ABSTRACT

Context. Giant radio galaxy (GRG) lobes are excellent laboratories for studying the evolution of the particle and magnetic field energetics and the past activity of radiogalaxy jets, as indicated by recent results of X-ray observations with *Suzaku*. However, these results are based on assumptions of the shape and extension of the GRG lobe electron spectrum.

Aims. We re-examine the energetics of GRG lobes as derived by inverse Compton scattering of cosmic microwave background (CMB) photons (ICS-CMB) by relativistic electrons in RG lobes to assess the realistic physical conditions of RG lobes, their energetics, and their radiation regime. We consider the steep-spectrum GRG DA 240 recently observed by *Suzaku* as a reference case and we also discuss other RG lobes observed with *Chandra* and XMM.

Methods. We model the spectral energy distribution (SED) of the GRG DA 240 East lobe to obtain constraints on the shape and on the extension of the electron spectrum by using multi-frequency information from radio to gamma-rays. We use radio and X-ray data to constrain the shape and normalization of the electron spectrum and we then calculate the Sunyaev-Zel'dovich (SZ) effect expected in GRG lobes that is sensitive to the total electron energy density.

Results. We show that the electron energy density U_e derived from X-ray observations can yield only a rough lower limit to its actual value and that most of the estimates of U_e based on X-ray measurements have to be increased even by a large factor by considering realistic estimates of the lower electron momentum p_1 . This moves RG lobes away from the equipartition condition toward a particle-dominated and Compton power dominance regime. We propose to use the distribution of RG lobes in the U_e/U_B vs. U_e/U_{CMB} plane as another divide divide between the different physical regimes of particle and field dominance and radiation mechanism dominance in RG lobes.

Conclusions. We conclude that the SZ effect produced by ICS-CMB mechanism observable in RG lobes provides reliable estimate of p_1 and U_e and is the best tool to determine the total energy density of RG lobes and to assess their physical regime. This observational tool is available with the sensitive high-frequency radio and mm experiments.

Key words. cosmic background radiation – galaxies: active – cosmology: theory

1. Introduction

Giant radio galaxy (GRG) lobes are considered the final stage of the evolution of radiogalaxy (RG) jets and are likely the evolutionary connection to the inverse Compton ghosts of GRGs. The details of this evolutionary process are, however, not yet satisfactorily understood. In this context, GRG lobes are excellent laboratories for studying the evolution of the particle and magnetic field energy density as well as the past activity of RG jets.

Determining the total particle and magnetic energy density in GRG lobes is a difficult task because of the lack of precise indicators of the overall particle energy spectrum (especially in the low-energy part, where most of the energy is stored in steep spectrum sources) and of the distribution and power spectrum of the magnetic field.

The electron and magnetic energies stored in GRG lobes are usually measured through the diffuse radio synchrotron emission and the inverse Compton scattering (ICS) X-ray emission where these X-rays are produced by cosmic microwave background (CMB) photons up-scattered by the ICS with the relativistic electrons (hereafter ICS-CMB) injected to the GRG lobe.

The results of the ICS-CMB X-ray emission from RG lobes obtained with ROSAT (e.g. Feigelson et al. 1995), ASCA (e.g., Kaneda et al. 1995; Tashiro et al. 1998, 2001), *Chandra* (e.g., Isobe et al. 2002; Croston et al. 2005; Yaji et al. 2010), *XMM-Newton* (e.g., Isobe et al. 2005, 2006) and *Suzaku* (Isobe et al. 2009, 2011a,b) indicate a dominance of the electron energy density U_e over the magnetic one U_B by typically an order of magnitude in many RG lobes (see Croston et al. 2005; Isobe et al. 2009, 2011a,b), even though several lobes are also found in almost equipartition condition $U_e = U_B$ (see, e.g., discussion in Isobe et al. 2011a).

The *Suzaku* satellite recently measured ICS-CMB X-ray emission from a few GRG lobes (e.g. 3C 326, Isobe et al. 2009; DA240, Isobe et al. 2011a; 3C 35, Isobe et al. 2011b) and these results seem to indicate that GRG lobes have a very low particle and magnetic field energy density that would set these objects at the lower end of the $U_B - U_e$ correlation. These results strengthen the idea that the dominance of the ICS-CMB radiative losses over the synchrotron one is a common property in the lobes of GRGs (see, e.g., Ishwara-Chandra & Saikia 1999), and that RG lobes developing from a size $D \lesssim 100$ kpc to a

size $D \sim \text{Mpc}$ induce an evolution of their energetics from the electron dominance regime (mainly in the jet) to the equipartition regime (mainly in the lobe), following the adiabatic evolution $U_e \propto D^{-2}$, in addition to a significant decrease in both U_e and U_B (see the discussion in Isobe et al. 2011a).

The specific entity of these results depends, however, on a detailed knowledge of the electron spectrum over the whole range of electron energies, which is not easily obtainable from X-ray ICS-CMB observations. These are sensitive to electron Lorentz factors $\gamma \gtrsim 10^3$ (i.e. only in the high-energy branch of the electron spectrum), while most of the CMB photon Comptonization is produced in the low-energy part of the electron spectrum (see, e.g., Croston et al. 2005; Colafrancesco 2008). This is especially so for GRG lobes with steep energy spectra.

We here re-examine the derivation of the GRG lobe energetic and B -field estimates based on a detailed modeling of the multi-frequency ICS-CMB spectra and of their associated synchrotron spectra. To provide a specific and quantitative discussion, we discuss the reference case of the GRG DA 240 observed recently with *Suzaku* (Isobe et al. 2011a) which is the object with the steepest energy spectrum in its radio lobes among those observed with *Suzaku*. The GRG DA 240 is also one of the steepest spectra objects with respect to the RG sample discussed in Croston et al. (2005).

