ABSTRACT

We study one of the most X-ray luminous cluster of galaxies in the REFLEX survey, RXC J1504.1-0248 (hereafter R1504; \(z_\text{cl} = 0.2153\)), using XMM-Newton X-ray imaging spectroscopy, VLT/VIMOS optical spectroscopy, and WFI optical imaging. The mass distributions were determined using both the so-called hydrostatic method with X-ray imaging spectroscopy and the dynamical method with optical spectroscopy, respectively, which yield \(M_{\text{H}} = (5.81 \pm 0.49) \times 10^{14} M_\odot\) and \(M_{\text{E}}^{\text{dynamical}} = (4.17 \pm 0.42) \times 10^{14} M_\odot\). According to recent calibrations, the richness-derived mass estimates closely agree with the hydrostatic and dynamical mass estimates. The line-of-sight velocities of spectroscopic members reveal a group of galaxies with high velocities (\(>1000 \text{ km s}^{-1}\)) at a projected distance of about \(r_{\text{proj}} = 1.18 \pm 0.03\) Mpc south-east of the cluster centroid, which is also indicated in the X-ray two-dimensional (2D) temperature, density, entropy, and pressure maps. The dynamical mass estimate is 80\% of the hydrostatic mass estimate at \(r_{\text{500}}\). It can be partially explained by the \(\sim 20\%\) scatter in the 2D pressure map that can be propagated into the hydrostatic mass estimate. The uncertainty in the dynamical mass estimate caused by the substructure of the high velocity group is \(\sim 14\%\). The dynamical mass estimate using blue members is 1.23 times that obtained using red members. The global properties of R1504 obey the observed scaling relations of nearby clusters, although its stellar-mass fraction is rather low.

1. Introduction

Simulations show that the formation of galaxy clusters is not a purely gravitational process. For instance, the galaxy velocity dispersion in clusters provides evidence of heating when compared to the cold dark matter velocity dispersion normalized to the WMAP result and large-scale structure distributions (e.g. Evrard et al. 2008). Cluster mergers do not only disturb the X-ray appearance of the hot intracluster medium (ICM; e.g. Ricker & Sarazin 2001; Poole et al. 2006; Zhang et al. 2009; Böhringer et al. 2010), but also affect the properties of the cluster galaxies (e.g. Sun et al. 2007). The ICM and galaxies react on different timescales during merging (e.g. Roettiger et al. 1999). Clusters with similar X-ray global properties can contain rather different galaxy populations (e.g. Popesso et al. 2007). There is a higher fraction of blue galaxies in rich galaxy clusters at \(z \geq 0.2\) than in local clusters (Butcher & Oemler 1978, the so-called Butcher-Oemler effect). This effect may be due to episodes of star formation in a subset of cluster members driven by merging (e.g. Saintonge et al. 2008). The kinematic analysis thus complements the X-ray analysis in probing the dynamical structure of a cluster and the consequences of this for the mass measurement.

Comparisons between X-ray and weak-lensing mass estimates suggest that there is a 10–20\% deviations from hydrostatic equilibrium at \(r_{\text{500}}\) for relaxed clusters of galaxies, and yield controversial findings for disturbed clusters based on different observations (e.g. Zhang et al. 2008, 2010; Mahdavi et al. 2008). The comparison between the X-ray hydrostatic and optical dynamical mass measurements complements the X-ray versus weak-lensing mass comparison, and can thus cross check deviations from hydrostatic equilibrium. Lensing is strongly affected by projection effects because it is sensitive to all mass along the line-of-sight. Line-of-sight velocities of cluster galaxies via the redshifts of cluster galaxies can probe substructures along the line-of-sight. Even for undisturbed clusters, the dynamically relaxed central regions are surrounded by infalling regions in which galaxies are bound to the clusters but not in equilibrium (e.g. Biviano et al. 2006; Rines & Diaferio 2006). Optical spectroscopy can constrain the dynamical properties out to large radii (e.g. Braglia et al. 2007; Ziparo et al. 2012), where it is difficult to probe with current X-ray satellites. On the other hand, X-ray data can be used to derive two-dimensional (2D) cluster morphology projected on the sky. We use these two tools together with the optical colour information to constrain substructures, and model causes of deviations from hydrostatic equilibrium.

RXC J1504.1-0248 (hereafter R1504; \(z_\text{cl} = 0.2153\)), a prominent cool-core cluster, is one of the most relaxed clusters in the REFLEX galaxy cluster survey (Böhringer et al. 2001). Böhringer et al. (2005) investigated the central region of R1504 with Chandra, and found that the core region of R1504 appears to be quite relaxed. Using optical data obtained from integral field spectroscopy and X-ray data from XMM-Newton, Ogure et al. (2010) found that feedback from active galactic nuclei (AGN) can slow down the cooling flow to the observed mass deposition rate in R1504, if the black-hole accretion rate is of the order of \(0.5 M_\odot\text{yr}^{-1}\) with 10\% energy output efficiency. The XMM-Newton data in the R1504 field cover about a two times...
larger radial range than the Chandra data, and the large effective area of XMM-Newton ensures high quality photon statistics for a 2D spectral analysis. Follow-up observations of R1504 were also performed by the ESO Visible Multi-Object Spectrograph at the 8.2 m UT3 of the Very Large Telescope (VLT/VIMOS) out to about 3 Mpc. In addition, we have at our disposal optical imaging data from the ESO Wide-Field Imager (WFI) in three bands and Subaru in two bands.

We present our analysis of both the radial and 2D gas and galaxy properties of R1504 based on XMM-Newton, VLT/VIMOS, and WFI data as follows. We describe the X-ray analysis and results in Sect. 2, and optical spectroscopic and imaging analyses and results in Sects. 3 and 4. We discuss the systematic uncertainties in and interpretations of the results in Sect. 5. In Sect. 6, we summarize our conclusions. Throughout the paper, we assume that \( \Omega_m = 0.3, \Omega_\Lambda = 0.7, \) and \( H_0 = 70 \) km s\(^{-1}\) Mpc\(^{-1}\). Thus, an extent of 1’ at the distance of R1504 corresponds to 209.8 kpc. Confidence intervals correspond to the 68\% confidence level.

### 2. X-ray data analysis and results

#### 2.1. XMM-Newton observations and data preparation

The XMM-Newton observations (ID: 0401040101) were taken in 2007 with a thin filter in full frame (FF) mode for MOS and extended full frame (EFF) mode for pn. The fraction of out-of-time (OOT) events amounts to 2.32\%, which we used to normalize the pn OOT product before subtracting it from the pn normal product.

