## ABSTRACT

Constraining the physical properties of dust requires observations at submm wavelengths. This will provide important insight into the gas content of galaxies. We mapped NGC 1365 at 870  $\mu\text{m}$  with LABOCA, the Large APEX Bolometer Camera, allowing us to probe the central mass concentration as well as the rate at which the gas flows to the center. We obtained the dust physical properties both globally and locally for different locations in the galaxy. A 20 K modified black body represents about 98% of the total dust content of the galaxy, the rest can be represented by a warmer dust component of 40 K. The bar exhibits an east-west asymmetry in the dust distribution: The eastern bar is heavier than the western bar by more than a factor of 4. Integrating the dust spectral energy distribution, we derived a total infrared luminosity,  $L_{\text{TIR}}$ , of  $9.8 \times 10^{10} L_{\odot}$ , leading to a dust-enshrouded star formation rate of  $SFR_{\text{TIR}} \approx 16.7 M_{\odot} \text{yr}^{-1}$  in NGC 1365. We derived the gas mass from the measurements of the dust emission, resulting in a CO-to- $\text{H}_2$  conversion factor of  $X_{\text{CO}} \approx 1.2 \times 10^{20} \text{mol cm}^{-2} (\text{K km s}^{-1})^{-1}$  in the central disk, including the bar. Taking into account the metallicity variation, the central gas mass concentration is only  $\approx 20\%$  at  $R < 40''$  (3.6 kpc). On the other hand, the timescale on which the gas flows into the center,  $\approx 300 \text{Myr}$ , is relatively short. This indicates that the current central mass in NGC 1365 is evolving fast because of the strong bar.

## 1. Introduction

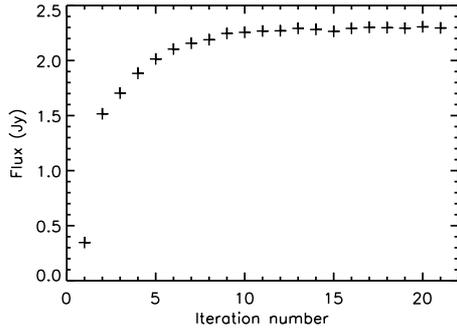

Bars are generally considered as an important transform mechanism of molecular gas toward the central regions of galaxies, fueling central starbursts and active nuclei. This is confirmed by an enhancement of CO emission along the bar (e.g. Gerin et al. 1988; Benedict et al. 1996; Sakamoto et al. 1999a) and by the resolved offset ridges along the leading edges of the rotating bar (Ishizuki et al. 1990). However, key questions about the formation and evolution of bars and the influence of bars on the physical and chemical evolution of the interstellar medium (ISM) remain open. Numerical simulations suggest that barred galaxies tend to have more of their gas mass concentrated in their centers than nonbarred galaxies (e.g. Combes & Gerin 1985). This is tentatively confirmed by  $^{12}\text{CO}(J = 1-0)$  observations (Sakamoto et al. 1999b). However, the observational evidence to date is sparse, and has its shortcomings. On the other hand, it is possible that the central mass concentration is affected by more than just the presence of bars. For example, Komugi et al. (2008) showed that the Hubble type could play a more important role than bars. As such, the distribution of gas contained in the disk of barred galaxies could shed light on the question.

Although CO observations directly probe the gas in its molecular phase ( $\text{H}_2$ ), there are indications that bars can contain gravitationally unbound molecular gas (e.g. Das & Jog 1995; Hüttemeister et al. 2000). Thus, in barred environments the mass of the molecular gas might be overestimated since the standard Galactic CO to  $\text{H}_2$  mass factor  $X_{\text{CO}}$  (the virial X-conversion factor) is not necessarily applicable. Moreover, the dependence of the  $X_{\text{CO}}$  conversion factor on the metallicity (Wilson 1995) and

the optical thickness of the CO line introduce an uncertainty on the estimate of the total gas mass in general.

As an alternative method of measuring the gas mass, observations of the dust continuum emission have been suggested and used by several authors (e.g. Hildebrand 1983; Guélin et al. 1993; James et al. 2002). Furthermore, studies based on the  $\gamma$ -ray observations of the Milky Way with the EGRET (Grenier et al. 2005) and *Fermi* (Abdo et al. 2010) space telescopes indicate that dust is a promising tracer of the gas, even of gas invisible in HI and CO (the so-called dark gas). Detailed studies of the mm and submm continuum emission from the Milky Way and other nearby galaxies show that about 90% of the dust mass is as cold as 14–16 K, and that dust is well-mixed with molecular gas so that cold dust emission can be used to probe the molecular hydrogen (e.g. Misiriotis et al. 2006). The cold dust can be best studied at submm wavelengths. Moreover, the importance of the submm data in constraining the dust spectral energy distribution (SED) and extracting dust mass and temperature has previously been indicated in numerous studies (e.g. Gordon et al. 2010). Therefore, submm observations of barred galaxies are important for studying the physics of the dominant component of the ISM in both disks and bars.