Steep energy spectra make the determination of U_e more uncertain if only X-ray observations are used, and the strong sensitivity to the value of the minimum electron energy requires a more refined analysis. That is why we explore the parameter space region allowed by the data to study the amount of variation on the electron energy density U_e . We show in Sect. 2 that the X-ray estimates of U_e provide only a rough lower limit for U_e and of the minimum energy $\gamma_{\min}$ of the electron population, and we discuss the consequences of these assumptions on the RG lobe energy and radiation regime and on their multi-frequency spectral energy distributions (SEDs). We then show in Sect. 3 that observations of the SZ effect produced in GRG lobes (as originally proposed by Colafrancesco 2008) are the only ones able to provide the missing information on the total electron energy density U_e and also provide reliable estimates of the quantity U_e/U_B and of the structure and evolution of GRG lobes. We discuss in Sect. 4 that similar arguments apply to other RG lobes studied in the X-ray energy band, and we discuss the various physical regimes in which RG lobes are found based on their distribution in the U_e/U_B vs. U_e/U_{CMB} plane. We summarize our results and draw our conclusions in Sect. 5.

Throughout the paper we use a flat, vacuum-dominated cosmological model with $\Omega_m = 0.27$, $\Omega_\Lambda = 0.73$ and $H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1}$.

2. A tale of a GRG: DA 240

The GRG DA 240 at $z = 0.03561$ (Rines et al. 2000) has a radius of the East lobe, in which the ICS-CMB X-ray emission has been measured by *Suzaku*, of ~ 7 arcmin (Isobe et al. 2011a), which corresponds to a linear size of 294 kpc at the GRG redshift. This is a prototype of a GRG with extended lobes that is well-suited for testing our analysis.

The radio synchrotron spectral index in the East lobe is $\alpha_r = 0.95 \pm 0.01$ (Mack et al. 1997) in the range 326 to 609 MHz, and flattens at higher frequency, reaching a value ≈ 0.74 . The radio spectrum measured between 4.8 and 10.6 GHz appears to be even flatter with $\alpha_r \approx 0.58$, because the hot spot emission is likely dominant in this high-frequency range.

The X-ray ICS-CMB emission measured by *Suzaku* has a spectral index $\alpha_X = 0.92^{+0.13, +0.04}_{-0.17, -0.06}$ compatible with the radio spectral index α_r measured at low- ν between 326 and 609 MHz, but certainly steeper than the radio spectral index measured between 2.7 and 10.5 GHz (see Mack et al. 1997).

Under the assumption $\alpha_X = \alpha_r$, Isobe et al. (2011a) derived the X-ray ICS-CMB flux $F_{1 \text{ keV}} = 51.5 \pm 3.9^{+6.2}_{-5.4} \text{ nJy}$ (with a best-fit reduced χ^2 smaller w.r.t. the fit leaving α_X as a free parameter), an overall B -field value inside the lobe of $B = 0.87 \pm 0.03^{+0.05}_{-0.06} \mu\text{G}$ corresponding to $U_B \approx (3.0 \pm 0.2 \pm 0.4) \times 10^{-14} \text{ erg cm}^{-3}$, and a value $U_e = (3.4^{+0.3, +0.5}_{-0.2, -0.4}) \times 10^{-14} \text{ erg cm}^{-3}$ integrated over the range of electron energies $\gamma = 10^3 - 10^5$. Here $\gamma = E/m_e c^2$. The previous analysis done using $\gamma_{\min} = 10^3$ yields $U_e/U_B \approx 1.1$, $U_B/U_{\text{CMB}} \sim 0.06$ (where $U_{\text{CMB}} \approx 4.8 \times 10^{-13} \text{ erg cm}^{-3}$ at the redshift of DA 240) and $U_e/U_{\text{CMB}} \approx 0.07$.

We stress that the previous values of the particle energy density U_e strongly depends on the assumed electron spectrum at low energy (where most of the ICS-CMB originates) and specifically on the spectral index α and on the minimum momentum p_1 (or equivalently $\gamma_{\min}$) of the electron population.

We notice that the previous values of U_e and U_B have been obtained by Isobe et al. (2011a) by deriving the electron density and the B -field intensity using the approximate analytical formulae given in Harris & Grindlay (1979) which are based on various assumptions: the monochromatic approximation of the ICS emission, according to which an electron with energy E emits by ICS at a single frequency that is derived by assuming a monochromatic CMB photon spectrum; the monochromatic approximation for the synchrotron emission according to which an electron with energy E in a magnetic field with intensity B emits a single frequency.

In the following we make use of the complete formulae for the synchrotron and ICS emission mechanisms (see, e.g., Schlickeiser 2002), which yield the correct results of the same order of magnitude as the approximate relations, but with some numerical difference in some specific case with respect to the approximated calculations used in Harris & Grindlay (1979).

To determine precisely U_e , we use a power-law electron spectrum to model the low- ν part of the radio spectrum

$$N(p) = k_0 p^{-\alpha} \quad p \geq p_1, \quad (1)$$

where $p = \beta\gamma$. With this electron spectrum, the total energy density of the electron population in the RG lobe can be directly obtained (see Colafrancesco 2008; Colafrancesco et al. 2011; Enßlin & Kaiser 2000; Colafrancesco et al. 2003) as

$$U_e = \int_{p_1}^{\infty} dp N(p) \left(\sqrt{1 + p^2} - 1 \right) m_e c^2. \quad (2)$$

We consider, for the sake of generality, values of the minimum electron momentum in the range $p_1 = 1 - 10^3$. A value $p_1 \approx 10^3$ corresponds to the lower energy observable in the X-ray band, of the order of $\sim 1 \text{ keV}$ (see Isobe et al. 2011a), while values $p_1 \sim 10^2 - 10^3$ are derived from observations of hotspots (see e.g., Carilli et al. 1991), and even lower values $p_1 \sim 1 - 10$ are expected owing to the effects of adiabatic expansion of the RG lobe (see, e.g., discussion in Croston et al. 2005). Exploring a wide range of possible values for p_1 is crucial for our discussion because its specific value plays a crucial role in the derivation of the actual value of U_e (see Eq. (2)). We will discuss a new observational strategy aimed at the derivation of p_1 in Sect. 3 below.

