$, $U$, and $Q$ maps in areas without obvious structures. A hyper plane defined by these corner mean values was subtracted to obtain the “intrinsinc” total intensity ($I$) and polarization intensity ($PI$) images of the objects (see Figs. 1 and 2). The $PI$ values were calculated as $PI = (U^2 + Q^2 - 1.2UQ^{1/2})^{1/2}$ following Wardle & Kronberg (1974). To study these objects and obtain their integrated flux densities, it is necessary to first subtract point-like sources in the field of the objects. Obvious discrete point-like radio sources were directly subtracted from the Urumqi λ6 cm, and also the Effelsberg λ11 cm and λ21 cm maps by Gaussian fitting, as we will use in the next section. Some unresolved sources were identified in the NVSS catalog (Condon et al. 1998). The flux densities of these sources in our observing bands were extrapolated from the NVSS flux density at 1.4 GHz, $S_{1.4 \text{ GHz}}$, using a spectral index either derived between the flux densities from the NVSS and the Effelsberg λ11 cm survey or quoted from Vollmer et al. (2005). Otherwise, the mean spectral index for a large sample of radio sources in the NVSS and WSRT surveys,
Fig. 2. Same as Fig. 1, but for G25.1−2.3. Here the $\lambda$6 cm and $\lambda$11 cm maps were extracted from the Effelsberg $\lambda$11 cm survey (Reich et al. 1990a) and $\lambda$21 cm survey (Reich et al. 1990b), respectively. The contours in the $\lambda$6 cm total-intensity maps are $2^{n-1/2} \times 12.8 (4\sigma)$ mK $T_B (n = 1, 2, 3 \ldots)$, in the $\lambda$11 cm total-intensity maps are $2^{n-1/2} \times 72.0 (4\sigma)$ mK $T_B (n = 1, 2, 3 \ldots)$, and in the $\lambda$21 cm total-intensity maps are $2^{n-1/2} \times 200.0 (4\sigma)$ mK $T_B (n = 1, 2, 3 \ldots)$. The polarization intensity threshold for the $B$-vectors is 12.0 mK $T_B$ at $\lambda$6 cm and 75.0 mK $T_B$ at $\lambda$11 cm. No polarization data at $\lambda$21 cm are presently available. The star-symbols in the $\lambda$6 cm image in top left panel indicate known pulsars in the field. The polygon in the $\lambda$6 cm image in top central panel outlines the area for the TT-plot spectral analysis shown in Fig. 5.

\[ \alpha = -0.9 \] (Zhang et al. 2003), was used if the spectral index of a source could not be determined. The total-intensity maps with point-like sources subtracted are shown in the central panels of Figs. 1 and 2.

2.1. G178.2−4.2

G178.2−4.2 is located in the anti-center region of the Galaxy and displays a circular morphology with a prominent shell in its north. Three strong radio sources, NVSS J052423+281232, NVSS J052427+281255, and NVSS J052432+281313 are located in the center of the SNR, which are the three components of the double-sided radio source 3C 139.2 (Leahy & Williams 1984; Liu & Zhang 2002) and not related to the SNR. Subtracting these and other point-like sources, the extended emission of the entire SNR G178.2−4.2 is clearly visible (see the central panels of Fig. 1). Strong polarized emission from the northern shell of G178.2−4.2 is detected at $\lambda$6 cm, with B-field directions orientated tangential to the shell.

2.2. G25.1−2.3

A well-pronounced half-shell structure of 80' in length is visible at $\ell = 25^\circ.1, b = -2^\circ.3$ after strong diffuse emission from the Galactic plane is filtered out (see Fig. 2). The background radio source centered at $\ell = 24^\circ.9, b = -1^\circ.7$ is composed by NVSS J184245−075613 and NVSS J184249−075604 (Condon et al. 1998) and is subtracted. It is not clear whether the extended structure around $\ell = 25^\circ.65, b = -1^\circ.95$ is a part of G25.1−2.3, because its spectral index from a TT-plot analysis

remains inconclusive. In this paper we only discuss the radio properties of the shell region outlined in Fig. 2.

3. Radio properties of G178.2–4.2 and G251–2.3

The radio morphologies of G178.2–4.2 and G251–2.3 at $\lambda$6 cm, as well as the properties discussed below, suggest that both objects are SNRs. Using the radio maps at three bands, i.e. $\lambda$6 cm observed by using the Urumqi 25-m telescope as described above, $\lambda$11 cm and $\lambda$21 cm by the Effelsberg 100-m telescope, we hereby study the radio spectrum and polarization properties of G178.2–4.2 and G251–2.3.