The total infrared emission (integrated in the wavelength range from, e.g., 8 to 1000  $\mu\text{m}$ ) is known to be a good tracer of the embedded star formation in galaxies (see Kennicutt & Evans 2012, and references therein). Nevertheless, it is still not clear how much of this emission is linked to dust heating sources other than the ongoing star formation, e.g., to non-ionizing UV photons or old stellar population.

**Fig. 1.** Integrated flux density obtained after each iteration in the data reduction. The convergence is reached after the tenth iteration.

We investigate the central mass concentration and the physical properties of the cold dust in the great barred spiral galaxy NGC 1365. With a diameter of twice that of the Milky Way ( $\sim 60$  kpc) and a mild inclination ( $\sim 41^\circ$ ), NGC 1365 is among the best-studied barred galaxies from the X-ray to the radio regimes, providing a rich multi-wavelength data archive ideal for in-depth studies. This galaxy hosts a Seyfert 1.5 (Schulz et al. 1999) as well as strong star formation activity (starburst) in the center (e.g. see Lindblad 1999, and references therein). NGC 1365 has a nuclear bar of about one kpc embedded in the large-scale bar (Jungwiert et al. 1997). This galaxy does not host a circumnuclear ring, in contrast to many barred galaxies. The shape of the central starburst region is asymmetric, with two massive dust lanes, with strong and aligned magnetic fields (Beck et al. 2005). NGC 1365 has been observed with the 1.8-m Balloon-borne Large Aperture Submm Telescope (BLAST) at 250, 350, and 500  $\mu\text{m}$  at resolutions 36'', 42'', and 60'', respectively (Wiebe et al. 2009). At these wavelengths, the central part of the galaxy has also been observed with the *Herschel* Space Observatory (Alonso-Herrero et al. 2012). Here, we present submm observations of this galaxy at 870  $\mu\text{m}$  with the APEX bolometer camera (LABOCA) at a resolution of about 20'', which is much higher than that of the BLAST and *Herschel* submm data at 500  $\mu\text{m}$ .

Through a comparison with various tracers of the ISM, we study the energy sources of the 870  $\mu\text{m}$  emission. We also revisit the dust physical properties such as temperature, mass, and total infra-red luminosity  $L_{\text{TIR}}$  and use this information to estimate the  $X_{\text{CO}}$  conversion factor as well as the star formation rate in NGC 1365. In a different approach, we also present the dust physical properties along the bar using the LABOCA 870  $\mu\text{m}$  and the BLAST 250  $\mu\text{m}$  data in apertures of 36''. The 870  $\mu\text{m}$  data are also used as a constraint for a gas flow model in this barred system.

The paper is organized as follows. The 870  $\mu\text{m}$  observations and data reduction as well as the relevant auxiliary data sets used are described in Sect. 2. We investigate the morphology and origin of the 870  $\mu\text{m}$  emission and derive the dust physical parameters in Sect. 3. Based on these results, the gas mass concentration and the role of  $X_{\text{CO}}$  conversion factor are discussed in Sect. 4. We also update estimates of the star formation rate as well as the rate of the gas flow in the center. The final results are then summarized in Sect. 5.

## 2. Data

### 2.1. Sub-mm observations and data reduction

The 870  $\mu\text{m}$  data were taken with the Large APEX Bolometer Camera (LABOCA Siringo et al. 2009), a 295-pixel bolometer

**Table 1.** Positional data adopted for NGC 1365.

Position of nucleus <sup>1</sup> (J2000)	RA = 03 <sup>h</sup> 33 <sup>m</sup> 36.37 <sup>s</sup> Dec = -36°08'25.4''
PA line of nodes <sup>2</sup>	220°
Inclination <sup>2</sup>	41° (0° = face on)
Distance <sup>3</sup>	18.6 Mpc

**Notes.** <sup>(1)</sup> Lindblad et al. (1996). <sup>(2)</sup> Jorsater & van Moorsel (1995). <sup>(3)</sup> Madore et al. (1999), 1'' = 90.2 pc.

array, operated on the Atacama Pathfinder EXperiment 12-m diameter telescope (Güsten et al. 2006) in Chanjantor, Chile. We observed NGC 1365 in 2008 December and 2009 August in mostly good weather conditions (the precipitable water vapour PWV content ranged from 0.1 mm to 0.9 mm). NGC 1365 was mapped in the spiral raster mode, providing a fully sampled map in the LABOCA field of view (11'  $\times$  11') in each scan. The total on-source integration time was about 12 h. The data were calibrated by observing Mars and Uranus together with the secondary calibrators and was found to be accurate within 15%. The data were reduced using the BOA (Bolometer array Analysis) software (Siringo et al. 2009; Schuller et al. 2009). After flagging for bad and noisy pixels, the data were despiked and correlated noise was removed for each scan. Then the scans were coadded (weighted by  $\text{rms}^{-2}$ ) to create the final map.