The measured value of α_r at low frequencies corresponds to a value of the electron spectral index $\alpha = 2.9$ (here $\alpha = 2\alpha_r + 1$) for the spectrum at low energies.

An electron spectrum with a break p_b at low energy, with $\alpha = \alpha_1$ for $p < p_b$ and $\alpha = \alpha_2$ for $p > p_b$, as produced by electron energy losses, effectively behaves for our purposes like the single power-law spectrum but with the difference that here the crucial quantity (both for the determination of U_e and for the spectral properties of the SZE) is the value of the break p_b instead of p_1 .

We notice that the radio spectrum of the East lobe of DA 240 is dominated at high frequencies by the hot spot. For this reason, we decided to describe the hot spot emission with a single self-synchrotron Compton (SSC) model that reproduces both the high- ν radio data and the X-ray *Suzaku* observation at 1 keV. The X-ray spectral shape around 1 keV of the hotspot is fairly uncertain with α_X in the range 0.72–1.27 (Isobe et al. 2011a; Evans et al. 2008) that allow either decreasing or increasing SED shapes in the $\nu f(\nu) - \nu$ plot of Fig. 1. We calculated the SED of the hotspot with a single zone SSC model with parameters describing the X-ray flux by synchrotron (cyan solid) or by ICS (dashed green), because the available data do not allow us to distinguish between the two alternatives. In both cases the hotspot is not dominating the overall SED of the East lobe of DA 240 in the X-ray and gamma-ray frequency range, thus confirming the idea that most of the gamma-ray emission associated to GRG lobes comes from ICS-CMB emission from the diffuse electron population in the radio lobes (see, e.g., the recent results on the *Fermi*-LAT observations of the CenA lobes, Abdo et al. 2010).

We describe the total SED of the lobe as the sum of a power-law spectrum SED model for the diffuse electron population and a SSC model for the hot spot.

We discuss below the multi-frequency SED of the diffuse electron population of the East lobe of DA 240 to better constrain the shape of the electron spectrum in this radio lobe. We assume that electrons and B -field are uniformly distributed within the spherical volume of the GRG lobe with a radius equal to that of the projected area of the lobe. We normalize the ICS-CMB emission expected with the previous spectrum with $p_1 = 1$ to the X-ray flux observed by *Suzaku* at 1 keV (see Isobe et al. 2011a) and we obtain $k_0 = 1.02 \times 10^{-5} \text{ cm}^{-3}$. This spectrum fits the synchrotron radio spectrum observed in the range 326–609 MHz (Mack et al. 1997) with a value of the magnetic field $B_\mu = 1.5$, where B_μ is the magnetic field in μG units. The previous values of the normalization k_0 and of the B -field are independent of p_1 for values lower than the value of p at which electrons emit by ICS at the observed energy E_X : for an observed energy $E_X = 1 \text{ keV}$ one obtains a value of $p \sim 685$ by using the approximate relations that an electron with energy E_e emits ICS-CMB at the energy

$$E_X \sim 8 \left(\frac{E_e}{\text{GeV}} \right)^2 \text{ keV}, \quad (3)$$

and, correspondingly, synchrotron at a frequency

$$\nu \sim 16 \left(\frac{E_e}{\text{GeV}} \right)^2 \frac{B}{\mu\text{G}} \text{ MHz}. \quad (4)$$

This explains why the value of k_0 is independent of p_1 in the range $p \approx 1$ – 10^2 , while the situation changes for $p_1 \sim 10^3$. The difference in the values of k_0 and B that we obtain here for this last case and those derived by Isobe et al. (2011a) is consequently caused by the different calculations performed (see also discussion above).

Fig. 1. SED of the East lobe of DA 240 calculated with a power-law spectrum recovering the low- ν radio data for $p_1 = 1$ and $B_\mu = 1.5$ (red solid for the radio spectrum and red dotted for the high- ν spectrum) and $p_1 = 10^3$ $B_\mu = 0.87$ (magenta dashed for the high- ν spectrum). The electron spectrum has a cutoff at $p_{\text{cut}} = 5 \times 10^5$ to produce an ICS-CMB gamma-ray emission below the *Fermi*-LAT 5-yr sensitivity limit that is exceeded for the case $p_1 = 10^3$ with a power-law spectrum without high- ν cutoff. SSC SED model for the hot spot that fits the X-ray flux at 1 keV (open square point plus errorbars) with the synchrotron branch (cyan solid) or with the Compton branch (green dashed) is also shown for comparison. Various instrument sensitivities for point-like sources are shown for comparison. Instrument sensitivities are taken from the ASI-ASDC SED builder tool at <http://tools.asdc.asi.it/>.

The same power-law spectrum (with $\alpha = 2.9$) but with a higher $p_1 = 10^3$ fits the *Suzaku* X-ray flux at 1 keV with a normalization of $k_0 = 3.04 \times 10^{-5} \text{ cm}^{-3}$ and the low- ν radio spectrum with a magnetic field of $B_\mu = 0.87$ (in agreement with the result of Isobe et al. 2011a).

Figure 1 shows the multi-frequency SED of the East lobe of DA 240 for the two extreme values $p_1 = 1$ and $p_1 = 10^3$ to encompass the possible realistic values of this relevant parameter. The SED of DA 240 shows that the X-ray ICS-CMB emission spectrum measured by *Suzaku* is consistent only with the low-frequency radio data. In addition, the X-ray ICS-CMB SED for $p_1 = 10^3$ has a shape that is not consistent (within the uncertainties) with the slope measured by *Suzaku* under the assumption of using the same radio spectral index. This is because the minimum value $p_1 = 10^3$ reflects in a cutoff in the X-ray spectrum as shown in Fig. 1 (see also discussion above).