We applied an iterative \(2\sigma\) clipping procedure (e.g., Sect. 2.1 of Zhang et al. 2006) to filter flares using the light curves in both the soft band (0.3–10 keV) binned in 10 s intervals and the hard band (10–12 keV for MOS and 12–14 keV for pn) binned in 100 s intervals. There are 34.9 ks clean data for MOS1, 34.5 ks for MOS2, and 31.6 ks for pn left. We generated a list of bright point sources detected with the XMMSAS task edetect_chain applied to five energy bands: 0.3–0.5 keV, 0.5–2 keV, 2–4.5 keV, 4.5–7.5 keV, and 7.5–12 keV. All confirmed sources were subtracted from the event lists using a radius of 25\''', which encloses ~80\% of the flux of the point sources according to the XMM-Newton point spread function (PSF). A weight column was created with the XMMSAS evigweight command, which accounts for the vignetting correction for off-axis observations.

#### 2.2. Temperature and surface brightness distributions

Following Sect. 2.3 of Zhang et al. (2010), we measured the X-ray flux-weighted centroid to be \( R = 15^\circ 04^\prime 07^\prime\prime 801, \delta = -02^\circ 48^\prime 10^\prime 29^\prime\prime (J2000)\). We applied the double-background subtraction method developed for clusters at similar redshifts by Zhang et al. (2006, the so-called DBS II method therein). We chose the XMM-Newton blank sky accumulations in both the soft band (0.3–10 keV) and hard band (10–12 keV for MOS and 12–14 keV for pn) binned in 100 s intervals. There are 34.9 ks clean data for MOS1, 34.5 ks for MOS2, and 31.6 ks for pn left. We generated a list of bright point sources detected with the XMMSAS task edetect_chain applied to five energy bands: 0.3–0.5 keV, 0.5–2 keV, 2–4.5 keV, 4.5–7.5 keV, and 7.5–12 keV. All confirmed sources were subtracted from the event lists using a radius of 25''', which encloses ~80\% of the flux of the point sources according to the XMM-Newton point spread function (PSF). A weight column was created with the XMMSAS evigweight command, which accounts for the vignetting correction for off-axis observations.

#### 2.3. Mass distribution using the hydrostatic method

We assumed that the ICM is in hydrostatic equilibrium within the gravitational potential dominated by dark matter, and that the matter distribution is spherically symmetric. The mass could

The left panel of Fig. 2 shows that the radial temperature distribution follows the universal profile of relaxed clusters (e.g., Markevitch et al. 1998; Vikhlinin et al. 2006; Zhang et al. 2006; Pratt et al. 2007). The observed strong core is also shown in Chandra data by Böhringer et al. (2005). The amplitude of the temperature distribution is, however, 20\% lower than that of the Chandra measurements. Snowden et al. (2008) found that temperature measurements with Chandra are overestimated for those that are hotter than 5 keV owing to a calibration problem, which was corrected only recently with Chandra CALDB v3.5.2. The temperature overestimation made by analyses of previous Chandra CALDB thus accounts for the amplitude difference between the temperature distributions measured with Chandra by Böhringer et al. (2005) and with XMM-Newton in this work. The right panel of Fig. 2 shows the surface brightness distribution. We carried out the PSF deconvolution and deprojection as detailed in Sect. 2.3 of Zhang et al. (2007), in which the XMM-Newton PSF matrices were created according to Ghizzardi (2001).

![Fig. 1. MOS1 (black), MOS2 (red), and pn (green) spectra extracted from the central ≤0.5 circle. The lower panel shows deviations of the models from the data points normalized by the 1σ errors.](image-url)
thus be calculated from the X-ray measured radial density and temperature distributions of the ICM by

\[
\frac{1}{\mu m_p n_e(r)} \frac{d[n_e(r)kT(r)]}{dr} = -\frac{GM(\leq r)}{r^2},
\]

in which \( \mu = 0.62 \) is the mean molecular weight per hydrogen atom, and \( k \) is the Boltzmann constant. The mass estimate was computed from a set of input parameters \( \beta, n_{e0}, \) and \( r_{ci} \) (\( i = 1, 2 \)) representing the double-\( \beta \) electron number-density profile \( n_i(r) = n_{e01}(1 + r^2 r_{ci}^{-2})^{-1/2} + n_{e02}(1 + r^2 r_{ci}^{-2})^{-1/2} \), and \( P_i \) (\( i = 1, ..., 7 \)) representing the deprojected temperature profile, \( T(r) = P_3 \exp[-(r - P_1)^2 P_4^{-2}] + P_6 (1 + r^2 P_5^{-2}) P_7 \). We propagated the uncertainties in the electron number-density and temperature measurements using Monte Carlo simulations to compute the mass uncertainty. The cluster radius \( r_{500} \) (e.g. 500) was defined as the radius within which the mass density is \( \Delta \) (e.g. 500) times of the critical density at the cluster redshift, \( \rho_c(z) = 3H_0^2(8\pi G)^{-1}E^2(z) \), in which \( E^2(z) = \Omega_m(1 + z)^3 + \Omega_\Lambda + (1 - \Omega_m - \Omega_\Lambda)(1 + z)^2 \).

The cumulative mass distribution using the hydrostatic method is shown in Fig. 3 as filled squares. The cluster radius is \( r_{500}^{HE} = 1.18 \pm 0.03 \) Mpc, and the total mass estimate is \( M_{500}^{HE} = (5.81 \pm 0.49) \times 10^{14} M_\odot \), as listed in Table 1. The mass profile can be well-fitted by an NFW model (Navarro et al. 1997) with a concentration parameter of \( c_{500} = 2.93 \pm 0.14 \).

### 2.4. Two-dimensional spectrally measured maps

We adopted the adaptive-binning methods developed by Sanders (2006) and Cappellari & Copin (2003; see also Diehl & Statler 2006), respectively, to define the masks for the 2D analysis. We followed the steps in Sect. 5 of Zhang et al. (2009), except for two changes: (i) we adopted a threshold of signal-to-noise ratio (S/N) of 30 instead of 45 to ensure an adequate number of bins in the mask. (ii) We used the double-background-subtraction strategy (i.e. DBS II) since there is a sufficient outer area within the XMM-Newton field of view (FoV) to model the residual background.

The X-ray spectrally measured 2D maps using the Sanders (2006) mask are shown in Fig. 4. Those using the Cappellari & Copin (2003) mask appear in Fig. A.1. At a projected distance of \( r_{500}^{HE} \) south-east of the centroid, the surface brightness shows a clump with its value 2.25 times the azimuthal average of \( (2.4 \pm 0.4) \times 10^{-3} \) counts s\(^{-1}\) arcmin\(^{-2}\), at the same projected distance. This enables us to carry out the 2D spectral analysis toward larger radii in the south-east direction than the other directions. In the temperature map, we also observe a hot stripe at \( \sim 0.3 r_{500}^{HE} \) west of the centroid.