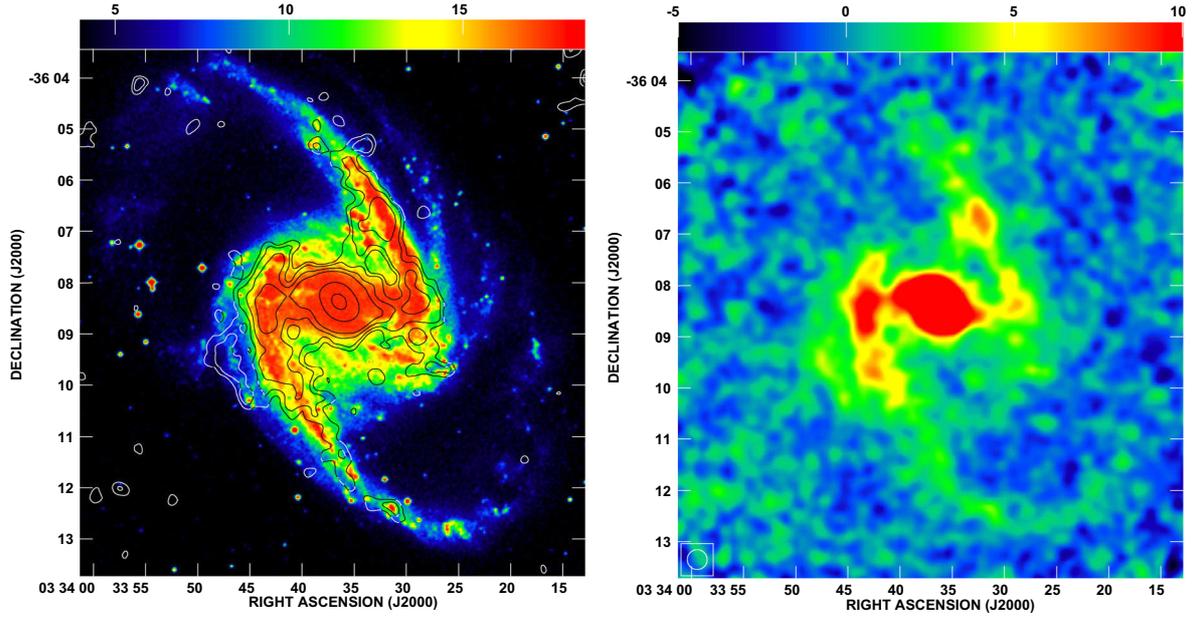

This process was performed 21 times in an iterative approach following Belloche et al. (2011). After a first iteration of the reduction, we made a source model by setting the map to zero below a signal-to-noise ratio of 4. Then the source map was used to flag bright sources and the data were reduced again. After the fourth iteration, the map resulting from the previous iteration was set to zero below a signal-to-noise ratio of 2.5. The remaining signal was subtracted from the data before reduction and added back after reduction. This way, negative artifacts that appear around the bright sources are much reduced, more extended emission can be recovered, and a more stable background noise level in the central region is obtained. Figure 1 shows a fast increase in the integrated flux density from the first to the fifth iteration, reaching a stable situation after the tenth iteration.

The HPBW of the telescope at 870  $\mu\text{m}$  is 19.2''. The map was convolved to 23'' to achieve a better signal-to-noise ratio without losing too much spatial information about the emission properties. Figure 2 shows the convolved map with an rms noise of 3 mJy/beam.

### 2.2. Complementary data

This study is supplemented with other tracers of the neutral and ionized gas. Table 2 summarizes the data used in this work. Jorsater & van Moorsel (1995) mapped NGC 1365 in 21-cm HI line emission with the VLA using hybrid BnA, CnB, and DnC configurations at a resolution of 11.6''  $\times$  6.3'' (Fig. 3). This dataset has been corrected for missing spacings. NGC 1365 was observed in  $^{12}\text{CO}(1-0)$  over a 204''  $\times$  164'' region centered on the nucleus with the Swedish/ESO Submillimeter Telescope (SEST) by Sandqvist et al. (1995) at a resolution of 44''. To subtract its contribution in the LABOCA band, the SEST observations of the  $^{12}\text{CO}(3-2)$  line (Sandqvist 1999) were used as well.

Wiebe et al. (2009) presented the BLAST observations of NGC 1365 at 250, 350, and 500  $\mu\text{m}$  at resolutions 36'', 42'', and 60'', respectively. We used their maps clipped in an area of 13'  $\times$  13' centered on the nucleus. Moreover, the far-infrared (FIR) measurements of ISOPHOT (Spinoglio et al. 2002) and

**Fig. 2.** *Left:* submm 870  $\mu\text{m}$  emission (contours) superimposed on an optical image (B-band, taken from the STScI Digitized Sky Survey) of NGC 1365. The contour levels are 6, 9, 15, 24, 150, and 500 mJy/beam. The bar shows the optical surface brightness in arbitrary units. *Right:* submm 870  $\mu\text{m}$  emission, normalized to the one  $\sigma$  noise rms level (signal-to-noise ratio). The angular resolution of 23'' is shown in the lower left corner.