We also find that the extrapolation at high frequencies of the ICS-CMB power-law spectrum for $p_1 = 10^3$ is inconsistent with the *Fermi*-LAT sensitivity limit, and therefore a high-E cutoff must be introduced in the electron spectrum for this case. We adopt a cutoff at $p_{\text{cut}} = 5 \times 10^5$ to be consistent with the *Fermi*-LAT sensitivity limit, and this spectral cutoff modifies both the ICS-CMB emission SED and the shape of the radio SED. We adopt for consistency the same cutoff in the electron spectrum also for the cases with $p_1 = 1$.

To summarize, the SED analysis of the ICS-CMB emission constrains the electron spectrum to have i) a high-E cutoff at $E_{e,\text{cut}} \sim 255 \text{ GeV}$, ii) a spectral shape at low energies of $\alpha \approx 2.9$, iii) a minimum momentum p_1 certainly lower than 10^3 but not yet determined by the available X-ray data.

We stress that X-ray ICS-CMB data provide the normalization of the electron spectrum at $E_e = 0.35 \text{ GeV} (E_X/\text{keV})^{1/2}$

and the spectral index of the electron spectrum in the energy range corresponding to the instrument sensitivity ($\Delta E_e = 0.29\text{--}0.93$ GeV for the *Suzaku* window $E_X = 0.7\text{--}7$ keV), but these measurements are not sufficient to determine the total energy density of the electron population that depends strongly on the value of p_1 , which cannot be determined by typical X-ray ICS-CMB observations, as discussed in Colafrancesco (2008) and Colafrancesco et al. (2011). As a consequence, all the considerations on the ratio U_e/U_B , the possible equipartition regime, and particle domination regimes are misleading and need to be revised on the basis of a more realistic estimate of the total electron energy density. This is possible by using another observational feature of the ICS-CMB emission, i.e., the SZ effect (SZE) from the RG lobe (see Colafrancesco 2008), as we discuss in the next section.

3. The SZE from the East lobe of DA 240

It has been shown (Colafrancesco 2008; see also Colafrancesco et al. 2011) that the same ICS-CMB mechanism that accounts for the X-ray emission from the lobes of GRGs also provides an SZE from GRG lobes and that its amplitude and spectral characteristics depend on the total electronic energy density of the GRG lobe. The CMB intensity change $\Delta I_{\text{lobe}}(x)$ caused by the SZE in the lobe writes as

$$\Delta I_{\text{lobe}}(x) = 2 \frac{(k_B T_{\text{CMB}})^3}{(hc)^2} y_{\text{lobe}} \tilde{g}(x), \quad (5)$$

with

$$y_{\text{lobe}} = \frac{\sigma_T}{m_e c^2} \int P_e d\ell \quad (6)$$

(see Colafrancesco 2008), where $P_e = \varepsilon U_e$ is the pressure of electrons

$$P_e = \int_0^\infty dp N(p) \frac{1}{3} p v(p) m_e c, \quad (7)$$

and $v(p)$ is the velocity corresponding to the momentum p ; we note that for a relativistic population of particles $\varepsilon = 1/3$ and the relation $P_e = U_e/3$ holds. The relativistic SZE spectral function in Eq. (5) writes

$$\tilde{g}(x) = \frac{m_e c^2}{\langle \varepsilon_e \rangle} \left\{ \frac{1}{\tau_e} \left[\int_{-\infty}^{+\infty} i_0(xe^{-s}) P(s) ds - i_0(x) \right] \right\}, \quad (8)$$

where $x \equiv h\nu/kT_{\text{CMB}}$, in terms of the photon redistribution function $P(s)$ and of $i_0(x) = I_0(x)/[2(k_B T_{\text{CMB}})^3/(hc)^2] = x^3/(e^x - 1)$, where

$$\langle \varepsilon_e \rangle \equiv \frac{\sigma_T}{\tau_e} \int P_e d\ell \quad (9)$$

is the average energy of the electron plasma (see Colafrancesco et al. 2003). The optical depth of the electron population along the line of sight ℓ passing through the center of the lobe writes

$$\tau_e(p_1) = \sigma_T \int d\ell N_{\text{tot}}(p_1) = 2\sigma_T R N_{\text{tot}}(p_1), \quad (10)$$

where R is the radius of the lobe (we assume here a spherical symmetry and a uniform distribution of the electron density within the lobe as in Isobe et al. 2011a), and $N_{\text{tot}}(p_1) = \int_{p_1}^\infty N(p)$.

Because the amplitude and spectral shape of the GRG lobe SZE depends on the amplitude and spectral shape of the electron

Fig. 2. Absolute value of the SZE spectrum at the center of the East lobe of DA 240 for different values of the lowest electron momentum p_1 (as labelled). We adopt a value of the electron spectrum normalization $k_0 = 1.02 \times 10^{-5} \text{ cm}^{-3}$ as found from the normalization to the *Suzaku* X-ray spectrum with $p_1 = 1$ and $\alpha = 2.9$.

spectrum $N(p)$, the SZE can be used to determine the total energy density U_e reliably, and in an unbiased way, and to assess the particle and B -field regime in which RG lobes are found.