We followed Zhang et al. (2009) to calculate the scatter in the fluctuations in the 2D maps and analyse the ICM substructure. In Fig. 5, the temperature, electron number-density, entropy, and pressure distributions in the 2D maps are shown as a function of projected distance from the X-ray flux-weighted centroid. Their non-parametric locally weighted regression (e.g. Becker et al. 1988) was used as the mean profile. The differential scatter and error were calculated from the area-weighted absolute fluctuations with all bins at that projected distance. The temperature, electron number-density, entropy and pressure maps have scatters of smaller than \( \sim 15\%, 30\%, 20\% \), and \( 25\% \), respectively. The scatter in the temperature measurements increases with radius, and is \( \sim 12\% \) at the radii beyond \( 0.3 r_{500}^{HE} \). In contrast, the electron number-density measurements appear to have a smaller scatter at large radii, which may reflect the different relaxation timescales of the ICM temperature and electron number density.

The 2D maps using the Cappellari & Copin (2003) mask demonstrate a mild elongation along the east-west major axis on the scale of \( \sim r_{500}^{HE} \).

3. Optical spectroscopic data analysis and results

3.1. VLT/VIMOS observations and data preparation

Multi-object spectroscopy in the R1504 field was performed with the VLT/VIMOS spectrograph using the low-resolution blue grism (LR-blue) with the OS-blue filter, which samples the [3700–6700]Å wavelength range with λ/Δλ = 180 (PID: 077.A-0058). The observations were carried out in service mode, which include a bias, dark, and flat calibration sequence with the VLT Multi-object spectroscopy in the R1504 field was performed.

The cluster R1504 was observed with air masses of between 1.124 and 1.172. The seeing was less than 1″ for two pointed observations and >2″ for one pointed observation. Individual targets for the spectroscopic follow-up were selected based on their I-band magnitudes in the pre-imaging data. In total, 784 slits were placed in the 12 masks spread over three pointed observations.

Data were reduced with the VIPGI pipeline (Scodedgeg et al. 2005). Redshifts were computed by comparing the observed spectra to galaxy and stellar templates with the EZ software (Garilli et al. 2010) and improved with customized tools from Verdugo et al. (2008) by fitting a Gaussian profile to each of the observed strong spectral features. Not all lines, namely [O II] λ3726, 3729 Å, [Ca II K] λ3934 Å, [Ca II H] λ3968 Å, H6 λ4102 Å, Hβ λ4861 Å, G-band (~ λ4304 Å), [OIII] λ4959, 5007 Å, Mg I b (~5050–5430 Å), and [Fe II] λ5535 Å, are present in each spectrum. The redshift determined from each spectrum is the mean of the individual shifts for all visible line features. The error is the standard deviation in these shifts, which takes into account systematic errors in the wavelength calibration and differences in the S/N. The average error in the individual redshift estimates is Δz = 0.00076.

The R1504 field overlaps with the stellar stream of the globular cluster Palomar-5 (e.g. Odenkirchen et al. 2001). There are thus a large number of white- and red-dwarf stars contaminating the spectroscopic sample. Interlopers were removed by applying the member selection procedure in Sect. 3.2.

3.2. Spectroscopic member selection

In hierarchical structure-formation scenarios, the spherical infalling model predicts a trumpet-shaped region in the diagram of line-of-sight velocity versus projected distance, the so-called caustic (e.g. Kaiser 1987). The boundary defines galaxies inside the caustic as cluster members and those outside the caustic as foreground and background galaxies.

Several methods can select cluster members according to their line-of-sight velocities. A constant gap or gaps weighted by projected distances can separate member galaxies from foreground and background galaxies (e.g. Beers et al. 1990; Girardi et al. 1993; den Hartog & Katgert 1996; Katgert et al. 1996, 2004; Popesso et al. 2005a; Biviano et al. 2006). Alternatively, an adaptive kernel method, sensitive to the presence of peaks, has been widely used to select members (e.g. Pisani 1993, 1996; Fadda et al. 1996; Diaferio & Geller 1997; Diaferio 1999; Geller et al. 1999; Rines & Diaferio 2006).

We modified the adaptive kernel method of Diaferio (1999) for medium-distance clusters (e.g. Harrison & Noonan 1979; Danese et al. 1980), and used it to identify the interlopers as follows. Galaxies with redshifts |cz − czcl| ≤ 4000 km s^{-1} were preliminarily selected and located in the (r, v) diagram, where r is the galaxy transverse separation from the cluster centroid, and v is the line-of-sight velocity of the galaxy relative to the cluster. At the redshift of R1504, we modified the calculation of (r, v) to r = D_cl sin θ and v = (cz - czcl cos θ)/(1 + czcl).

Fig. 3. Cumulative mass distributions (1) using the X-ray hydrostatic method (filled squares), (2) using the caustic method (black solid curve), (3) of the gas mass estimate (black dotted curve), (4) of the stellar mass estimate of the red galaxies (red dash-dotted curve), and (5) of the stellar mass estimate of the blue galaxies (blue dash-dotted-dotted-dotted curve). The dashed curves and error bars denote 1σ intervals. The open star, triangle, diamond, and circle indicate the dynamical mass estimates (M_Dyn) using 53, 48, 24 red, and 29 blue cluster members according to the Biviano et al. (2006) method. The open square and cross denote the richness-derived mass estimates (M_Mer) based on photometric data using the definitions of Johnston et al. (2007) and Hansen et al. (2009).
Fig. 4. Two-dimensional X-ray spectrally measured temperature (upper left), electron number-density (upper right), entropy (lower left), and pressure (lower right) maps using the Sanders (2006) binning scheme. Overlaid circles in blue, red, and green denote cluster galaxies that have spectroscopic follow-up data with their clustercentric velocities toward the observer greater than 1000 km s$^{-1}$, away from the observer greater than 1000 km s$^{-1}$, and smaller than 1000 km s$^{-1}$, respectively. The radii of these circles are proportional to $\exp[\rho^2 DS]$. The black cross denotes the X-ray flux-weighted centroid and the black dashed circle denotes $r_{500}$. The white holes mask X-ray detected point sources. The colour scales logarithmically from 4 to 10 in keV for temperature, from 0.00005 to 0.12 in cm$^{-3}$ for electron number density, from 10 to 1800 in keV cm$^{-2}$ for entropy, and from 0.0001 to 0.54 in keV cm$^{-3}$ for pressure.

where $D_a$, $\theta$, $z$, and $z_{cl}$ are the angular diameter distance of the cluster, angular separation of the galaxy from the cluster centroid, galaxy redshift, and cluster redshift. The angular diameter distance is defined as $D_a = cH_0^{-1}(1 + z_{cl})^{-1} \int_0^{z_{cl}} E^{-1}(z)dz$. We scaled $r$ and $v$ to ensure approximately equal weights in $r$ and $v$, and computed the 2D adaptive density distribution $f(r,v)$. The boundary of the caustic is defined by $f(r,v) = \kappa$, in which $\kappa$ is determined by minimizing $\langle \psi_{\kappa_{\kappa_0}} \rangle_{R} - 4 \langle v^2 \rangle_R^2$. Here $\langle \psi_{\kappa_{\kappa_0}} \rangle_{R} = \int_0^R \mathcal{A}(r) \varphi(r)dr / \int_0^R \varphi(r)dr$ is the escape velocity, $R$ and $\langle v^2 \rangle_R$ are the mean projected distance and velocity dispersion of the members, and $\varphi(r) = \int f(r,v)dv$. In addition, $\mathcal{A}(r) = \min[|\psi_{ul}|, |\psi_{dl}|]$, which represents the minimum of the upper and lower solutions of $f(r,v) = \kappa$.