**Table 2.** NGC 1365 data used in this study.

Wavelength	Telescope	Reference
870 $\mu\text{m}$	APEX	This paper
250–500 $\mu\text{m}$	BLAST	Wiebe et al. (2009)
2.6 mm $^{12}\text{CO}(1-0)$	SEST	Sandqvist et al. (1995)
867 $\mu\text{m}$ $^{12}\text{CO}(3-2)$	SEST	Sandqvist (1999)
21 cm HI	VLA	Jorsater & van Moorsel (1995)
6.2 cm	VLA	Beck et al. (2005)
1.5 $\mu\text{m}$	2MASS	Jarrett et al. (2003)
120–200 $\mu\text{m}$	ISO-ISOPHOT	Spinoglio et al. (2002)
43–197 $\mu\text{m}$	ISO-LWS	Brauher et al. (2008)
1516 Å (FUV)	GALEX	Gil de Paz et al. (2007)

ISO-LWS (Brauher et al. 2008) made with the Infrared Space Observatory (ISO) as well as with the Infrared Astronomical Satellite (IRAS; Sanders et al. 2003) have been used to study the dust SED.

The radio continuum emission from NGC 1365 was mapped with VLA at 6.2 cm and at 13'' resolution (Beck et al. 2005). The radio 6.2 cm emission is mainly emerging from the central  $300'' \times 300''$  region. We used the 6.2 cm map after subtracting the bright background radio source in the northeast of the galaxy. In the far-ultraviolet (FUV), NGC 1365 was observed with the GALaxy Evolution EXplorer satellite (GALEX) at 4.5'' resolution as detailed in the GALEX ultraviolet atlas of nearby galaxies (Gil de Paz et al. 2007).

