ABSTRACT

We present Submillimeter Array observations of the young stellar object IRAS 04579+4703 in the 1.3 mm continuum and in the 12CO(2−1), 13CO(2−1), and C18O(2−1) lines. The 1.3 mm continuum image reveals a flattened structure with a mass of 13 M⊙. The 12CO(2−1) line map and position-velocity diagram, together with the broad wing (full width at half maximum) of the 12CO(2−1) line, clearly show that there is an outflow motion, which originates from an embedded massive YSO in this region. The lengths of the blue-shifted and red-shifted lobes are 0.14 pc and 0.13 pc, respectively. The total gas mass, average dynamical timescale, and mass entrainment rate of the outflow are 1.8 M⊙, 1.7 × 104 yr and 1.1 × 10−4 M⊙ yr−1, respectively. The flattened morphology of the continuum source perpendicular to the outflow direction, and the velocity gradient seen in the spectra of C18O(2−1) taken from different locations along the major axis of the continuum source, suggest that there is an accretion disk in this region.

Key words. ISM: individual objects: IRAS 04579+4703 – ISM: kinematics and dynamics – ISM: molecules – stars: formation

1. Introduction

Observational evidence suggests that massive stars may be formed by means of accretion-disk-outflow processes similar to those operating in low-mass stars (e.g. Shu et al. 1987; Cesaroni et al. 1999; Shepherd et al. 2001; Patel et al. 2005; Jiang et al. 2005; Zinnecker & Yorke 2007). This has been a rapid increase in the number of searches for collapse, accretion, and outflow with interferometers in massive star-formation regions (e.g. Beuther et al. 2004; Qin et al. 2008; Furuya et al. 2011), but the still limited available observations cannot provide the detailed information required to improve our understanding of massive star formation. The major difficulty is due to the large distances of the typical targets (≥1 kpc), the clustered formation environments, and the shorter evolutionary timescales of massive stars.

IRAS 04579+4703 is a young high-mass stellar object (YSO). Molinari et al. (1996) carried out the NH3 observation toward IRAS 04579+4703, and obtained a distance of 2.47 kpc from the Sun and a bolometric luminosity of 3.91 × 105 L⊙. However, Molinari et al. (1998a) failed to observe any 6 cm emission from IRAS 04579+4703. Sánchez-Monge et al. (2008) performed higher spatial resolution continuum observations at 1.2 mm, 7 mm, 1.3 cm, and 3.6 cm toward IRAS 04579+4703. Their observations showed that the 7 mm emission, which is similar to the 1.3 cm and 3.6 cm emission in terms of morphology, is elongated in the southwest-northeast direction. The location of their 1.2 mm continuum peak agrees well with that of the source detected at cm wavelengths as well as an H2O maser (Palla et al. 1991; Mignosa et al. 1999), indicating that the emission only concentrate on a small and compact region and that IRAS 04579+4703 is at an early evolutionary stage. Using the SED fit, Sánchez-Monge et al. (2008) derived a dust temperature of about 30 K and inferred a gas mass of 23 M⊙. The 12CO(2−1) line observations of Zhang et al. (2005) did not reveal molecular outflow from IRAS 04579+4703, while Wouterloot & Brand (1989) observed the 12CO(1−0) emission with a linewidth of 6.1 km s−1. Additionally, Varricatt et al. (2010) detected jet-like H2 knots in the northwest-southeast direction. However, these observations cannot provide sufficient evidence of the outflow. Higher spatial resolution observations of the molecular lines and continuum in submillimeter/millimeter waveband are needed to reveal the detailed source structure and kinematics in this region.

In this Letter, we present Submillimeter Array (SMA) observations of the young stellar object IRAS 04579+4703 obtained in the 1.3 mm continuum and in the 12CO(2−1), 13CO(2−1), and C18O(2−1) lines. Our observations at high angular resolution reveal bipolar outflow motion and gas accretion for IRAS 04579+4703.