Figure 7 shows the histogram of the line-of-sight velocity and the diagram of line-of-sight velocity versus projected distance of galaxies. The 53 galaxies inside the caustic boundary are considered as members. Our further dynamical analysis is based on these 53 spectroscopic member galaxies.

3.3. Mass distribution using the caustic method

We applied the biweight estimator developed by Beers et al. (1990) to measure the redshift and velocity dispersion, in which the errors are estimated by means of 1000 bootstrap simulations. The cluster redshift was assumed to be the biweight estimator of location of the recessional velocities, $c_{zi}$. The velocities in the cluster reference frame $v_{\text{rest,}i}$ were derived from the recessional velocities $c_{zi}$ using the formula $v_{\text{rest,}i} = (c_{zi} - c_{zcl})(1 + z_{cl})^{-1}$. The velocity dispersion was given by the biweight estimator of scale of these $v_{\text{rest,}i}$ values. With all 53 spectroscopic members, the measured redshift is $(0.2165 \pm 0.0005)$, and the velocity dispersion is $(1132 \pm 94)$ km s$^{-1}$. 
The escape velocities of galaxies extracted from the amplitude of the caustic scale with the gravitational potential of the dark matter halo (e.g. Diaferio & Geller 1997; Diaferio 1999; Rines & Diaferio 2006)

\[ G M(<r) = \frac{1}{2} \int_0^r \mathcal{A}^2(x) dx. \]  

The error in the cumulative mass estimate within \( r_i \) is defined as

\[ \delta M_i = \sum_{j=1}^{i} \left[ 2m_j \delta \mathcal{A}(r_j)/\mathcal{A}(r_j) \right], \]

in which \( m_j \) is the mass estimate in the \( j \)th shell, \( \delta \mathcal{A}(r)/\mathcal{A}(r) = \kappa / \max[f(r, v)] \) and \( \max[f(r, v)] \) is the maximum value of \( f(r, v) \) at fixed \( r \). Since the caustic of a spherical system is symmetric, the minimum of the upper and lower caustics is taken as the caustic amplitude at each radius, which excludes interlopers more effectively than taking the average of the upper and lower caustics as the caustic amplitude. The caustic method does not assume dynamical equilibrium, and is thus able to measure cluster masses out to large radii. The mass distribution using the caustic method is shown in Fig. 3, and implies that \( r_{500}^{\text{caustic}} = (1.06 \pm 0.04) \) Mpc (Table 1).

### 3.4. Two-dimensional kinematic structure

As clusters of galaxies formed at moderate look-back times, they often contain substructures caused by the accretion of and

---

Fig. 5. Temperature (upper left), electron number-density (upper right), entropy (lower left), and pressure (lower right) distributions of the spectrally measured 2D maps using the Sanders (2006) binning scheme are shown as crosses with their local regression fits in black curves. The solid and dashed grey curves in the upper left plot show the parametrization of the deprojected temperature profile and its 1-σ interval derived in Sect. 2.3. Differential scatter and its 1-σ intervals of the temperature, electron number-density, entropy, and pressure fluctuations in the 2D maps are shown in solid and dashed black curves in their upper panels.
merging with smaller systems. The quantification of substructures is thus important to assess the reliability of different mass measurements and infer the dynamical history of the cluster. It is, however, difficult to quantify substructures at large radii with XMM-Newton data because of the high background level relative to the faint X-ray emission near r_{500}. Optical spectroscopic data provide a promising alternative means of quantifying substructures at all radii.

Dressler & Shectman (1988, DS hereafter) developed a statistical method for detecting substructures in galaxy clusters related to systematic deviations from the average spatial and/or velocity structure, which we summarize as follows. The deviation in the local velocity mean and dispersion from the global mean and dispersion of the cluster is defined as

$$\rho_{DS} = \frac{N_{local} + 1}{\sigma^2} \left[ (\bar{v}_{local} - \bar{v})^2 + (\sigma_{local} - \sigma)^2 \right].$$

The local line-of-sight velocity and dispersion, $\bar{v}_{local}$ and $\sigma_{local}$, are measured with its $N_{local} = 10$ nearest neighbours in projection. The global line-of-sight velocity and dispersion, $\bar{v} = 64950$ km s$^{-1}$ and $\sigma = 1132$ km s$^{-1}$, are given in Sect. 3.3 as measured for all (i.e. N$_{all} = 53$ for R1504) spectroscopic cluster members. A cumulative deviation $\Delta_{DS} = \sum_{i=1}^{N_{all}} \rho_{DS,i}$ is of the order of N$_{all}$ when the line-of-sight velocity obeys a Gaussian distribution and local variations are only random fluctuations, but differs from N$_{all}$ when the line-of-sight velocity distribution deviates from a Gaussian. Therefore, the $\Delta_{DS}$ statistic is sensitive to the presence of substructures. A higher $\Delta_{DS}$ value indicates a higher possibility of containing substructures.

In Fig. 4, we display the 53 spectroscopic galaxies by circles with their radii proportional to $\exp[\rho_{DS}^2]$. The blue, red, and green colours denote cluster galaxies that have spectroscopic follow-up data with their clustercentric velocities toward the observer greater than 1000 km s$^{-1}$, away from the observer greater than 1000 km s$^{-1}$, and smaller than 1000 km s$^{-1}$. The DS test yields $\Delta_{DS,obs} = 86.8$, and reveals a clustering of galaxies with large $\rho_{DS}$ values at a projected distance of $\sim r_{500}^{HE}$ south-east of the cluster centroid. This may be indicative of a relatively high-velocity (>1000 km s$^{-1}$) group associated with the main cluster.

To estimate the robustness of the $\Delta_{DS}$ statistic, we carried out 10000 Monte Carlo simulations by randomly shuffling the line-of-sight velocities of the member galaxies. This procedure erases any true correlations between the line-of-sight velocities and positions. The probability of having substructures can be estimated by $P_{DS} = \sum_{j=1}^{N_{MC}} \delta_j / N_{MC}$, in which $\delta_j = \Delta_{DS,j}$ when $\Delta_{DS,j} > \Delta_{DS,obs}$, and $\delta_j = 0$ otherwise (e.g. Hou et al. 2012). Therefore, systems with significant substructures show low-$P_{DS}$ values. The Monte Carlo realization of the $\Delta_{DS}$ statistic yields $P_{DS} = 0.06$ for R1504, which only corresponds to a ~10% false detection according to Hou et al. (2012). This $P_{DS}$ value thus represents a non-negligible possibility that the high velocity group exists. The histogram of the line-of-sight velocities of possible member galaxies of the high velocity group is shown as (red) dashed lines in the left panel of Fig. 7.