### 3. Results

#### 3.1. Morphology of the 870 $\mu\text{m}$ continuum map

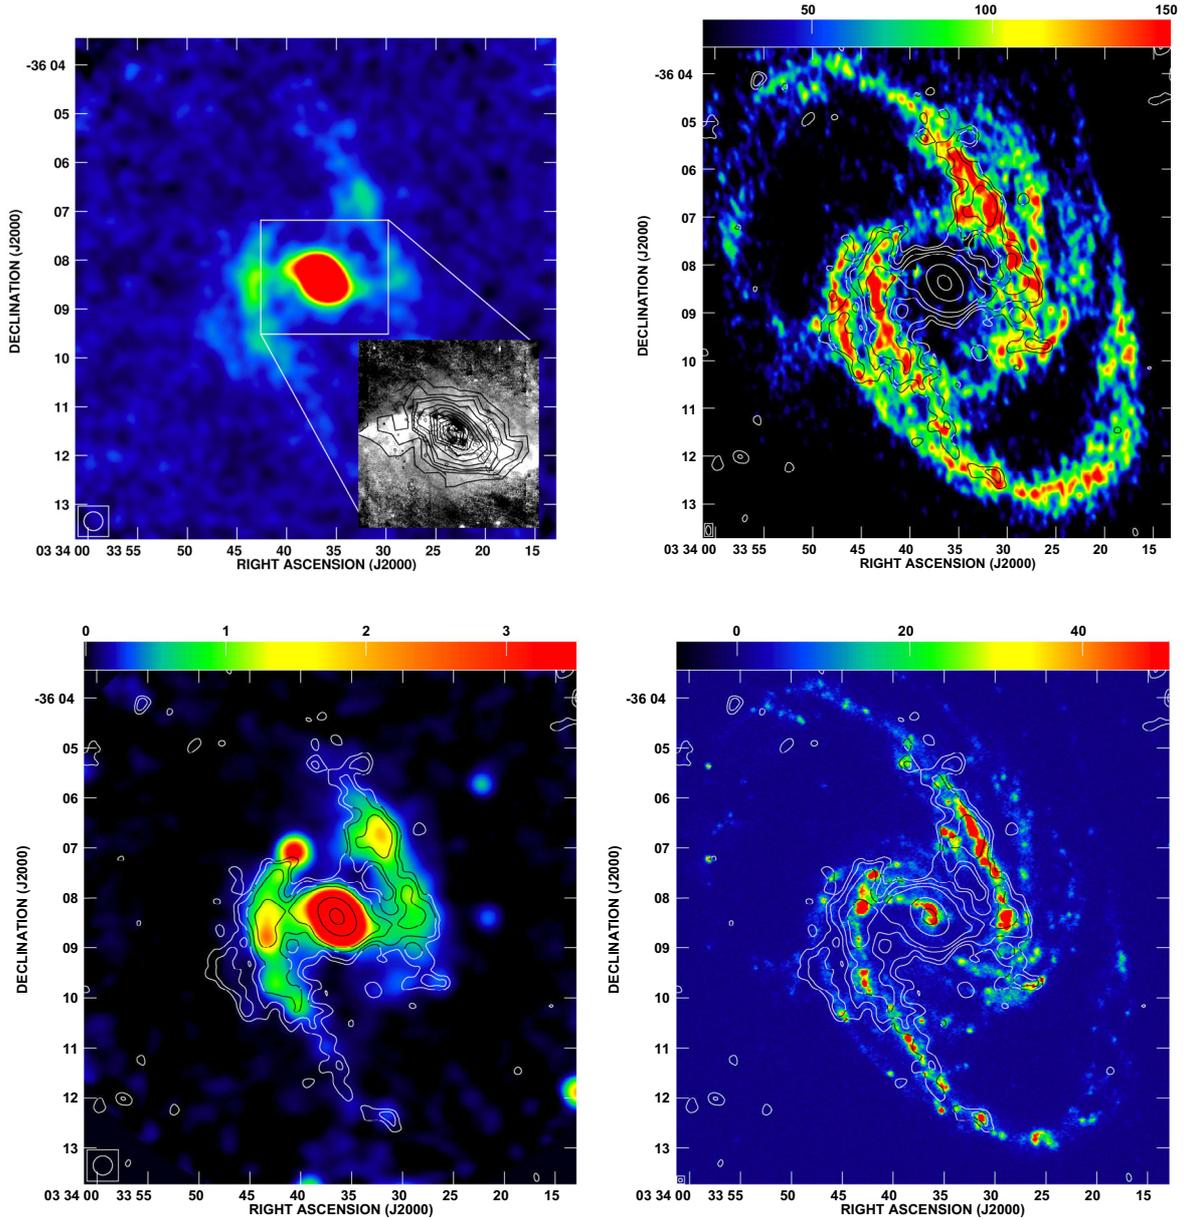

NGC 1365 is illuminated by its oval-shaped core of  $\sim 80''$  diameter at 870  $\mu\text{m}$  (Fig. 2). In this region, the 870  $\mu\text{m}$  intensities are higher than 100 mJy/beam with a maximum of  $\sim 600$  mJy/beam. The bar is brighter in the eastern edge than in the western edge. The two main spiral arms appear pronounced by bright clumps corresponding to the complexes of star-forming regions followed

by faint emission ( $\sim 3\sigma$ ) in the outer parts. A segment of the secondary arm in the south-east of the galaxy, which is weak in optical images but bright in HI, is detected at 870  $\mu\text{m}$  as well (see the 870  $\mu\text{m}$  contours overlaid on a HI map in Fig. 3). Apart from their similarity along the spiral arms, the 870  $\mu\text{m}$  and the HI emission show a striking difference in the central part, including the nucleus and the bar: while this region is the brightest part at 870  $\mu\text{m}$ , it is the darkest in HI. The central part is also the most dominant region in the CO(1–0) line emission as well as in the radio continuum emission (e.g. at 6 cm, Fig. 3). While, for instance, Ondrechen & van der Hulst (1989) found weak HI absorption in a limited velocity range, the virtually complete absence of HI toward the center of NGC 1365 and most of its bar is explained by the fact that almost all gas in these dense regions is in molecular form (and is traced by the strong CO emission). Generally, the 870  $\mu\text{m}$  emission is very similar to the 6 cm radio continuum emission, particularly in the extent of the main arms and the east-west asymmetry of the bar. On the other hand, the radio continuum emission is very weak in the secondary arm in the south-east of the galaxy, which is bright at 870  $\mu\text{m}$  (and HI). This must be a region of high gas density, but with only little star formation. In the 6 cm radio continuum map, the strong source in the northeast is a background radio source (Sandqvist et al. 1982). In the FUV, the core does not dominate the emission. The strong central 870  $\mu\text{m}$  emission indicates a significant attenuation of the UV emission by dust emitting in the FIR/submm range.

The integrated flux density of the 870  $\mu\text{m}$  emission in the plane of the galaxy (using parameters listed in Table 1) around the center out to a radius of 220'' (20 kpc) is  $S = 2.3 \pm 0.3$  Jy. The integrated flux density in the core ( $R < 40''$  or 3.6 kpc) is  $S = 1.1 \pm 0.2$  Jy, about half of the total value.

#### 3.2. Origin of the observed emission

Generally, the broad-band emission at 870  $\mu\text{m}$  could consist of four main components: thermal dust emission, free-free

**Fig. 3.** *Top left:* LABOCA 870  $\mu\text{m}$  emission compared with CO(2-1) observations of the central part of NGC 1365 (contours on top of an optical image, see Sandqvist et al. 1995). *Top right:* contours of the 870  $\mu\text{m}$  emission overlaid on the HI map. *Bottom left:* the same contours on top of the radio continuum emission at 6 cm and the GALEX FUV map (*bottom right*). In all panels the resolution of the 870  $\mu\text{m}$  emission is 23'' with contour levels of 6, 9, 15, 24, 150, and 500 mJy/beam.

emission from thermal electrons, synchrotron radiation from relativistic electrons, and contamination by CO(3-2) line emission. Because we are interested in the thermal dust emission alone, we have to investigate the contribution of the other components to the data.

