ABSTRACT

Aims. We have used deep V-band and JHKs-band observations to investigate variability and stellar populations near the Galactic plane in Centaurus, and compared the observations with the Galactic model of Besançon.

Methods. By applying image subtraction technique to a series of over 580 V-band frames taken with the ESO VLT/VIMOS instrument during two contiguous nights in April 2005, we have detected 333 variables among 84 734 stars in the brightness range 12.7 < V < 26.0 mag. Infrared data collected in March 2010 with the new ESO VISTA telescope allowed us to construct deep combined optical-IR colour-magnitude and colour–colour diagrams.

Results. All detected variables but four transit candidates are reported for the first time. The majority of the variables are eclipsing/ellipsoidal binaries and δ Scuti-type pulsators. The occurrence rate of eclipsing/ellipsoidal variables reached ~0.28% of all stars. This is very close to the highest fraction of binary systems detected using ground-based data so far (0.30%), but still about four times less than the average occurrence rate recently obtained from the Kepler space mission after 44 days of operation. Comparison of the observed Ks vs. V − Ks diagram with a diagram based on the Besançon model shows significant effects of both distance and reddening in the investigated direction of the sky. We demonstrate that the best model indicates the presence of absorbing clouds at distances 11–13 kpc from the Sun in the minor Carina-Sagittarius arm.

1. Introduction

In recent years our knowledge on the structure of the Milky Way Galaxy has greatly improved thanks to wide-field photometric surveys conducted from ground-based and orbital telescopes. They are usually dedicated to the detection of particular objects, such as transiting extrasolar planets, microlensing events, or gamma ray burst afterglows, e.g., MACHO (Alcock et al. 2000), OGLE (Udalski et al. 2003), HAT (Bakos et al. 2004), ROTSE (Woźniak 2004), ASAS (Pojmański 2001), and the Kepler space mission (Koch et al. 2010). However, these surveys also discover an enormous amount of new variable objects of different types (e.g., Woźniak et al. 2002; Pojmankaś 2005; Natal et al. 2010). Variable stars provide important information about the structure and evolution of stars as well as the whole Galaxy (e.g., Alcock et al. 1998; Szczygieł et al. 2009).

The most recent view of the Galactic plane regions has been presented by Churchwell et al. (2009) based on the Spitzer/GLIMPSE surveys. The large-scale structure of the Galaxy has been traced by red-clump giants to reveal the radius and orientation of the central bar, thanks to characteristic changes in star counts for |l| < 65° as a function of Galactic longitude at a wavelength of 4.5 μm.

A useful method to investigate structure and stellar populations in the Galaxy is the comparison of synthetic magnitude histograms, colour–magnitude diagrams (CMDs), and colour–colour diagrams with real data (Lucas et al. 2008). Here, we construct deep (down to V ≈ 26.0 mag and Ks ≈ 18.6 mag) optical-IR colour–colour and colour–magnitude diagrams of two southern Galactic plane fields. For one of these fields we present the results of a search for variable stars and compare the observed Ks vs. V − Ks diagram with a theoretical one based on the Galactic model of Besançon (Robin et al. 2003). Our results show the great potential of ongoing and upcoming large visual and near-infrared surveys, such as LSST (Large Synoptic Survey Telescope, Ivezić et al. 2008), VVV (Vista Variables in the Via Lactea, Minniti et al. 2010), or Pan-STARRS (Kaiser et al. 2002).

2. Observations and data reduction

The observations presented in this work were carried out with the ESO VISTA and UT3 telescope at Paranal Observatory. The infrared observations were collected with the new 4.1-m Visible and Infrared Survey Telescope for Astronomy (VISTA) as a part of the VISTA Variables in the Via Lactea (VVV) ESO Public Survey (Minniti et al. 2010). The telescope is equipped with a 16 × 2048 × 2048 pixel near-IR camera with a pixel size of 0′.34. The monitored area of the VVV survey covers the Galactic bulge

Notes. Coordinates are given for the centres of the fields. Reddening values were taken from Schlegel et al. (1998).

\(-10^\circ < l < +10.5^\circ, -10^\circ < b < +5.6^\circ\) and an adjacent section of the Galactic plane \((-65^\circ < l < -10^\circ, -2.25^\circ < b < +2.25^\circ)\). Planned observations span the years 2010-2014 with the main variability monitoring campaigns in 2012 (bulge area) and 2013 (disc area). We used the DOPHOT package (Schechter et al. 1993) to extract photometry from images obtained with VISTA.