The SZE spectrum expected for a population of relativistic electrons filling the East lobe of DA 240 is shown in Fig. 2 and depends sensitively on the value of p_1 : indeed, once the values of α and k_0 are fixed from radio and X-ray observations, respectively, both the intensity and the spectral shape of the SZE (as well as the minimum, crossover and the maximum of the SZE) depend only on the specific value of p_1 . Figure 2 shows the absolute value of $|\Delta I_{\text{lobe}}(x)|$ produced in the E lobe of DA 240 over a wide frequency range, up to 10^3 GHz, where the GRG lobe SZE spectrum is situated, and shows its main spectral characteristics: i) the negative part of the SZE spectrum from low- ν up to the crossover frequency (indicated in Fig. 2 by the dip in the spectrum located at $\nu \approx 300, 565, 855$ GHz for $p_1 = 1, 10, 100$ respectively) shows a minimum (negative in sign) of its amplitude (i.e. a maximum in $|\Delta I_{\text{lobe}}|$) that is located at $\nu \approx 150$ GHz independently of p_1 ; ii) a crossover frequency from the negative to the positive part of the spectrum that increases its frequency location for increasing values of p_1 ; iii) a maximum (positive in sign) of the SZE amplitude whose frequency location strongly increases with increasing values of p_1 . Interestingly, the SZE for $p_1 = 10^3$ remains always negative at all frequencies less than 10^3 GHz, and with a minimum amplitude of $\Delta I \approx -3 \times 10^{-7} \text{ mJy arcmin}^{-2}$ (this is plotted as a maximum in the value of $|\Delta I_{\text{lobe}}|$ in Fig. 2). For lower values of p_1 , the SZE spectrum shows both the negative and positive parts of the spectrum. The strong differences of the SZE spectrum therefore allow us, hence, to distinguish various values of p_1 from a multi-frequency SZE analysis. This strong dependence allows us to use observations of the SZE to measure p_1 from a wide-frequency ($\sim 10^2 \div 10^3$ GHz) analysis of the SZE in GRG lobes.

The non-thermal SZE spectrum of DA 240 shown in Fig. 2 has been computed following the approach described in Colafrancesco (2008) using the spectral index $\alpha = 2.9$ from low- ν radio data and the normalization k_0 derived from the assumption that the X-ray flux at 1 keV from *Suzaku* is caused by ICS-CMB and has a spectrum consistent with $\alpha = 2.9$. We note here that this is a valid approach if the value of p_1 is sufficiently low to ensure a true power-law ICS-CMB X-ray spectrum for recovering the electron spectrum normalization k_0 from X-ray measurements. For $p_1 = 10^3$ the effect of the spectrum cutoff becomes visible at 1 keV and it is necessary to use a higher

Table 1. Values of the electron energy density U_e for DA 240 East, 3C 326 West and 3C 35.

p_1	U_e (DA 240) erg cm ⁻³	U_e (3C 326) erg cm ⁻³	U_e (3C 35) erg cm ⁻³
1	6.15×10^{-12}	3.21×10^{-12}	7.91×10^{-13}
5	1.98×10^{-12}	1.56×10^{-12}	4.98×10^{-13}
10	1.11×10^{-12}	1.07×10^{-12}	3.88×10^{-13}
50	2.71×10^{-13}	4.18×10^{-13}	2.08×10^{-13}
100	1.46×10^{-13}	2.77×10^{-13}	1.58×10^{-13}
1000	1.85×10^{-14}	6.99×10^{-14}	6.27×10^{-14}

normalization of the electron spectrum to reproduce the X-ray ICS-CMB data (see Sect. 2). Observations of ICS-CMB in the hard X-ray band (with Astro-H or NuSTAR) or in the gamma-ray band (with *Fermi* and the future CTA in the high-energy gamma-rays, and soft gamma-ray spectrometers) would better recover the power-law spectrum indicated by the low- ν radio data and are therefore more suitable for a reliable normalization with high values of p_1 .

Once the value of p_1 has been derived from the SZE analysis (see Colafrancesco et al. 2011, for a detailed discussion of a sample of RG lobes), the total energy density of the electron population in the RG lobe can be directly obtained using Eq. (2) (see Colafrancesco 2008; Colafrancesco et al. 2011). Table 1 shows the values of U_e derived for three GRG lobes observed with *Suzaku*: the East lobe of DA 240 ($\alpha = 2.9$, $k_0 = 1.02 \times 10^{-5}$ cm⁻³), the West lobe of 3C 326 ($\alpha = 2.6$, $k_0 = 3.24 \times 10^{-6}$ cm⁻³) and the lobes of 3C 35 ($\alpha = 2.4$, $k_0 = 4.91 \times 10^{-7}$ cm⁻³).

The minimum electron momentum p_1 can be directly derived from SZE observations by using Eqs. (2)–(8), with Eqs. (21), (22) from Colafrancesco (2008) for an analytical expression for U_e , which yield for steep spectrum sources, such as GRG lobes with $\alpha > 2$, the equation:

$$\frac{1}{p_1^{1-\alpha}} \left[\frac{1}{2} B_{\frac{1}{1+p_1^2}} \left(\frac{\alpha-2}{2}, \frac{3-\alpha}{2} \right) + p_1^{1-\alpha} \left((1+p_1^2)^{1/2} - 1 \right) \right] = \frac{\Delta I_{\text{lobe}}}{I_0} \frac{1}{2\epsilon R \sigma_T k_0 \tilde{g}(x)}, \quad (11)$$

which can be inverted to obtain p_1 from the observable quantities ΔI_{lobe} , R , k_0 at the frequency x .

Once the parameter p_1 (or equivalently $\gamma_{\min}$) is obtained, it allows us also to estimate the ICS-CMB radiative timescale of the electron population in GRG lobes that is given by

$$\tau_{\text{ICS}} = \frac{E}{(dE/dt)_{\text{ICS}}} \quad (12)$$

and is evaluated at the minimum electron energy $\gamma_{\min}$. It turns out that $\tau_{\text{ICS}} \approx 2 \times 10^8$ yr for $\gamma_{\min} = 10^3$, and it is longer for lower values of $\gamma_{\min}$ (see Fig. 3). The radiative timescale τ_{ICS} is always shorter than the synchrotron-loss time scale $\tau_{\text{synch}} = \frac{E}{(dE/dt)_{\text{synch}}}$ for all electron energies responsible for the radio emission in the 326–609 GHz range for values of B_μ fitting the radio emission, and it is also shorter than the Hubble time $t_H = H_0^{-1} \approx 9.8 h^{-1} \times 10^9$ yr for $\gamma \gtrsim 144$. Typical spectral aging and dynamical analysis for GRGs (see, e.g., Jamrozy et al. 2005, and references therein) show that the dynamical age of GRG lobes are $\gtrsim$ four times the maximum synchrotron age of the emitting electrons, and hence $\gtrsim 2 \times 10^8$ yr (see the specific case of the

Fig. 3. ICS (red) and synchrotron (blue) timescales for electrons with energy γ_e . The cyan-shaded region encloses synchrotron losses for B_μ in the range 0.3–3.