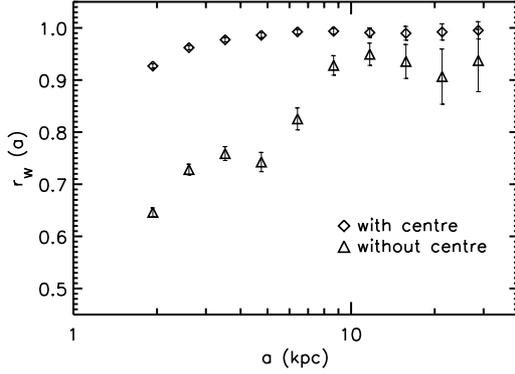

The contribution of the CO(3-2) line emission to the surface brightness measured with the bolometer with a bandwidth of  $\Delta\nu_{\text{bol}}$  and a beam width of  $\Omega_{\text{beam}}$  can be calculated through

$$F_{\text{line}} = \frac{2K\nu^3 c^{-3}}{\Delta\nu_{\text{bol}}} \Omega_{\text{beam}} I_{\text{CO}(3-2)}, \quad (1)$$

where  $I_{\text{CO}(3-2)}$  is the velocity-integrated main-beam brightness temperature ( $I_{\text{CO}(3-2)} = \int T_{\text{mb}}^{\text{CO}(3-2)} dv$ ) in  $\text{K km s}^{-1}$ . Thus,  $F_{\text{line}} [\text{mJy}] = 0.973 I_{\text{CO}(3-2)} [\text{K km s}^{-1}]$  for the LABOCA bandwidth of 60 GHz and at 23'' resolution. Using the

SEST data, the contribution of the CO(3-2) line emission to the observed 870  $\mu\text{m}$  continuum emission varies in the range 16%–25% in different locations. In the central 80'' area, the CO(3-2) flux is  $\approx 220$  mJy, i.e., 20% of the observed 870  $\mu\text{m}$  flux ( $S = 1.1 \pm 0.2$  Jy). The contribution of the CO(3-2) line emission was subtracted from the observed 870  $\mu\text{m}$  emission before studying the dust physical properties.

In the core, where the contribution of the radio continuum emission has its maximum, the integrated flux density of the 6 cm radio continuum emission is  $\approx 163$  mJy. The thermal free-free fraction at 6 cm is about 20% (Beck et al. 2005). Since the free-free flux changes with wavelength as  $\lambda^{0.1}$ , the corresponding thermal free-free flux at 870  $\mu\text{m}$  is 21 mJy. Assuming a nonthermal spectral index of  $\alpha_n = 0.8$ , the contribution of the synchrotron emission ( $\sim \lambda^{\alpha_n}$ ) is about 4 mJy. This is an upper limit, because the synchrotron spectrum is likely to steepen due

**Fig. 4.** Scale-by-scale correlation between the cold dust emission at  $870\ \mu\text{m}$  and the radio continuum emission at 6 cm from NGC 1365 before and after subtracting the central  $80''$  region. The cross-correlation coefficient  $r_w(a)$  is higher on spatial scales  $a$  where correlations are tighter.

to CRE energy losses. Thus, only 1–2% of the total  $870\ \mu\text{m}$  flux is contaminated by the free-free and synchrotron emission.

### 3.3. Heating sources of cold dust in NGC 1365

About 99% of the energy released by galaxies in the FIR and submm wavebands is produced by thermal emission from dust grains. However, the energy sources that heat the dust and power this emission are often uncertain. Any effective source of optical/ultraviolet (UV) radiation, either young massive stars or an accretion disk surrounding an AGN, would heat dust grains. Regions of intense dust emission are opaque at short wavelengths, and thus little information can be derived by optical or UV observations. As an extinction-free tracer of the ionized gas and star formation, the radio continuum emission can be used, instead, to probe the heating sources of dust. Such studies are most informative when performed locally and at resolved scales in galaxies. Global studies are possibly biased toward the brightest emitting components in a galaxy. For example, the well-known radio-FIR correlation is weighted by regions of massive star formation when studied globally and in galaxy samples (Tabatabaei et al. 2013). Only recently and through studying smaller scales within galaxies, variations of such tight correlations have become apparent (e.g. Hughes et al. 2006; Tabatabaei et al. 2007; Tabatabaei & Berkhuijsen 2010; Dumas et al. 2011).

We performed a scale-by-scale comparison of the  $870\ \mu\text{m}$  and the 6 cm radio continuum emission using a wavelet cross-correlation analysis. After convolving the 6 cm radio map to the resolution of the  $870\ \mu\text{m}$  map ( $23''$ ), the maps were normalized in grid size, reference coordinates, and field of view. The maps of the  $870\ \mu\text{m}$  and 6 cm emission were first decomposed into ten scales from  $23''$  ( $\sim 2$  kpc) to about  $300''$  ( $\sim 27$  kpc) using the Pet-Hat wavelet function as detailed in Frick et al. (2001), Tabatabaei et al. (2007), Laine et al. (2010), and Dumas et al. (2011). Then, we cross-correlated the resulting decomposed maps of the  $870\ \mu\text{m}$  and 6 cm emission at each of the ten spatial scales. In Fig. 4, the cross-correlation coefficients  $r_w$  (for pure correlation or anti-correlation  $r_w = \pm 1$ ) are plotted vs. the spatial scale  $a$  before and after subtracting the central  $80''$ . Before subtracting the core, the two emissions are perfectly correlated as  $r_w > 0.9$  on all scales. After the subtraction, however, the radio-submm correlation decreases particularly on scales  $a < 8$  kpc. This shows that the good radio-submm correlation is mainly due to the core

strongly emitting at both radio and submm wavelengths, under starburst conditions.