We extracted the $\lambda$11 cm maps of G178.2–4.2 from the Effelsberg $\lambda$11 cm Galactic plane survey (Fürst et al. 1990; Reich et al. 1990a) and $\lambda$21 cm maps from an unpublished section of the “Effelsberg Medium Latitude Survey (EMLS)” (Reich et al. 2004). For G251–2.3, the $\lambda$11 cm and $\lambda$21 cm maps are from the Effelsberg $\lambda$11 cm (Fürst et al. 1990; Reich et al. 1990a) and $\lambda$21 cm Galactic plane surveys (Reich et al. 1990b, 1997). The angular resolution is 4.4 for the $\lambda$11 cm Effelsberg observations and 9.4 for the $\lambda$21 cm observations.

We noticed, however, that G178.2–4.2 was poorly traced in the $\lambda$11 cm survey map because of its limited sensitivity. The northern part of G178.2–4.2 is clearly detected near the edge of the recent Effelsberg $\lambda$11 cm map of S147 (Xiao et al. 2008) made with a new receiver. We therefore observed G178.2–4.2 again in March 2011 with the Effelsberg 100-m telescope for the new $\lambda$11 cm map. The 80 MHz bandwidth of the $\lambda$11 cm receiver was connected to an 8-channel polarimeter centered at 2639 MHz. The lowest 10 MHz channel was corrupted by interference and could not be used. The radio source, 3C 286, was used as the main calibrator assuming $S_{11 cm} = 104$ Jy and 9.9% linear polarization and a polarization angle of 33°. We obtained six full coverages of the 2° × 2° field with in total 4 s integration time per 2° pixel. We added the maps of seven channels without interference, and applied the standard data reduction and calibration procedures as already described by Xiao et al. (2008, 2009).

The rms-noise measured in emission-free areas was $3.2 \text{ mK} T_B$ in the total-intensity and $2.9 \text{ mK} T_B$ in the polarization-intensity map. The $\lambda$11 cm maps of G178.2–4.2 shown in Fig. 1 are from the new observations.

We measured the integrated flux densities of G178.2–4.2 and G251–2.3 from the radio maps at $\lambda$6 cm, $\lambda$11 cm, and $\lambda$21 cm. We got $S_{6cm} = 1.0 ± 0.1$ Jy, $S_{11cm} = 1.6 ± 0.2$ Jy, and $S_{21cm} = 1.8 ± 0.2$ Jy for G178.2–4.2, and $S_{6cm} = 3.7 ± 0.4$ Jy, $S_{11cm} = 4.7 ± 0.5$ Jy, and $S_{21cm} = 6.7 ± 0.7$ Jy for the outlined area of G251–2.3 (see Fig. 2). The spectral indices fitted from these integrated flux densities (see Fig. 3) are $\alpha = −0.48 ± 0.13$ for G178.2–4.2 and $\alpha = −0.49 ± 0.13$ for the shell of G251–2.3, which indicate the non-thermal nature of radio emission of these two objects. These results are summarized in Table 1.

Spectral index maps for these two objects were derived from radio maps at three wavelengths, as shown in Fig. 4. The spectral indices vary in different areas. The spectral index of the northern shell of G178.2–4.2 is about $\alpha ∼ −0.6$, and that of the southern shell of G251–2.3 is about $\alpha ∼ −0.5$. These spectral indices were verified by TT-plots (Turtle et al. 1962).

From the brightness temperatures $T_B$ at two frequencies plotted against each other, the brightness spectral index, $\beta$, is defined as $T_B = \theta^\beta$, so that $\alpha = \beta + 2$. As shown in Fig. 5, we obtained $\beta_6 cm−11 cm = −2.53 ± 0.16$ and $\beta_6 cm−21 cm = −2.63 ± 0.09$ for the northern shell of G178.2–4.2, and $\beta_6 cm−11 cm = −2.45 ± 0.60$ and $\beta_6 cm−21 cm = −2.59 ± 0.10$ for the southern shell of G251–2.3. These values all agree with the results derived from the integrated flux densities and spectral index maps.

Using the total intensity and the radio spectral index, we calculated the surface brightness of both objects at 1 GHz (e.g. Kothes et al. 1998), obtaining $\Sigma_1 GHz = 1.505 \times 10^{-18}$ Jy/arcmin$^2$. The surface brightness for G178.2–4.2 is $\Sigma_1 GHz = 7.2 \times 10^{-23}$ Wm$^{-2}$ Hz$^{-1}$ sr$^{-1}$ for G178.2–4.2, and $\Sigma_1 GHz = 5.0 \times 10^{-22}$ Wm$^{-2}$ Hz$^{-1}$ sr$^{-1}$ for the southern shell of G251–2.3. The surface brightness for G178.2–4.2 is the date the second lowest for a Galactic SNR, only slightly above that of the lowest, $5.8 \times 10^{-23}$ Wm$^{-2}$ Hz$^{-1}$ sr$^{-1}$ reported for SNR G156.2+5.7 (Reich et al. 1992).