GRG J1343+3758 studied by Jamrozy et al. 2005). We notice here that the spectral aging technique relies on the electron energy correspondent to the frequency of the break in the GRG radio spectrum, which is therefore a quite high electron energy (of the order of several to several tens GeV) with respect to the minimum electron energies observed in GRG radio spectra (which are of the order of a few GeV) thus yielding lower limits to the maximum radiative electron timescale. The ICS-CMB emission provides indications on even lower electron energies that hence probe larger electron radiative timescales. We conclude, therefore, that the SZE analysis of GRG lobes can provide an estimate of the maximum electron radiative timescale and hence an estimate of the lobe dynamical timescale $t_{\text{dyn}} \approx (1 + \eta)\tau_{\text{rad}}$, with η taking values of a few, if the lobe suffers substantial inflation from backflows (see discussion in Jamrozy et al. 2005).

This argument holds for electrons with relatively high energies that satisfy $\tau_{\text{ICS}} \lesssim \tau_H$ and $\tau_{\text{ICS}} \lesssim \tau_{\text{Coul}}$ or $\tau_{\text{ICS}} \lesssim \tau_{\text{brem}}$ because at low energies (less than a few hundreds MeV) Coulomb losses and Bremsstrahlung losses dominate the radiative timescales depending on the value of the ambient density (we recall the reader that $\tau_{\text{ICS}} = \gamma / [1.37 \times 10^{-20} \gamma^2 (1+z)^4]$ s, $\tau_{\text{sync}} = \gamma / (1.30 \times 10^{-21} \gamma^2 B_\mu^2)$ s, $\tau_{\text{brem}} = \gamma / \{1.51 \times 10^{-16} n_e \gamma [\ln \gamma + 0.36]\}$ s and $\tau_{\text{Coul}} = \gamma / \{1.2 \times 10^{-12} n_e [1.0 + \ln(\gamma/n_e)]/75\}$ s, where n_e is the number density of the ambient electrons; see, e.g., Colafrancesco et al. 2006; see also Longair 1993; Sarazin 1999).

The presence of a substantial thermal electron population provides a possible complication to the previous picture because of the presence of a fraction of thermal electrons that are heated by the processes that accelerate the majority of non-thermal electrons. In this case, a thermal SZE is produced in addition (or alternatively if the acceleration mechanism is inefficient) to the non-thermal relativistic SZE discussed above (see also discussion in Yamada et al. 2010). To discuss this possible option, we show in Fig. 4 the thermal and non-thermal SZE generated from the E lobe of DA 240. The non-thermal SZE is shown for the electron spectrum as in Fig. 2 and for the two values of $p_1 = 1$ and 5. The possible thermal SZE in the lobe was computed for two values of the thermal electron temperature of $kT = 2$ and 5 keV and assuming a reference density $n_e = 10^{-4}$ cm⁻³ of the thermal particles in the lobe.

Fig. 4. Non-thermal SZE in a GRG lobe such as the E lobe of DA 240 is shown for two values of $p_1 = 1, 5$ (solid and dashed lines, respectively) and is compared with the thermal SZE in the same environment for two values of the thermal electron temperature $kT = 2, 5$ keV and a reference density $n_e = 10^{-4} \text{ cm}^{-3}$ (three dots-dashed and dot-dashed lines, respectively). We note that the lines corresponding to the non-thermal SZE are the same as those plotted in Fig. 2.

Again a multi-frequency analysis of the SZE signals (but with a higher precision of the observations, see Colafrancesco & Marchegiani 2010, for a quantitative discussion) over a wide frequency range is able to distinguish the two sources of the SZE and consequently the two electron populations.

4. Other RG lobes

The GRG DA 240 is only a representative case of an increasing database of GRGs with lobes studied through ICS-CMB emission. Studies of the energetics of GRG lobes through X-ray ICS-CMB observations become statistically relevant with the advent of *Chandra*, *XMM* and *Suzaku*. To widen our discussion, we compare in this section our findings for DA 240 with another two GRGs observed with *Suzaku* (see Table 1) and with the sample of FR II RG lobes studied in X-rays by Croston et al. (2005). For all these objects, information on U_e and U_B are available from the combination of radio and X-ray data.

Figure 5 shows the position of the three GRG lobes DA 240E, 3C 326W and 3C 35 in the $U_e - U_B$ plane. We find that GRG lobes are likely away from equipartition for any value $p_1 < 10^3$ and that their energy density is largely particle-dominated. The RG lobes analyzed by Croston et al. (2005) under the assumption $p_1 = 10$ and a constant power-law index $\alpha = 2$ for all the RG lobes also indicate $U_e/U_B \sim 10-10^2$ when accurate X-ray spectra are also indicated (filled green dots in Fig. 5). The other RG lobes with an X-ray detection but without reliable spectra (a necessary information to fully characterize the ICS-CMB emission) are subject to strong uncertainties in determining the nature of their X-ray emission (see, e.g., discussion in Croston et al. 2005). Indeed, their distribution in the $U_B - U_e$ plane is very sparse and uncertain, with the lobes distributed over very different physical regimes from below-equipartition condition ($U_e < U_B$) to a regime of strong particle dominance ($U_e \gtrsim (10-100)U_B$).

The shape of the correlation between U_e and U_B for RG lobes depends, as we already discussed, on the specific value of p_1 for each RG lobe, and it can show if GRGs are systematically different from normal RGs in their energetics and therefore in their lower energy spectrum cutoff.