2. Observations and data reduction

The observations toward IRAS 04579+4703 were performed with the SMA on 2008 March 21, at 220 GHz (lower sideband) and 230 GHz (upper sideband). The two sidebands of the SMA covered frequency ranges of 219.4–221.4 GHz and 229.4–231.4 GHz, respectively. The projected baselines ranged from 7 kλ to 100 kλ. The phase track center was RA(J2000.0) = 05h01m39s92 and Dec(J2000.0) = 47°07′21″. The typical system temperature was 186 K. The spectral resolution is 0.406 MHz, corresponding to a velocity resolution of 0.5 km s−1. The bright quasar 3C 279 was used for bandpass calibration, while absolute flux density scales were determined from observations of Titan. QSO 0533+483 and QSO 0359+509 were observed for antenna gain corrections. The calibration and

with frequency (Sánchez-Monge et al. 2008), association with an H2O maser, and compact source structure suggest that there is a hypercompact Hα region in this region (Sewilo et al. 2004). Therefore the 1.3 mm continuum emission may comprise free-free emission from the hypercompact Hα region and the thermal emission from the warm dust from its surroundings (Keto et al. 1988; Beltrán et al. 2011). The emission from the free-free component of the continuum flux in our source can be estimated by \( S_f \propto \nu^2 \), where the free-free spectral index \( \alpha \) is 1.1 from 3.6 cm to 1.3 cm continuum emission. The contribution of the free-free emission to the 1.3 mm continuum is \( \sim 4.4 \) mJy (much lower than our total integrated flux 0.11 Jy at 1.3 mm), and can then safely be ignored.

To determine the total gas mass of the continuum source, we make the optically thin approximation for the dust continuum emission. The total gas mass of the continuum source can be estimated by \( M_{\text{gas}} = S_\nu D^2/\kappa \nu R_B(T_D) \), where \( S_\nu \) is the flux at the frequency \( \nu \) and \( D \) is the distance to the source. We assume \( \kappa = 0.05(\nu/230)^{0.5} \text{m}^2\text{kg}^{-1} \) for the opacity (Testi & Sargent 1998), where we adopt \( \beta = 2 \) (Drain & Lee 1984) and a dust-to-gas mass ratio \( R = 0.01 \) (Lis et al. 1991), and \( B_\nu(T_D) \) is the Planck function for a dust temperature \( T_D \) at frequency \( \nu \). Using a dust temperature of \( \sim 30 \) K (Sánchez-Monge et al. 2008), we derive a total gas mass of 13 \( M_\odot \). Because the extended envelope can be filtered by the interferometers, which are missing short spacing data, the mass of the gas derived from our data is lower than 23 \( M_\odot \) according to the single dish observations (Sánchez-Monge et al. 2008).

### 3.2. Molecular line emission

Figure 2 shows the spectra of \(^{12}\text{CO}(2\rightarrow1), ^{13}\text{CO}(2\rightarrow1), \) and \(^{13}\text{CO}(2\rightarrow1)\) emission at the peak position of the continuum image. The \(^{12}\text{CO}(2\rightarrow1)\) and \(^{13}\text{CO}(2\rightarrow1)\) lines clearly display asymmetric profiles with double peaks, which may be caused by large optical depths (André et al. 1999; Belloche et al. 2002). The \(^{13}\text{CO}(2\rightarrow1)\) line with a single emission peak can be considered as optically thin, hence can be used to determine the systemic velocity. We measure a systemic velocity of \( \sim 17.0 \) km s\(^{-1}\) for this line. The velocities of the blue and red emission peaks of \(^{12}\text{CO}(2\rightarrow1)\) are \( \sim 20 \) km s\(^{-1}\) and \( \sim 13 \) km s\(^{-1}\). For \(^{13}\text{CO}(2\rightarrow1)\), the velocities of the blue and red emission peaks are \( \sim 19 \) km s\(^{-1}\) and \( \sim 16 \) km s\(^{-1}\).