4. **Optical imaging data analysis and results**

4.1. **WFI observations and data preparation**

The cluster R1504 was observed with the ESO/MPG 2.2 m telescope with the WFI (Baade et al. 1999) in the B/123- , V/89- , and R/162-bands (hereafter B-, V-, and R-bands) during three runs in June 2009, 2010, and 2011 mostly under non-photometric conditions. The WFI has a 4 × 2 mosaic detector of 2k × 4k CCDs, which has a pixel size of 0′′238 and a FoV of 34′ × 33′. We reduced the data and co-added the single exposures using the THELI pipeline (Erben et al. 2005). The coadded B-, V-, and R-band images have total exposure times of 9238 s, 8317 s, and 11 035 s with 1′′52, 1′′21, and 0′′96 seeing. Figure 8 shows the WFI B-band image.

Since the observing conditions of the imaging varied slightly, photometric calibration of the WFI R-band data was tied to the shallower SDSS r-band data in the same field. The B- and V-band images were calibrated against the R-band by fitting the observed main sequence of stars with that of a photometrically calibrated field. Cross-checks were applied by comparing predicted with observed colours for galaxies with spectroscopic redshifts using procedures typical of photometric redshift codes. The absolute calibration of the photometric zero point is more accurate than 0.1 mag. The internal colour calibration is more accurate than 0.04 mag.

Photometry was carried out with SExtractor (Bertin & Arnouts 1996) in dual mode with the R-band image set as the detection frame. Galaxy colours were measured in an aperture of 2′′5 diameter.

4.2. **Photometric member selection**

The broad B- and R-bands can probe the spectral range across the 4000 Å break for galaxy clusters at z ~ 0.2–0.3, which can be used to characterize the bulk of stellar populations. Early-type galaxies display red colours and reside in a narrow band, the so-called red sequence (e.g. Baum 1959), in the colour–magnitude diagram. The B – R colour versus R-band magnitude is shown in the left panel of Fig. 9 for all galaxies within r_{500}^{HE}, in which we highlight the 29 blue and 24 red spectroscopic members regardless of their clustercentric distances.
Fig. 7. Left: histogram of the line-of-sight velocities. Member galaxies of the cluster, member galaxies of the high velocity group, and non-member galaxies are in solid (black), dashed (red), and dash-dotted (grey) lines. The arrow shows the cluster redshift. Right: line-of-sight velocity versus projected radius, in which filled blue diamonds and red stars show blue and red member galaxies in the caustic (black curve), and open squares show fore- and background galaxies. The grey curve shows the symmetric boundary by choosing the minimum of the values on both sides of the caustic boundary relative to the cluster redshift. The cluster radii, $r_{caustic}^{500}$ and $r_{caustic}^{200}$, derived from the mass distribution using the caustic method are shown as solid and dashed vertical lines, respectively.

We fit the red sequence with a robust biweight linear-fitting algorithm, which is negligibly affected by skewness (e.g. Beers et al. 1990; Gladders et al. 1998). The best-fit relation is $B - R = -0.097R + 3.88$ with a scatter of $\sigma = 0.083$ mag.

Fig. 8. WFI $B$-band imaging. Overlaid circles in blue, red and green denote cluster galaxies with spectroscopic follow-up data that have clustercentric velocities toward the observer greater than 1000 km s$^{-1}$, away from the observer greater than 1000 km s$^{-1}$, and smaller than 1000 km s$^{-1}$, respectively. The radii of these circles are proportional to $\exp[\rho_{500}]$.

We define red members as galaxies within $3\sigma$ of the best-fit red sequence. Galaxies that are more than $3\sigma$ bluer than the red sequence are considered as blue galaxies, whereas galaxies that are more than $3\sigma$ redder than the red sequence are discarded.
because they are most likely background galaxies. We also discard galaxies bluer by more than 1.5 mag than the red sequence to reduce foreground contamination. These limits are marked in Fig. 9.

The comparison between the galaxy number counts in the R1504 field and the Garching-Bonn Deep Survey (GaBoDS, Erben et al. 2005; Hildebrandt et al. 2006) fields shows that our photometric sample is 100% complete down to $R = 22$ mag. This limit corresponds to $M_R \approx -18$ mag for galaxies of different colours at $z_d = 0.2153$, and is indicated by an oblique curve in Fig. 9. The CLASS_STAR parameter provided by Sextractor is completely reliable down to $R = 21.5$ mag and 90% reliable down to $R = 22$ mag. We thus limit the analysis to the galaxies brighter than $R = 22$ mag. The limiting magnitude is $R = 24.44$ mag at 5$\sigma$, which was calculated in an aperture of 1″ diameter. The stellar contamination should be quite low in the photometric sample because of the high quality of the WFI imaging.

4.3. Galaxy luminosity function and stellar mass

To determine the photometric properties of the cluster population, we corrected for contamination by both foreground and background galaxies along the line-of-sight by applying a statistical subtraction using a subset (2.25 deg$^2$) of the GaBoDS, whose photometric data are complete in all bands. We applied the same magnitude and colour cuts to the GaBoDS fields as we did to the R1504 field, and constructed the galaxy number counts as a function of magnitude for red and blue galaxies, respectively.

The galaxy number counts in the GaBoDS fields were normalized to the R1504 sky area and subtracted from the corresponding galaxy number counts in the R1504 field. The size of the magnitude bin used to construct the galaxy number counts was chosen to be large enough to ensure that there were positive counts in all magnitude bins after subtracting the background.

The errors are a combination of the Poisson statistical error and cosmic variance. The latter was measured to be the standard deviation in the galaxy number counts across the GaBoDS fields. The Poisson statistical error dominates the error budget at inner radii because there are relatively fewer objects, whereas cosmic variance dominates at large radii.

The right panel of Fig. 9 shows the $R$-band galaxy luminosity functions for red (red), blue (blue), and all (black) members within $r_{500}^{500}$. We derived the best-fit Schechter (1976) functions for red and all members, respectively, with a $\chi^2$ minimization algorithm. The red members show a shallower slope at the faint end than that of all members. As listed in Table 1, both the characteristic $R$-band magnitude, $M_R^*$, and the slope at the faint end, $\alpha$, agree with that of nearby clusters (e.g. Christlein & Zabludoff 2003; Pope 2005b; Durret et al. 2011). No fit was possible for blue galaxies.