To further discuss the point, we also show in Fig. 6 the trajectory of DA 240 in the U_e/U_B vs. U_e/U_{CMB} plane for

Fig. 5. Trajectory of the RG lobe DA240 in the $U_e - U_B$ plane calculated with $B_\mu = 1.5$ (which fits the radio spectrum with $p_1 = 1$) for decreasing values of $p_1 = 10^3 - 1$ (from left to right) is shown by the red open circles. The results of Isobe et al. (2009, 2011a,b) for the GRGs DA240E, 3C 35 and 3C 326W assuming $p_1 = 10^3$ are shown by the cyan dots. RG lobes from the analysis of Croston et al. (2005) obtained assuming $\alpha = 2$ and $p_1 = 10$ for all lobes are also shown as green dots: filled dots refer to lobes with reliable X-ray spectral estimates. Note these last data are not directly comparable to those of Isobe et al. (2009, 2011a,b) for GRGs.

Fig. 6. Trajectory of the GRG lobes of DA240 (open blue circles), in the U_e/U_B vs. U_e/U_{CMB} plane is shown for decreasing values of p_1 from 10^3 to 1 as in Table 1. The positions of DA 240 (filled blue circle), 3C 35 (blue filled square) and 3C 326 (blue filled triangles) for $p_1 = 10$ are also shown. The shaded areas show the regions of Compton (radiation) dominance ($P_{\text{ICS}} > P_{\text{synch}}$ or $U_B < U_{\text{CMB}}$: cyan) and synchrotron (B-field) dominance ($P_{\text{ICS}} < P_{\text{synch}}$ or $U_B > U_{\text{CMB}}$: yellow) for the single particle limit. The equipartition lines $U_e = U_B$, $U_e = U_{\text{CMB}}$ and $U_B = U_{\text{CMB}}$ are also shown for comparison. The magenta dots show the RG lobes analyzed by Croston et al. (2005) assuming $p_1 = 10$ and $\alpha = 2$: filled magenta dots refer to lobes with reliable X-ray spectral estimates (see text for discussion).

Table 2. Physical regimes for RG lobes in the U_e/U_B vs. U_e/U_{CMB} plane of Fig. 6.

Region	Regime	Condition	Notes
I	Synch. dominance	$P_{\text{ICS}} < P_{\text{synch}}$	Synch.
	B -field dominance	$U_B > U_{\text{CMB}}$	High- B
		$U_e < U_B$	Low $N(p)$
		$U_e < U_{\text{CMB}}$	
II	Synch. dominance	$P_{\text{ICS}} < P_{\text{synch}}$	Synch.
	B -field dominance	$U_B > U_{\text{CMB}}$	High- B
		$U_e < U_B$	High $N(p)$
		$U_e > U_{\text{CMB}}$	
III	Synch. dominance	$P_{\text{ICS}} < P_{\text{synch}}$	Synch.
	Particle dominance	$U_B > U_{\text{CMB}}$	Low- B
		$U_e > U_B$	High $N(p)$
		$U_e > U_{\text{CMB}}$	
IV	Compton dominance	$P_{\text{ICS}} > P_{\text{synch}}$	ICS-CMB
	Particle dominance	$U_B < U_{\text{CMB}}$	Low- B
		$U_e > U_B$	High $N(p)$
		$U_e > U_{\text{CMB}}$	
V	Compton dominance	$P_{\text{ICS}} > P_{\text{synch}}$	ICS-CMB
	Particle dominance	$U_B < U_{\text{CMB}}$	Low- B
		$U_e > U_B$	Low $N(p)$
		$U_e < U_{\text{CMB}}$	
VI	Compton dominance	$P_{\text{ICS}} > P_{\text{synch}}$	ICS-CMB
	B -field dominance	$U_B < U_{\text{CMB}}$	High- B
		$U_e < U_B$	Low $N(p)$
		$U_e < U_{\text{CMB}}$	

values $p_1 = 1, 10, 10^2, 10^3$ and the location of 3C 35 and 3C 326 for $p_1 = 10$ to compare these objects with the RG lobes analyzed by Croston et al. (2005) under the same assumptions (i.e., $p_1 = 10$).

The plot of Fig. 6 is useful to determine the physical conditions of each RG lobe. The different sectors in this plane (see Table 2) specify whether a RG lobe is particle- or radiation-dominated, Compton- or synchrotron-dominated and in which equipartition regime among U_e, U_B, U_{CMB} they are found. Table 2 describes synthetically the different physical regimes for the considered lobes in the U_e/U_B vs. U_e/U_{CMB} plane.

The GRG lobes of DA 240, 3C 326 and 3C 35 seem to be completely particle-dominated and in the Compton power dominance regime in which their total power is dominated by the ICS-CMB emission ($U_B < U_{\text{CMB}}$ and $(dE/dt)_{\text{ICS}} > (dE/dt)_{\text{syn}}$) off the electron population residing in their lobe.

To demonstrate the predictive power of our analysis, we notice that all of the Croston et al. (2005) RG lobes with good X-ray spectra are also particle-dominated and Compton-power-dominated except one, i.e., 3C 265W: this last lobe has, in fact, the highest value of the magnetic field $B_\mu = 13$. It has also been suggested that the ICS nuclear scattering emission might substantially contribute to its X-ray flux (see, e.g., Bondi et al. 2004; Croston et al. 2005), which would yield larger uncertainties on the nature of the X-ray emission and possibly overestimate artificially the value of U_e/U_{CMB} . If we take the value of U_e/U_B for 3C 265W at face value however, we should conclude that it is both particle-dominated ($U_e > U_B$) and synchrotron-dominated $U_B > U_{\text{CMB}}$ because of the quite high value of $B_\mu = 13$, which does not make this lobe a clean representative of the ICS-CMB-dominated system.

The extreme case of the 3C 280 lobe is found to be B -field- and synchrotron-dominated (lower-right quadrant II in Fig. 6) and it has the lowest value of $U_e/U_B = 0.2$. This RG lobe suffers from a lack of definite spectral measurement at X-rays which,

however, does not allow us to determine the nature of its X-ray emission. The difficulty of separating the different components of the X-ray emission in RG lobes correctly led to discrepant results in the literature (Croston et al. 2005). In this respect it is extremely unlikely that any flux measurements are underestimates of the lobe ICS-CMB emission, so that any systematic uncertainty in the value of U_e/U_B and U_e/U_{CMB} is more likely to be an overestimation.