Polarization observations of the G178.2–4.2 field are available at $\lambda$6 cm, $\lambda$11 cm, and $\lambda$21 cm. The diffuse extended polarized emission at $\lambda$21 cm (see the right bottom panel in Fig. 1) varies and has no obvious structural relation to G178.2–4.2. We therefore conclude that at $\lambda$21 cm, we most probably see polarized diffuse foreground or background Galactic emission and will not consider it in the following discussion.
the central patches inside the SNR are clearly not related to the total-intensity emission and thus are probably un-related to the SNR. Therefore, the polarized emission reliably detected from G178.2−4.2 at both 6 cm and 11 cm is of the shell region. The polarization angles of the two frequencies differ by about 20°, corresponding to a rotation measure $RM$ of about $36 + n \times 350 \text{ rad m}^{-2}$ ($n = \pm 1, \pm 2, \ldots$) by accounting for the $\pi$-ambiguity. Because of low $RM$ values in the anti-center region (e.g. Spoelstra 1984; Sun et al. 2008), $n = 0$ is the most reasonable choice, so that $RM = 36 \text{ rad m}^{-2}$. This value is slightly higher but comparable to $RM = 22.1 \pm 2.2 \text{ rad m}^{-2}$ for the source NVSS J052423+281232 at $\ell = 178\degree09, b = -4\degree31$ within the SNR and $RM = 11.8 \pm 1.1 \text{ rad m}^{-2}$ for NVSS J052734+285134 at $\ell = 177\degree94, b = -3\degree37$ outside the SNR (Taylor et al. 2009) and the mean $RM$ value of about 10 rad m$^{-2}$ found for the nearby SNR S147 region (Xiao et al. 2008).

Polarization observations of the G25.1−2.3 field are available at 6 cm, and 11 cm. Some weak polarization patches have been detected at 6 cm and 11 cm (see Fig. 2, right panels). They have a very different morphology to the total-intensity emission, and seem not to be associated with the southern shell of G25.1−2.3. In general, intrinsic polarized emission of an SNR should be detectable at a higher frequency. This is not the case for G25.1−2.3. Comparing the morphologies of the 6 cm and 11 cm polarization map of G25.1−2.3, we conclude that the detected polarized radio emission at both wavelengths is not associated with the SNR. This is not unusual in this direction of the inner Galaxy, where the polarized emission originates from diffuse emission in a complex environment within the 6 cm polarization horizon of about 3 kpc (see Sun et al. 2011).

4. Signatures in other bands

We have overlaid the radio maps of these two SNRs onto images from other bands to see whether there is any spatial coincidence.

We superimposed the 6 cm total-intensity contours of G178.2−4.2 and G25.1−2.3 onto the integrated CO image (Dame et al. 2001), the soft X-ray image in the 0.4−2.4 keV
Fig. 6. Total-intensity contour maps of G178.2−4.2 at Λ11 cm and G25.1−2.3 at Λ6 cm with point-like sources subtracted overlaid onto the VTSS Hα image for G178.2−4.2 (upper panel) and the SHASSA Hα image for G25.1−2.3 (lower panel).

Fig. 7. Total-intensity contour map of G25.1−2.3 at Λ6 cm overlaid onto the IRIS 60 μm infrared image.

band and the super-soft X-ray image in the 0.1–0.4 keV band. We could find no structural coincidence in these images with G178.2−4.2 and G25.1−2.3.

Using “The Virginia Tech Spectral-Line Survey (VTSS)” and “The Southern H-Alpha Sky Survey Atlas (SHASSA)” for arcmin-resolution digital images of interstellar Hα emission, we have overlaid the total-intensity contour map of G178.2−4.2 at Λ6 cm onto the VTSS Hα image and that of G25.1−2.3 at Λ11 cm onto the SHASSA Hα image (Fig. 6). In the area of G178.2−4.2, a very weak broad band of Hα emission runs across the SNR area and is considered to be background or foreground emission. In the field of G25.1−2.3, a strong Hα emission patch is found to the north of the radio shell. The Hα emission appears to be weak within the shell areas of both G178.2−4.2 and G25.1−2.3. Therefore, we consider that the Hα emissions present in these directions are probably not physically associated with the SNRs.

We compared the radio maps of G178.2−4.2 and G25.1−2.3 with the IRIS 60 μm infrared images (Miville-Deschênes & Lagache 2005). No coincidence was found for G178.2−4.2. Figure 7 shows G25.1−2.3, where the infrared patch positions have clear offsets to the radio shell. Therefore, we conclude that both G178.2−4.2 and G25.1−2.3 have no corresponding infrared emission.