The brightest cluster galaxy (BCG) is very blue ($B - R = 0.98$) and bright ($R = 16$ mag). Since the BCG cannot normally be described by the Schechter function, we explicitly removed the BCG from the photometric sample in the above calculation of the galaxy luminosity function. The total $R$-band luminosity of the cluster was computed by explicitly adding the BCG luminosity to the integration of the galaxy luminosity function. We tested how the BCG colour affects the measured optical luminosity by adding the BCG luminosity to the red and blue populations, respectively. The resulting uncertainty in the $R$-band luminosity is smaller than 3%. The measured $R$-band optical luminosity within $r_{500}^{500}$ is listed in Table 1.

We adopted the stellar mass-to-optical light ratio from Table 7 of Bell et al. (2003), $\log(M_*/L_B) = a + b(B - R)$, in which $a = -0.523$, $b = 0.683$, $B - R$ is the rest-frame colour, and a "diet" Salpeter (1955) stellar initial mass function (Bell & de Jong 2001) is adopted. We show the cumulative stellar mass profiles for red and blue galaxies, respectively, in Fig. 3. The stellar mass estimates for blue, red, and all photometric...
members within \( r_{500}^{\text{HE}} \) are given in Table 1. The cluster R1504 has a rather low stellar-mass fraction among nearby clusters (e.g. Biviano & Salucci 2006), although there is an agreement given the large scatter for nearby clusters (e.g. Andreon 2010; Zhang et al. 2011b). The contribution to the total stellar mass budget associated with intra-cluster light (e.g. Zibetti et al. 2005) could reach 10–20% level at the mass scale of galaxy groups (e.g. Gonzalez et al. 2007). The difference in the R-band luminosity caused by adding the BCG luminosity to the blue and red populations, respectively, is within 3% for R1504. Therefore, both the intra-cluster light and BCG play non-dominant roles to explain the low stellar-mass fraction.

### 4.4. Blue-galaxy fraction

Understanding rapid galaxy-morphology transformation is essential to model the mass assembly history of galaxy clusters. Red galaxies with low levels of ongoing star formation are assumed to be the descendants of blue star-forming galaxies that have been accreted from the surrounding filamentary structure and quenched by specific processes operating within the cluster environment (e.g. Braglia et al. 2007; Verdugo et al. 2012). How spirals were transformed into ellipticals remains unclear (e.g. Poggianti & Wu 2000). The efficiency of different transformation processes varies with environment. Ram pressure stripping, for instance, is more effective in the cluster core where there is dense ICM (e.g. Fujita & Nagashima 1999; Quilis et al. 2000). Galaxy-galaxy merging, on the other hand, is more effective in infalling groups at the cluster outskirts (e.g. Kauffmann et al. 1999).

In the left panel of Fig. 10, we present the number density profiles of the red and all member galaxies, respectively, as a function of projected distance from the X-ray flux-weighted centroid. Similar to the findings for other clusters (e.g. Lin et al. 2004), the red population in R1504 is well-fitted by a projected NFW profile (Navarro et al. 1997; Bartelmann 1996), in which the reduced \( \chi^2 = 1.03 \). The fit of a projected NFW profile to all members is relatively poor with \( \chi^2 = 2.24 \). The right panel of Fig. 10 displays the blue-galaxy fraction. Within a projected distance of 700 kpc, where the ICM is dense, the galaxy population is dominated by red galaxies with a fraction larger than 70%. Beyond 700 kpc, the blue-galaxy fraction first increases rapidly, reaching 60% at \( r_{500}^{\text{HE}} \), and then stays almost constant in the outskirts. The large error bars in the blue-galaxy fraction at large radii take into account the uncertainty in the background. The colours of the field galaxies have their own variation. One cannot exclude that the high blue-galaxy fraction is coincidently due to a larger field-galaxy contamination. A reliable measure of the blue-galaxy fraction free of background contamination requires extensive spectroscopy. Nevertheless, the high blue-galaxy fraction beyond \( r_{500}^{\text{HE}} \) may indicate a critical distance where specific processes in clusters such as starvation (e.g. Balogh et al. 2000) may start to affect the properties of infalling galaxies. This distance may, however, depend on the environment (e.g. Urquhart et al. 2010). Urquhart et al. (2010, Fig. 10 therein) pointed out an excess of extremely blue galaxies in massive groups, in which active starburst galaxies are driven by galaxy-galaxy interactions in the group environment. The radial blue-galaxy fraction and presence of the high velocity group in R1504 support this interpretation.

### 4.5. Richness-derived mass estimates

There are a number of approaches for calculating the cluster total mass based on photometric measurements (e.g. Hansen et al. 2005, 2009; Johnston et al. 2007; Reyes et al. 2008).

We can iteratively estimate the mass from the richness distribution according to existing scaling calibrations between richness and mass estimates at a fixed overdensity. The cluster total mass is measured within the radius where the mass density is 200 times the critical density in Johnston et al. (2007) and Hansen et al. (2009), but 200 times the mean density of the Universe in Hansen et al. (2005) and Reyes et al. (2008). To be consistent with the mass definition, we use the calibrations between richness and weak-lensing mass measurements.
in Johnston et al. (2007), Eq. (26), and Hansen et al. (2009), Eq. (10), respectively, to calculate the richness-derived mass estimates. In these calibrations, the richness was measured down to 0.4 L′ in the SDSS i-band, which is equivalent to (i′ + 1) magnitude. Since there were no i-band data for R1504, we used the R-band derived richness down to (R′ + 1) to approximate their i-band derived richness down to (i′ + 1). Nevertheless, the characteristic magnitude could be taken as a characteristic length-scale for galaxy formation at a similar cosmic epoch. Therefore, galaxies brighter than (i′ + 1) overlap significantly with those brighter than (R′ + 1). The richness-derived mass estimates (see Table 1) agree well with the hydrostatic and dynamical mass measurements.

5. Discussion

5.1. Uncertainties in the dynamical mass estimates

To quantify the uncertainties in the dynamical mass estimate due to substructures and infalling blue galaxies, we need a method to derive the dynamical mass estimate based on a small number of member galaxies. A different method from the caustic one, which was detailed in Sect. 3 of Biviano et al. (2006) based on a sample of simulated clusters, serves this purpose, and is summarized as follows.