The \(^{12}\text{CO}(2\rightarrow1)\) and \(^{13}\text{CO}(2\rightarrow1)\) spectra show a “blue profile” signature (Wu et al. 2007), and the blue peaks of both lines are stronger than their red peaks with an absorption dip near the systemic velocity, which may be produced by infall motion or accretion. In addition, the \(^{12}\text{CO}(2\rightarrow1)\) spectrum has an unusual full width of \( \sim 30 \) km s\(^{-1}\) from \( \sim 38 \) to \( \sim 8 \) km s\(^{-1}\). Such a broad wing is a strong indication of outflow motion.

To determine the velocity components and spatial extension of the outflow, we compiled a position-velocity (PV) diagram along the cuts at various position angles, and found that the redshifted and blueshifted components are the strongest at a position angle of \( \sim -40^\circ \) (40° west of north) as shown in Fig. 3. The PV diagram in Fig. 3 clearly shows bipolar components. The blueshifted and redshifted components have obvious velocity gradients from \( \sim -24.2 \) to \( \sim 20 \) km s\(^{-1}\) and \( \sim 13 \) to \( \sim 8.5 \) km s\(^{-1}\), respectively (see the blue and red vertical dashed lines in Fig. 3). The distributions of redshifted and blueshifted velocity components in Fig. 3 provide further evidence of a bipolar outflow in this region (Yamashita et al. 1989).

Using the velocity ranges determined from the PV diagram, we made velocity-integrated intensity maps superimposed on the

Fig. 2. Spectral profiles observed at the central position of IRAS 04579+4703 in the optically thick \(^{12}\)CO(2–1), \(^{13}\)CO(2–1) lines, and the optically thin C\(^{18}\)O(2–1) line. The dotted line in the spectra marks the cloud systemic velocity.

Fig. 3. The position–velocity plot of the \(^{12}\)CO(2–1) emission at a position angle of ~40\(^\circ\). The contour levels are 1.4, 1.8, 2.3, 2.7, 3.2, 3.6, 4.1, and 4.5 Jy beam\(^{-1}\), and 1 \(\sigma\) is 0.7 Jy beam\(^{-1}\). The black vertical dashed line marks the cloud systemic velocity. The blue and red vertical dashed lines mark the velocity ranges of the blueshifted and redshifted emission, respectively.

IRAS 04579+4703 and a near-IR source. Varricatt et al. (2010) suggested that the near-IR source may be the near-IR counterpart of IRAS 04579+4703 with the strong infrared excess. The position of the near-IR source agrees well with the peaks of the 1.3 mm, 7 mm, 1.3 cm and 3.6 cm emission within the positional uncertainty. Both H\(_2\) and Br\(_y\) emission are very close to the near-IR source (Ishii et al. 2001; Varricatt et al. 2010). Interpreting the data together, we conclude that the near-IR source may be an embedded massive YSO, which is likely to drive the bipolar outflow.

Under conditions of local thermodynamical equilibrium (LTE), since \(^{12}\)CO(2–1) is optically thick, and the beam is completely filled by the source (the filling factor \(f = 1\)), the column density of the outflow is estimated following Garden et al. (1991) with a relation \(N_{H_2} = 10^4 N_{CO}^{12}\) (Dickman 1978) using the equation:

\[
N_{H_2} = 1.08 \times 10^9 \frac{T_{ex} + 0.92}{\exp(-16.62/T_{ex})} T_{mb} \times \frac{\tau dv}{[1 - \exp(-\tau)]} \text{ cm}^{-2},
\]

where \(T_{ex}\) is the excitation temperature, \(T_{mb}\) is the corrected main-beam temperature, and \(\tau\) is the optical depth of the \(^{12}\)CO(2–1) line. We assume the solar abundance ratio \([^{12}\text{CO}] / C^{18}\text{O}] = \tau(^{12}\text{CO})/\tau(C^{18}\text{O}) = 490\) (Garden et al. 1991), and estimate \(T_{ex}\) following the equation \(T_{ex} = 11.1 \ln[1 + 1/(T_{mb}/11.1 + 0.02)]\) (Garden et al. 1991). The redlobe and blue-lobe peaks of the outflow near the continuum, then we assume that the \(^{13}\)CO and C\(^{18}\)O trace the same cloud components at the peak positions of the two lobes for in calculation, and the assumption is reasonable since both \(^{12}\)CO(2–1) and C\(^{18}\)O(2–1) are low energy transition with similar upper level energy. Under the assumption that C\(^{18}\)O is optically thin, we calculate \(\tau\) according to \(\tau = -490 \ln[1 - (e^{11.1/T_{ex}} - 1)]T_{mb}^{11.1/11.1}\) (Garden et al. 1991). Under the Rayleigh-Jeans approximation,
In Fig. 1, respectively, which are separated by 4°. The black vertical dashed line marks the cloud systemic velocity. The blue and red vertical dashed lines mark the peak velocities, respectively.