Optical data were obtained with VIMOS at the 8.2-m Unit Telescope 3 (UT3) of the Very Large Telescope in April 2005. VIMOS is an imager and multi-object spectrograph (LeFevre et al. 2003). Its field of view consists of four quadrants of about 7' × 8' each, separated by a cross, 2' wide. Each CCD has 2048 × 2440 pixels with a pixel size of 0.205'. The main goal of that programme was to perform a photometric follow-up of over 30 OGLE transiting candidates spread over four VIMOS fields in the constellations Carina, Centaurus and Musca. Some individual results were published by Fernández et al. (2006), Díaz et al. (2007), Hoyer et al. (2007), Minniti et al. (2007), Pietrukowicz et al. (2009) and Pietrukowicz et al. (2010).

The work presented here focuses on two VIMOS fields located within the VVV area in Centaurus. They contain OGLE-TR-167 and OGLE-TR-170, both classified as planetary transit candidates by Udalski et al. (2004), but currently known as eclipsing systems (Pietrukowicz et al. 2010). We will refer to the fields as F167 and F170, respectively. They are located within the VVV tiles\(^1\) d009 and d008, respectively. The field F167 was monitored for two hours in the night of 2005 April 9, and during the whole night of 2005 April 10, while the field F170 was observed for the whole two subsequent nights of 2005 April 11–12. All VIMOS images were taken in the V-band only. Three hundred ninety-five and 583 exposures were obtained in the fields F167 and F170, respectively. Table 1 gives basic information on these fields.

The periphery of each VIMOS quadrant suffers from coma. Therefore, we reduced the field of view to 1900 × 2100 pixels, which then covered 7'18 × 6'49. The total field in which we searched for variable objects equals 186.3 arcmin\(^2\). In Fig. 1 we show the location of the two VIMOS fields overlaid on a part of the VVV disc area.

Owing to the longer time span and larger number of images taken in the field F170, we decided to focus our search in this field. The photometry was extracted with the help of the Difference Image Analysis Package (DIAPL) written by Wozniak (2000) and modified by W. Pych\(^2\). The package is an implementation of a method developed by Alard & Lupton (1998). To obtain higher quality photometry, we divided the field into 475 × 525 pixel subfields.

Reference frames were constructed by combining nine of the highest quality individual images, i.e. with the best seeing

\(^1\) For the definition of the tile see the VVV description paper by Minniti et al. (2010).

\(^2\) The package is available at http://users.camk.edu.pl/pych/DIAPL/
We have matched the V-band data obtained with VIMOS for the fields F167 and F170 with JHK_s-band observations from VISTA using equatorial coordinates. Prior to this operation we prepared auxiliary maps showing positions of stars from both lists and we applied position corrections in each VIMOS quadrant. Because of the large difference in brightness of stars in the optical and infrared passbands and the effect of coma in the corners of the VIMOS detectors we decided to set a matching radius of 1′′.5, and to reject all ambiguous objects from the final list.

### 4.1. Star count histograms

Table 3 gives numbers of all detected and matched stars together with magnitude range in the V and K_s bands. The difference of 0.8 mag in the K_s-band limit for the brightest stars between the two fields results from different saturation values of chips of the infrared camera at the VISTA telescope.

Figures 7 and 8 illustrate the star count histograms for fields F167 and F170, respectively. The histograms clearly show that the number of stars in the K_s-band increases more rapidly than the one in the V-band. From the location of maxima in the V-band (upper panels) one can find that the optical data from VIMOS are about 1 mag deeper than the near-IR data from VISTA. In the lower panel of Fig. 8 we add a profile based on the Besançon Galactic model, which we describe in detail in Sect. 5. From the comparison of the models with the observations we can infer that the analysed data are complete down to K_s ∼ 17.5 mag.