We measured the velocity dispersion (σ_{ap} in Biviano et al. 2006) with a number of member galaxies defined according to Sects. 5.1.1 and 5.1.2, respectively. An initial estimate of the mass was derived using Eq. (2) in Biviano et al. (2006), namely \( M_v \equiv A[\sigma_v/(10^3 \text{ km s}^{-1})]^2 \times 10^{14} h^{-1} E^{-1} (z) M_\odot \) with \( A = 1.50 \pm 0.02 \) under the assumption of \( \sigma_v = \sqrt{5} \sigma_{ap} \). An estimate of the corresponding cluster radius, \( r_c \), was derived by following steps 7 and 9 in Biviano et al. (2006). Replacing the true quantities \( \sigma_v \) and \( \sigma_{ap} \) with their estimates \( \bar{\sigma}_v \) and \( \sqrt{5} \bar{\sigma}_{ap} \) in Fig. 4 in Biviano et al. (2006), we obtained an improved estimate of \( \sigma_v \). The final cluster mass estimate (\( M^{\text{B06}} \) hereafter) was calculated using Eq. (2) in Biviano et al. (2006) with the improved estimate of \( \sigma_v \). The mass error was derived by combining in quadrature the error in the velocity dispersion converted to mass, the additional error introduced by the uncertainty in \( \sigma_v \) in Fig. 4 in Biviano et al. (2006), and the 10% mass systematic according to the Biviano et al. (2006) sample. We computed \( M^{\text{B06}}_{500} \) from \( M^{\text{B06}} \) with the NFW model, in which the concentration parameter is given in step 7 of Biviano et al. (2006) as \( c^{\text{B06}} = 4[\sigma_{ap}/(700 \text{ km s}^{-1})]^{-0.306} \).

5.1.1. Uncertainty due to substructures

The high velocity group revealed by the DS test overlaps with the substructure in the 2D X-ray maps. In the high-resolution weak-lensing shear map by Klein et al. (in prep.) based on Subaru observations, there is a main lensing peak at the BCG position additional to a secondary peak near the high velocity group. The elongation of the surface mass density follows the elongation shown in the X-ray 2D maps.

The dynamical mass measurement overestimates the total mass of a cluster with substructures (e.g. Biviano et al. 2006). We quantified the uncertainty in the dynamical mass estimate due to the high velocity group as follows. The velocity dispersion is (1132 ± 94) km s\(^{-1}\) based on all 53 spectroscopic members. Excluding the five galaxies belonging to the high velocity group, which are shown as large red circles at \( r_{500}^{\text{HE}} \) south-east of the cluster centroid in Fig. 4, the velocity dispersion is reduced to (1079 ± 97) km s\(^{-1}\). As shown in Table 1 and Fig. 3, the total mass estimate is \( M^{\text{B06}}_{500,53m} = (6.355 \pm 1.711) \times 10^{14} M_\odot \) based on the 53 members and \( M^{\text{B06}}_{500,48m} = (5.452 \pm 1.573) \times 10^{14} M_\odot \) based on the 48 members excluding the high velocity group, following the Biviano et al. (2006) method. The mass uncertainty caused by the substructure of the high velocity group is \( \sim 14\% \). Excluding the high velocity group improves the agreement between the X-ray hydrostatic and dynamical mass estimates. This highlights the importance of a proper analysis of the structures of evolving systems such as cluster of galaxies in order to obtain robust mass measurements.

5.1.2. Mass discrepancy using red and blue galaxies

For a cluster in dynamical equilibrium, both blue and red galaxy populations behave similarly in the diagram of line-of-sight velocity versus projected distance, which reflects the same underlying mass distribution. For a cluster with a rich infalling population, the blue population tends to overestimate the total mass since the infalling members bias the velocity dispersion toward high values (e.g. Carlberg et al. 1997). Fifty-five percent of the spectroscopic member galaxies are blue galaxies. To quantify the uncertainty in the dynamical mass estimate due to infalling blue galaxies, we derived the velocity dispersion and dynamical mass estimates for blue members and red members separately. The blue population has a velocity dispersion of (1170 ± 125) km s\(^{-1}\), which yields a cluster mass estimate of \( M^{\text{B06}}_{500,\text{blue}} = (7.057 \pm 2.373) \times 10^{14} M_\odot \) according to Biviano et al. (2006). The red population has a velocity dispersion of (1096 ± 156) km s\(^{-1}\), which yields a cluster mass estimate of \( M^{\text{B06}}_{500,\text{red}} = (7.572 \pm 2.517) \times 10^{14} M_\odot \). The dynamical mass estimate derived from red members, \( M^{\text{B06}}_{500,\text{red}} \), is in closer agreement with the hydrostatic mass estimate than that using all members. The cluster mass estimate based on the blue population, \( M^{\text{B06}}_{500,\text{blue}} \), is 1.23 times the mass estimate based on the red population (Table 1 and Fig. 3). It indicates that R1504 may not contain a rich infalling population, which is also supported by the caustic comparison between R1504 and the simulated clusters (e.g. Fig. 6 of Gill et al. 2005).

5.2. Hydrostatic versus dynamical versus photometric mass estimates

We derived the mass distribution using the hydrostatic method based on X-ray imaging spectroscopy and the dynamical method based on optical spectroscopy, independently (Fig. 3). At \( r_{500}^{\text{HE}} \), the mass estimate from the caustic method is (4.66 ± 0.47) \times 10^{14} M_\odot, which is 80% of the X-ray hydrostatic mass estimate (Table 1). The discrepancy between the hydrostatic and dynamical mass estimates is comparable to the mass discrepancy between the results obtained using red and blue galaxies. In addition, the 2D pressure map shows a ~20% scatter, which can be propagated into the hydrostatic mass estimate. Despite the mass uncertainties, the X-ray hydrostatic mass estimate is slightly higher than the dynamical one at \( r_{500}^{\text{HE}} \) because the mass profile of the latter appears to be more concentrated than the former.

As shown in Table 1, the richness-derived mass estimates according to recent calibrations (e.g. Johnston et al. 2007; Hansen et al. 2009) agree well with the hydrostatic and dynamical mass estimates.

It is also important to compare the mass measurements at fixed overdensities (e.g. 500 and 200) as these masses are used
Yu-Ying Zhang et al.: Probing cluster dynamics in RXC J1504.1-0248 via radial and 2D gas and galaxy properties

in cosmological applications. At the overdensity of 500, the mass estimate from the caustic method is 72% of the hydrostatic mass estimate. This is due to the less-concentrated mass distribution determined using the hydrostatic method than that determined from the dynamical method, which can be caused by the disturbed ICM in the cluster core because of AGN feedback as discussed in Sect. 5.4. At the overdensity of 200, the richness-derived mass estimates according to Hansen et al. (2009) and Johnston et al. (2007) are about 0.8–1.2 times the hydrostatic mass estimate and 1.0–1.4 times the dynamical mass estimate.