The dynamical mass is estimated to be $1.36 \times 10^{-3} M_\odot$. Assuming that the rotation is Keplerian, the dynamical timescale can be determined by $t_d = v \pi / (2 \Omega)$, where $v$ is the maximum flow velocity relative to the cloud systemic velocity, and $\Omega$ is the length of the begin-to-end flow extension for each lobe. The lengths of the blueshifted and redshifted lobes obtained from Fig. 1 are 0.14 pc and 0.13 pc, respectively, which is only a lower limit owing to projection onto the sky plane. The mass entrainment rate of the outflow is calculated using $M_{\text{out}} = M_{\text{out}} / t_d$. The physical parameters and the calculated results of the outflow are summarized in Table 1. The difference in the parameters of the two lobes reflects that the lack of uniformity of the ambient material, hence the different masses and dynamics. The outflow has a total mass of $1.8 M_\odot$ and a mass entrainment rate of $1.1 \times 10^{-4} M_\odot$ yr$^{-1}$. The average dynamical timescale is about $1.7 \times 10^4$ yr.

4.2. Accretion

Our interferometric continuum image toward IRAS 04579+4703 reveals a flattened structure, perpendicular to the direction of the outflow detected in $^{12}$CO(2–1) and $H_2$. This is consistent with the accretion disk scenario proposed for the other high-mass star formation regions (Cesaroni et al. 1999; Shepherd et al. 2001; Patel et al. 2005). The $^{18}$CO(2–1) spectra from the two positions (the red and blue plus symbols in Fig. 1) perpendicular to the direction of the outflow are shown in Fig. 4. The velocity gradient is seen from the $^{18}$CO(2–1) spectra, suggesting that the disk is rotationally and gravitationally bound by the central YSO. Assuming that the rotation is Keplerian, the dynamical mass (binding mass) is estimated to be $M = 6.22 \times 10^{-3} (L/L_\odot)^{1/2} (M/M_\odot)^{-1/2}$. Assuming that the dynamical mass of $12 M_\odot$ is equal to the protostar mass, the expected accretion rate is $3.7 \times 10^{-4} M_\odot$ yr$^{-1}$.

The "blue profile" of the $^{12}$CO(2–1) line provide further evidence for the infall motion or accretion discussed in Sect. 3.2. The mass accretion rate is estimated to be $M = 4 \pi R^2 \dot{M}_\text{in}$ (Myers et al. 1996), where $\dot{M}$ is the number density is $n = 1.62 \times 10^{4} N_H/\pi L$, where $L$ is the cloud core diameter in parsecs, which is 0.056 pc (the major axis of the deconvolved size of the continuum) and $N(H)$ is the column density of molecular hydrogen obtained from Eq. (3) of Xu et al. (2010) for the $^{12}$CO line. The velocity difference ($V$) of 2.0 km s$^{-1}$ between the systemic velocity ($-17.0$ km s$^{-1}$) and the velocity of the redshifted absorbing dip ($-15.0$ km s$^{-1}$) and a source size ($R$) of 0.028 pc, then implies a mass accretion rate of $-2.3 \times 10^{-4} M_\odot$ yr$^{-1}$, which is roughly consistent with the value derived from bolometric luminosity, providing additional evidence of an accretion disk in this region, although observations at the presently achievable spatial resolution are inadequate to distinguish the disk accretion and the observations of other molecular tracers at higher spatial resolution are needed to resolve the detailed kinematics in this region.