Very often SNRs show an associated H1 cavity. The Leiden/Argentina/Bonn (LAB) H1 survey data with a velocity resolution of 1.3 km s−1 (Hartmann & Burton 1997; Kalberla et al. 2005) was used to search for H1 structures related to the SNRs in the velocity range from −450 to 400 km s−1, although the angular resolution of 36′ for the H1 data is coarse. In the area of G178.2−4.2, there is a 3° × 2° H1 shell centered at ℓ = 178°2′, b = −4°1′, seen at a central radial velocity of −3.2 km s−1 over a velocity range of 17.5 km s−1 (Ehlerová & Palouš 2005). This is clearly larger than the SNR extent, and its relation to the SNR cannot be settled. In the area of G25.1−2.3, an H1 cavity is found in the velocity range of 37.1 to 41.2 km s−1 (see Fig. 8), which has a very similar shape to G25.1−2.3 and hence might be related to the SNR. The kinetic distance for the central velocity of 39.2 km s−1 is 2.9 or 12.4 kpc according to the Galactic rotation model by Fich et al. (1989). These two values correspond to a span of 67 pc or 288 pc of the shell structure, respectively. Considering the physical size of an SNR shell, the nearer distance is preferred.

For some SNRs, the empirical relation between the surface brightness Σ and diameter D (e.g. Clark & Caswell 1976) is the only tool to estimate their distances, though with large uncertainties (e.g. Green 1984, 2004). We used the updated Σ−D relation of Case & Bhattacharya (1998) to estimate the distances of our two newly found objects. For G178.2−4.2, we found that the corresponding diameter of that surface brightness is 197 pc, so that its distance is 9.4 kpc, which places the object far outside the Galaxy, and seems possible. For G25.1−2.3, we found that the diameter for the shell is 72 pc and the distance is 3.1 kpc, consistent with those derived from the HI data. Note, however, that the uncertainties of these estimates could be as large as 40%.

Several pulsars are known within the field of G25.1−2.3 (Fig. 2). They have distances of 4–6 kpc according to the pulsar dispersion measure and the electron distribution model of the Galaxy, NE2001 (Cordes & Lazio 2002). It is not possible to associate any of these pulsars unambiguously with the SNR.
magnetic field runs along the northern shell of G178.2–4.2 from the Virginia Tech Spectral-Line Survey (VTSS), which is supported by the National Science Foundation. We thank Prof. Ernst Fürst for critically reading the manuscript.

5. Summary

We have found two shell-like objects, G178.2–4.2 and G25.1–2.3, from the radio map of the Sino-German \( \alpha \) cm polarization survey of the Galactic plane. In addition, using the Effelsberg \( \lambda \)11 cm and \( \lambda \)21 cm continuum and polarization maps, a shell-type morphology is confirmed for both. Their radio spectra are characteristic of non-thermal emission with spectral indices for the shells of \( \alpha \sim -0.6 \) for G178.2–4.2 and \( \alpha \sim -0.5 \) for G25.1–2.3. These values are typical for SNRs. An ordered magnetic field runs along the northern shell of G178.2–4.2. An H\( \alpha \) cavity, likely at a distance of about 2.9 kpc, is probably associated with the SNR G25.1–2.3, which implies a diameter of up to 67 pc in size.

Acknowledgements. We would like to thank the anonymous referee for helpful comments. The Sino-German \( \alpha \) cm polarization survey was carried out with a receiver system constructed by Mr. Otmar Lochner at MPIfR mounted at the Nanshan 25-m telescope of the Urumqi Observatory of NAOC. The MPG and the NAOC/CAS supported the construction of the receiving system by special funds. We thank Mr. Maoheng Chen and Mr. Jun Ma for qualified maintenance of the receiving system for many years. The new \( \lambda \)11 cm map of G178.2–4.2 is based on observations with the 100-m telescope of the MPIfR at Effelsberg. The Chinese authors are supported by the National Natural Science foundation of China (10773016, 10821061, and 10833003), the National Key Basic Research Foundation of China (2007CB815403), and the Partner group of the MPIfR at NAOC in the frame of the exchange program between MPG and CAS for many bilateral visits. X.Y.G. thanks the joint doctoral training plan between CAS and MPG and the financial support from CAS and MIPfR. X.H.S. thanks the MPG and Prof. Michael Kramer for the financial support during his stay at the MPIfR. We used the H\( \alpha \) image for G178.2–4.2 from the Virginia Tech Spectral-Line Survey (VTSS), which is supported by the National Science Foundation. We thank Prof. Ernst Fürst for critically reading the manuscript.