After subtracting the core, the situation resembles the radio-FIR correlation in normal star-forming galaxies, where the correlation decreases toward small scales (e.g. see Hughes et al. 2006; Dumas et al. 2011). The decreasing trend of the radio-FIR correlation could be attributed to different origins of the radio continuum emission and the dust emission. For instance, a weaker radio-FIR correlation is expected on small scales if the radio continuum emission is dominated by the synchrotron-radiating cosmic ray electrons (CREs) diffused on large scales along the interstellar magnetic field lines (Tabatabaei et al. 2013) or if the heating source of the dust is not linked to massive stars on small scales, but to a diffuse radiation field (ISRF). The latter is more likely the case for the cold dust emission traced at long FIR/submm wavelengths.

Looking at the wavelet-decomposed maps (Fig. 5), the greatest difference in the morphologies is detected at the smallest scale ( $\approx 2$  kpc). At this scale, the radio emission exhibits few point-like features as well as weaker filament-like structures following the spiral arms, while the cold dust emission shows dispersed clumpy structures. Such a non-coherent distribution is expected for diffuse emission, which fits to the dust heating scenario by a diffuse ISRF. We also note that strong noise could also provide a non-coherent morphology on small scales, reducing the correlation (Dumas et al. 2011). This, however, cannot be the entire reason of the observed decreasing trend in the radio-FIR correlation in galaxies, as the decreasing trend resists using more sensitive *Herschel* data (Tabatabaei et al. 2013). The morphologies of the radio and submm emission also differ significantly at scale of 3.5 kpc, becoming more similar toward larger scales. At  $a = 8$  kpc, both radio and submm maps are similarly dominated by diffuse emission from star-forming complexes in the ridges and along the spiral arms, leading to a perfect radio-submm correlation at this scale (see Fig. 4).

### 3.4. Dust physical properties

We derived the dust mass and temperature assuming that dust grains are in local thermodynamic equilibrium (LTE) and hence emit as a modified black body (MBB). This condition applies for thermalized dust grains that usually emit at FIR and submm wavelengths (emission in the mid-IR,  $\lambda < 40\ \mu\text{m}$ , is dominated by very small grains that are not thermalized). The dust SED derived based on the LABOCA and BLAST submm data together with the IRAS and the ISOPHOT FIR data can be best reproduced if a two-component MBB is used (Fig. 6):

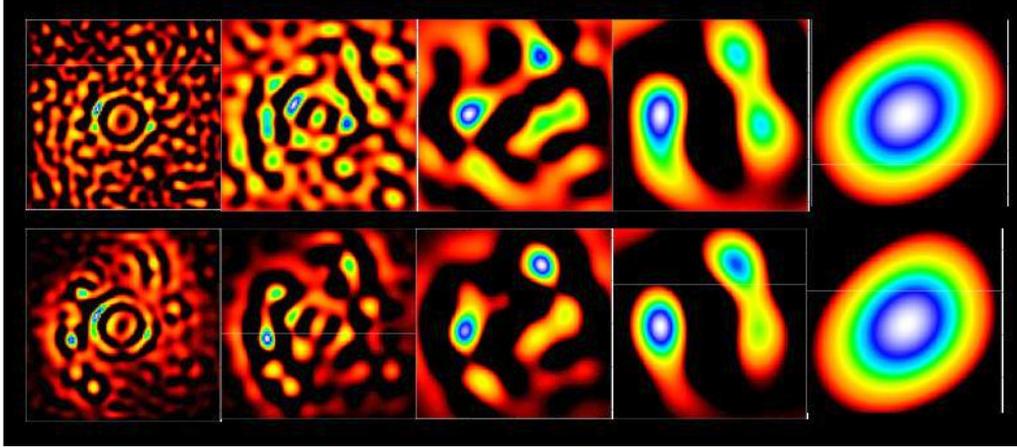

$$S_\nu = \Omega_s [B_\nu(T_c)(1 - e^{-\tau_{\nu,c}}) + B_\nu(T_w)(1 - e^{-\tau_{\nu,w}})], \quad (2)$$

where  $S_\nu$  is the FIR/submm flux,  $B_\nu$  the Planck function,  $\nu$  the frequency, and  $\Omega_s$  the solid angle of the emitting area subtended to the observer. The two components, i.e., the cold and warm dust components, are specified by their temperatures  $T_c$ ,  $T_w$  and mass surface densities  $\Sigma_c$ ,  $\Sigma_w$  given by their optical depths  $\tau_{\nu,c}$  and  $\tau_{\nu,w}$  as