Our analysis of RG lobes reported in Fig. 6 indicates that all GRG lobes with definite ICS-CMB spectral measurements are particle-dominated and ICS-CMB-power-dominated. The other RG lobes have X-ray spectral measurements that are likely contaminated by nuclear or hot-spot X-ray emission.

We propose here to use the $U_e/U_B - U_e/U_{\text{CMB}}$ plot to characterize the physical regime of RG lobes better, and we will present a more extensive analysis of RG lobe multi-frequency emission elsewhere (Colafrancesco et al., in prep.).

The condition $U_e/U_B \sim 10-100$ suggested by the GRG lobe data (see Figs. 5 and 6) indicates a substantial amount of electrons with energies above $\gamma_{\text{min}} \gtrsim 10$ and up to $\gamma_{\text{max}} \sim 10^5-10^6$ which seems to be required to explain the radio, mm, X-ray and (in a few observed cases) also the gamma-ray observations (see, e.g., Massaro & Ajello 2011, and references therein). This relatively energetic electron population spread over the GRG lobes could be sustained by turbulent acceleration mechanisms and diffusion in a filamentary B -field configuration (see Gopal-Krishna et al. 2001) that seems to be efficient in balancing their radiative energy losses along the late stage of the GRG lobe evolution.

More effective and definitive observations are required to probe the total energy density of RG lobes however. The results reported here demonstrate that SZE measurements are crucial to establish in an unbiased way the realistic estimates of U_e and hence the correlation between U_e and U_B for RG lobes.

5. Summary and conclusions

We have shown that the electron energy density U_e in GRG lobes derived from X-ray observations is only a rough lower limit to the actual value of U_e if p_1 is substantially less than 10^3 , as indicated by observations and theoretical expectations. This result is even stronger for larger spectral indices α , as those shown by GRG lobes. This indicates that – even though X-ray measurements are relevant to set the electron spectrum normalization at high- E_e – the properties of the low-energy electron population in the radio lobes are poorly constrained by X-ray measurements that probe electrons with $E_e \sim 0.1-1$ GeV (for $E_X \sim 0.1-10$ keV), which is particularly problematic when studying the overall power of the ICS-CMB process. Moreover this leads us to reconsider the physical regimes in which GRG lobes are found.

We have shown that all RG lobes with reliable ICS-CMB spectral measurements in the X-ray band are in a regime of radiative Compton dominance and particle domination with respect to the B -field energy density. Therefore RG lobes are likely expected to have $U_e/U_B \gtrsim 10-100$ and $U_e/U_{\text{CMB}} \gtrsim 1-20$, which indicates that they have a population of relatively energetic electrons providing a substantial energy and pressure support to the lobes, consistent with a turbulent MHD acceleration origin. Under this regime, we predict that many other RG lobes will be visible with the next-generation hard X-ray (Astro-H, NuSTAR) and some also with gamma-ray (CTA and the next-generation soft gamma-ray spectrometer) instruments. The importance of the future hard X-ray and gamma-ray observation

is their ability to set the electron spectrum normalization, even though they cannot definitely assess the value of the total U_e . We have shown that the SZE visible in the direction on many of these GRG lobes with the next coming microwave and mm spectroscopic experiments (see discussion in Colafrancesco & Marchegiani 2010; and Colafrancesco et al. 2011) ensures the capability of determining the total value of U_e because the SZE is sensitive to the overall energy spectrum extension and in particular to the minimum energies of the electron population.

A final point we stress is that the determination of the RG lobe B -field from radio and X-ray observations implies the assumption of a model for the electron spectrum (as also pointed out in Croston et al. 2005). In fact, electrons that emit in the radio (by synchrotron) and in the X-rays (by ICS-CMB) are not identical except for a specific choice of the B -field. For the DA 240 East lobe, an X-ray observation at 1 keV implies that these electrons have an energy of $E_e \sim 0.35$ GeV, and that the same electrons emit synchrotron at a frequency $\nu \sim 2B_\mu$ MHz with $B_\mu = 1.5 \div 0.87$ for $p_1 = 1-10^3$, respectively. Electrons that emit synchrotron in the observed range ($\nu = 326 \div 609$ MHz) have energies $E_e \sim (4.5 \div 6.2)B_\mu^{-1/2}$ GeV, and emit by ICS-CMB in the range $E_X \sim (160 \div 310)B_\mu^{-1}$ keV. The assumption of using the same electron spectrum in the two electron energy ranges is likely reasonable only if the radio and X-ray spectral indices are compatible within the uncertainties.

Future studies of RG lobes with high-sensitivity radio experiments (like SKA and its precursors, MeerKAT in South Africa and ASKAP in Australia) will be able to measure the electron spectrum and the magnetic field with high precision and spatial resolution from observation over a wide frequency range $\sim 0.1-45$ GHz, and their high- ν bands at $\gtrsim 30$ GHz will also be able to measure simultaneously the radio and SZE spectrum at low frequencies, while mm experiments (e.g. *Planck*, OLIMPO, HERSCHEL, ALMA) will be able to fully measure the SZE spectrum and the RG lobe energetics. In this context, hard X-rays (NuSTAR, Astro-H) and gamma-rays (*Fermi*, CTA) will be crucial for determining the high-E spectrum normalization and for indicating on the high-E energy cutoff. The recent observations on Centaurus A with the *Fermi*-LAT instrument (Abdo et al. 2010) and of Fornax-A with *Suzaku* (Tashiro et al. 2009) indicate that ICS-CMB emission dominates the GRG lobe SEDs at very high frequencies and opens the way to the determination

of their electron spectrum at the high-E tail. These observations will be crucial for exploiting the SZE observational techniques of GRG lobes.