### 4.2. Colour–magnitude and colour–colour diagrams

In Fig. 9 we show K_s vs. V − K_s CMDs for the two observed VIMOS fields. The main features in both diagrams are the main sequence and the area of red giants. This is particularly obvious in field F170, where the saturation level is higher. Significant distance and reddening effects can be easily noted. The red giants spread over at least 2 mag in the K_s-band (12.5 < K_s < 14.5 mag) and 1 mag in colour (4.5 < V − K_s < 5.5 mag). According to the newest view of our Galaxy (Churchwell et al. 2009), most observed stars in these two fields are very likely objects located in the Scutum-Centaurus arm, which is tangent to the line of sight in this direction. Distances of these stars are very likely in the range from 4 to 10 kpc. Assuming a maximum reddening of E(B − V) ∼ 2.1 mag in the investigated disc fields (Schlegel et al. 1998), and a “universal” extinction law A_V = 3.1E(B − V), we obtain a maximum absorption of A_V ∼ 6.5 mag.

Figure 9 also shows a lack of faint clump giants (with K_s < 15 mag), which can be interpreted as the line of sight leaving the stellar edge of the Milky Way plane (Minniti et al. 2011).

For the two VIMOS fields we have also constructed Hess diagrams using a bin size of 0.2 mag in K_s and 0.4 mag in V − K_s, and shown in Fig. 10 together with the subtraction of the F167 diagram from that of F170. The results confirm that the reddening in field F167 is higher than in F170, as it is to be expected because of its slightly closer position to the Galactic plane (B_V(F170) ≈ −2.0′′ vs. B_V(F167) ≈ −1.5′′).

Figure 11 shows J vs. J − K_s CMDs for the two VIMOS fields. Here we arbitrarily separated red giants from main sequence stars with a solid line. The two luminosity classes are also marked in the colour–colour diagrams presented in Fig. 12.
Fig. 3. Examples of phased light curves of eclipsing/ellipsoidal variables with estimated period (in days).

Fig. 4. Examples of light curves of eclipsing variables with unknown period.

Of the 333 detected variables in field F170 we have obtained $K_s$-band magnitudes for 223 with VISTA. We marked the positions of these objects in the $K_s$ vs. $V - K_s$ diagram presented in Fig. 13. We stress that their positions in the CMD are still uncertain, because $K_s$-band light curves and consequently average magnitudes are not available yet. At this point we are able to infer the following: (1) probably all observed eclipsing and ellipsoidal variables are main-sequence binaries; (2) four transiting objects are main-sequence stars; (3) most of the detected $\delta$-Scuti pulsators seem to be located in the closer part of the Scutum-Centaurus arm. The last point results from the fact that $\delta$-Scuti variables have low amplitudes of $0.01 - 0.12$ mag. This type of stars placed in the arm should have $13 < V < 24$ mag (assuming $A_V < 6.5$ mag), whereas we have detected $\delta$-Scuti pulsators with $15.7 < V < 19.6$ mag.

5. Comparison with the Galactic model of Besançon

We have compared our data with the stellar population synthesis model of our Galaxy developed by the Besançon group (Robin et al. 2003). For the purpose of this work we have simulated a model assuming a total integration time of 10 Gyr, constant star-formation rate, and no kinematic effects. This was done for stars of absolute brightness \(-7 < M_V < +20 \) mag, spectral types between O0 and D5, luminosity classes I to VI, and distances up to 50 kpc from the Galactic center. The selected sky region in our study includes the thin disc, thick disc, and the spheroidal halo. In the Besançon model the disc truncates at 14.0 kpc from the Galactic centre located at a distance of 8.5 kpc from the Sun. The profile densities of stars and interstellar matter are described by the Einasto law. We have tested models with different values of diffuse extinction \( a_V \) and additional discrete clouds of a given absorption \( A_V \). The model output is a list of synthetic stars with information on distance, absolute magnitude, luminosity class, age, mass, metallicity, and observed magnitudes and colours.

In Fig. 14 we compare two modelled \( K_s \) vs. \( V - K_s \) diagrams with the observed one for field F170. The colours in the

6. Conclusions

We have used deep optical data from VLT/VIMOS and near-IR data from VISTA to search for variable stars and to investigate stellar populations near the Galactic plane in the constellation Centaurus. In the VIMOS field F170 in a series of 583 V-band images spread over two nights we have detected 333 variables among 84 734 stars with brightness in the range 12.7 < V < 26 mag. Only four of these objects were previously known. For 263 variables we were able to assess the periods. Fifty-three of the newly discovered variables are pulsating stars, mostly of δ Scuti type. Thirty-eight objects show brightness variations on long-time scales, and require a longer timeline of observations to derive their period and mean luminosity.