5.3. Agreement with the scaling relations

The X-ray properties of R1504 are tabulated in Table 1. The global temperature and metallicity are measured with the XMM-Newton global temperature and metallicity are measured with the [0.2, 0.4] times solar abundance (Fig. 6). Guo & Mathews (2010) obtained a relatively flat radial distribution of iron abundance ranging within ±0.18 dex. Strong cool-core systems usually show peaked iron abundance (Fig. 6). However, R1504 displays a relatively flat radial distribution of iron abundance ranging within ±0.18 dex. The X-ray luminosity was derived by integrating the surface brightness out to $r_{500}^{HE}$. We show the X-ray luminosity of the 0.1–2.4 keV band and 0.01–100 keV (bol) hereafter band, respectively, in the rest frame including the cool core (incc hereafter) and correcting for the cool core (cocc hereafter), respectively. The X-ray luminosity corrected for the cool core is computed by assuming a constant value of the surface brightness distribution in the cluster core, $S_X^{200}(R < 0.2r_{500}^{HE}) = S_X(0.2r_{500}^{HE})$ for the reason detailed in e.g. Zhang et al. (2007).

The global properties of R1504 obey the scaling relations of nearby clusters. R1504, for instance, closely matches the $M_M - Y_X$, $M_{gas,M} - T$, and $M_{L^{200}}$ relations provided by e.g. Arnaud et al. (2005, 2007), Vikhlinin et al. (2006), and Zhang et al. (2008). This supports the finding that the ICM in R1504 is quite relaxed within $r_{500}^{HE}$. Regardless of whether the high velocity substructure is excluded, R1504 is well within the 26% scatter of the $L_{200}^{200} - Y_{X}$ relation for the clusters at similar redshifts studied by Zhang et al. (2011a). According to the dynamical mass estimate $M_{200}^{dynamical}$ and the richness within $r_{200}^{200}$, R1504 agrees with the mass versus richness scaling relations of Johnston et al. (2007) and Hansen et al. (2009), who instead used weak-lensing masses.

5.4. Cluster core

Strong cool-core systems usually show peaked iron abundances in the cluster cores. However, R1504 displays a relatively flat radial distribution of iron abundance ranging within [0.2, 0.4] times solar abundance (Fig. 6). Guo & Mathews (2010) pointed out in simulations that AGN outbursts efficiently mix metals in the cluster core and may even remove the central abundance peak if it is insufficiently broad.

R1504 is one of nine known clusters hosting radio mini-halos. The presence of mini-halos supports the above interpretation of mixing metals in the cluster core. The BCG is blue with a B−R colour of 0.98, and has strong emission lines. The BCG sky position, $\delta = -02^h48'14''26$ (2000), is offset by 4° (14 kpc) from the X-ray flux-weighted centroid, which is within the XMM-Newton special resolution with a 6° full width at half maximum. The BCG harbours a radio source with a brightness of 62 mJy at 1.4 GHz (Bauer et al. 2000). Giacintucci et al. (2011) reveal gas sloshing in the cluster core, where turbulence may generate particle acceleration to form mini-halos. The gas sloshing in the cluster core may partially account for the slightly less-concentrated mass distribution using the X-ray hydrostatic method than that determined from the caustic method (Fig. 3).

6. Conclusions

We have studied one of the most X-ray luminous clusters of galaxies in the REFLEX survey, R1504, using XMM-Newton imaging spectroscopy, VLT/VIMOS spectroscopy, and WFI photometry. The mass distribution determined using the hydrostatic method based on X-ray imaging spectroscopy agrees with that using the caustic method based on optical spectroscopy within the 1σ uncertainties at most radii, although the former appears to be less concentrated than the latter. The mass estimate obtained using the caustic method is 80% of the hydrostatic mass estimate at the X-ray mass determined radius $r_{500}^{HE}$.

At the overdensity of 500, the dynamical mass estimate is 72% of the hydrostatic mass estimate. At the overdensity of 200, the richness-derived mass estimates according to more recent calibrations of the mass–richness relation (e.g. Johnston et al. 2007; Hansen et al. 2009) are about 0.8–1.2 times the hydrostatic mass measurement and 1.0–1.4 times the dynamical mass measurement.

On the basis of the line-of-sight velocities of spectroscopic members, our DS test has revealed a relatively high-velocity ($>1000$ km s$^{-1}$) group at a projected distance of $\sim 0.8$ times the cluster centroid. The high velocity group was also present in the 2D X-ray maps and weak-lensing shear map. The dynamical mass estimate is reduced by 14% when the substructure of the high velocity group is excluded. This highlights the importance of a proper analysis of the structures of evolving systems such as cluster of galaxies in order to obtain precise mass measurements.

The cluster R1504 has a rather low stellar-mass fraction among nearby clusters (e.g. Biviano & Salucci 2006), although there is an agreement given the large scatter for nearby clusters (e.g. Andreon 2010; Zhang et al. 2011b). Both the intracluster light and BCG play limited roles in accounting for the low stellar-mass fraction. Within a projected distance of 700 kpc, the galaxy population is dominated by red galaxies (>70%) based on photometric data. Beyond 700 kpc, there is a rapid increase in the fraction of blue galaxies. The blue-galaxy fraction reaches about 60% at $r_{500}^{HE}$ and stays almost constant beyond. The dynamical mass measurement calculated using blue spectroscopic members is 1.23 times the value derived using red spectroscopic galaxies.

Despite the high velocity group in the cluster outskirts and the gas sloshing in the cluster core, R1504 appears to be relatively relaxed out to $r_{500}^{HE}$, and obeys the observed scaling relations found for similar nearby clusters.

The XMM-Newton project is supported by the Bundesministerium für Wirtschaft und Technologie/Deutsches Zentrum für Luft- und Raumfahrt (BMV/DFR, FKZ 50 OX 0001) and the Max-Planck Society. We have made use of VLT/VIMOS observations taken with the ESO Telescope at the Paranal Observatory under programme 077.A-0058 and WFI observations partially supported by the Deutsche Forschungsgemeinschaft (DFG) through Transregional Collaborative Research Centre TRR 33. The VLT/VIMOS data presented in this paper were reduced using the VIMOS Interactive Pipeline and Graphical Interface (VIPGI) designed by the VIRMOS Consortium. This research has made use of the SIMBAD database, operated at CDS, Strasbourg, France.
Appendix A: X-ray 2D spectrally measured maps

**Fig. A.1.** Two-dimensional X-ray spectrally measured temperature (upper left), electron number-density (upper right), entropy (lower left), and pressure (lower right) maps using the Cappellari & Copin (2003) binning scheme. Overlaid circles in blue, red, and green denote cluster galaxies that have spectroscopic follow-up data with their clustercentric velocities toward the observer greater than 1000 km s$^{-1}$, away from the observer greater than 1000 km s$^{-1}$, and smaller than 1000 km s$^{-1}$, respectively. The radii of these circles are proportional to $\exp[p_{500}]$. The black cross denotes the X-ray flux-weighted centroid and the black dashed circle denotes $r_{500}$. The white holes mask X-ray detected point sources. The colour scales logarithmically from 4 to 10 in keV for temperature, from 0.00005 to 0.12 in cm$^{-3}$ for electron number density, from 10 to 1800 in keV cm$^{-2}$ for entropy, and from 0.0001 to 0.54 in keV cm$^{-3}$ for pressure.