Among all observed variables 241 are classified as eclipsing/ellipsoidal binaries, which is 0.284% of the whole sample of searched stars. In Table 4 we compare this result with the rate of binaries detected in Galactic fields in other recent ground-based variability studies as well as in the Kepler space mission.

The simple search method we applied to our short-period data, the eye inspection of all light curves, turned out to be very effective. It is interesting that we have obtained almost the same
rate of eclipsing/ellipsoidal systems as in our previous search in a VIMOS field in Carina (Pietrukowicz et al. 2009). The binary detection rate would be very probably higher if the observations lasted considerably longer than only two days. Preliminary results from the Kepler space mission show that after the first 44 days of operation the average occurrence rate of binary systems is $\sim 1.2\%$ (Prša et al. 2011). However, the Kepler photometry is much more accurate, which allows the detection of a larger part of lower amplitude variables than the other ground-based surveys. About 51% of 1879 eclipsing/ellipsoidal binary stars detected by Kepler have orbital periods shorter than 1.44 days, whereas in the VIMOS sample 203 out of 241 binary systems have orbital periods $<1.44$ d. Assuming the same binary occurrence rate in all directions of the Milky Way we estimate that one can find up to $\sim 0.5\%$ of binaries in ground-based data using an image subtraction technique.

In the second part of this work we have combined the $V$-band data from VIMOS with $JHK_s$-band photometry from VISTA.

**Fig. 10.** Hess $K_s$ vs. $V - K_s$ diagram for the field F170 (left panel) and F167 (middle panel). The subtraction of these two diagrams is shown in the right panel.

**Fig. 11.** $J$ vs. $J - K_s$ colour–magnitude diagrams for common VIMOS-VVV stars in the VIMOS fields F167 (left panel) and F170 (right panel). The solid lines roughly separate main-sequence from red giant stars.

**Fig. 12.** Two $(V - J$ vs. $J - K_s$ and $J - H$ vs. $H - K_s)$ colour–colour diagrams for common VIMOS-VVV stars in the VIMOS fields F167 and F170. Red giants selected in the CMDs in the previous figure are shown in red.

**Fig. 13.** $K_s$ vs. $V - K_s$ diagram with marked positions of 223 variables found in the VIMOS field F170.
Fig. 14. Comparison of the observed (left panel) and two modelled $K_s$ vs. $V - K_s$ diagrams for the field F170. Stars of different luminosity classes are shown in colours: supergiants (class I) and bright giants (class II) in black, giants (class III) in red, subgiants (class IV) in green, main-sequence stars (class V) in blue. Both models are for the standard extinction $a_V = 0.70$ mag/kpc, but the one in the right panel contains additional interstellar clouds at distances 11–13 kpc from the Sun. The wider spread in the $V - K_s$ colour for giants and proper number of stars in the small box indicate that the model with the clouds provides the better fits.

Fig. 15. Observed (left) and modelled (middle) Hess $K_s$ vs. $V - K_s$ CMDs. The subtraction of these two diagrams is shown in the right panel. For objects fainter than $K_s \sim 17.5$ mag the data are incomplete.

This has been done for the VIMOS fields F167 and F170. We presented optical-IR colour–magnitude and colour–colour diagrams. By subtracting CMDs for field F167 from field F170 we confirmed that the reddening in field F167, which is located slightly closer to the Galactic plane, is indeed higher than in F170. From the location of the detected variables in the CMD we conclude that probably all objects belong to main-sequence stars in the Scutum-Centaurus arm.

From the comparison of the observed $K_s$ vs. $V - K_s$ diagrams with different synthetic diagrams based on the Galactic model of Besançon we conclude the presence of interstellar clouds at distances 11–13 kpc from the Sun. The clouds may belong to
the minor Carina-Sagittarius arm located between the Scutum-Centaurus arm and the distant extended spiral arm of the Milky Way.

The results presented in this paper, including the large number of newly discovered variables in a relatively small field, high-quality photometry, and the construction of deep optical-IR colour–magnitude diagrams demonstrate that ground-based wide-field multiple-band variability surveys are powerful tools for drawing a detailed picture of our Galaxy.