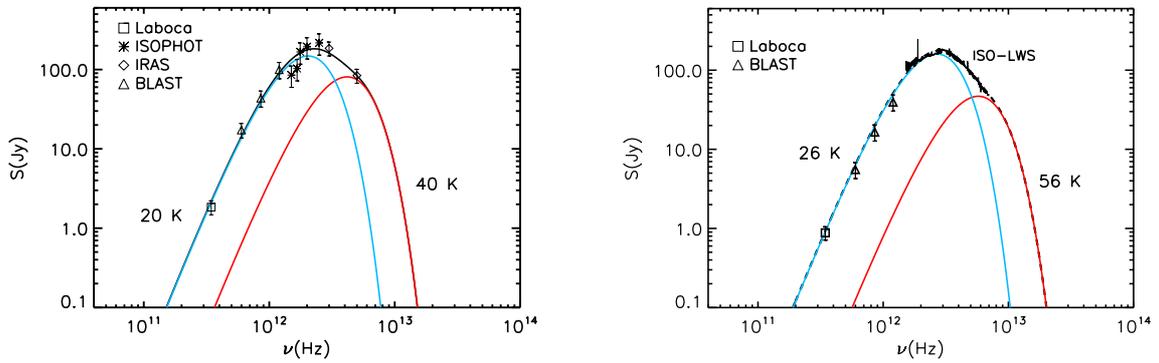

$$\Sigma_c = \tau_{\nu,c} / \kappa_\nu,$$

$$\Sigma_w = \tau_{\nu,w} / \kappa_\nu,$$

where  $\kappa_\nu$  is the dust opacity or absorption coefficient. We adopted  $\kappa_\nu = 0.04 \left(\frac{\nu}{250\ \text{GHz}}\right)^\beta$  in units of  $\text{m}^2$  per kilogram of a standard dust including silicates and amorphous carbon (Weiß et al. 2008; Krügel 2003, Chap. 14).

**Fig. 5.** Wavelet-decomposed maps at 870  $\mu\text{m}$  (first row) and 6 cm (second row) on scales  $a \approx 2, 3.5, 6.4, 8,$  and 29 kpc.

**Fig. 6.** Spectral energy distribution of NGC 1365 (left) and of the central 80'' (right). The colder component provides about 99% of the total dust content in the central part, and 98% in the entire area toward which 870  $\mu\text{m}$  emission is detected.

**Table 3.** Dust temperature and mass surface densities for disk and core of NGC 1365.

Integrated region	$T_c$ (K)	$T_w$ (K)	$\Sigma_c$ ( $M_\odot \text{pc}^{-2}$ )	$\Sigma_w$ ( $10^{-3} M_\odot \text{pc}^{-2}$ )	$M_d$ ( $10^7 M_\odot$ )
Disk	$20 \pm 1$	$40 \pm 5$	$0.11 \pm 0.01$	$1.6 \pm 0.6$	$10.1 \pm 0.8$
Core	$26 \pm 1$	$56 \pm 4$	$0.64 \pm 0.06$	$4.3 \pm 1.3$	$2.9 \pm 0.2$

**Notes.** The dust mass is also calculated for each area. The errors indicate the range of parameters that provide statistically good fits ( $\chi^2 < 2\chi^2_{\text{min}}$ ).

Using a standard  $\chi^2$  minimization technique, the best-fitted MBB model to the observed SED results in a cold dust temperature  $T_c$  of 20 K and a warm dust temperature  $T_w$  of 40 K. The mass surface densities are about  $0.1 M_\odot \text{pc}^{-2}$  and  $1.6 \times 10^{-3} M_\odot \text{pc}^{-2}$  for the cold and warm dust components, respectively. Thus, about 98% of the total dust content in this galaxy can be described with a temperature of 20 K. This model is equally well described by dust emissivity indices in the range  $\beta = 2.0 \pm 0.1$  (providing  $\chi^2 < 2\chi^2_{\text{min}}$ ). This leads to a dust absorption coefficient at 870  $\mu\text{m}$  of  $\kappa_{870} = 0.076 \pm 0.002 \text{ m}^2 \text{kg}^{-1}$ , which agrees with James et al. (2002).

We also derived the SED for the central 80'' area (core) for which the LABOCA submm data were used together with the BLAST data and the ISO long-wavelength spectrometer (LWS) data with a good coverage of the peak of the SED (Fig. 6b). In this region, the temperature of the cold and warm dust components are 26 K and 56 K, respectively (see Table 3). The best-fitted  $\beta$  in the core is the same as in the disk. The temperatures agree with those reported by Alonso-Herrero et al. (2012), who fitted the SED using the *Herschel* data.

We derived a total dust mass of  $M_d \approx 10^8 M_\odot$  for the entire galaxy taking into account only the points with intensities

higher than  $3\sigma$  at 870  $\mu\text{m}$ . This agrees closely with Wiebe et al. (2009), taking into account the different absorption coefficients they used ( $\kappa_{870} \approx 0.02 \text{ m}^2 \text{kg}^{-1}$ ). In the core,  $M_d \approx 2.9 \times 10^7 M_\odot$ , constituting about 30% of the total dust mass in the galaxy.

In a second approach, we investigated the dust physical properties along the bar using the BLAST 250  $\mu\text{m}$ -to-LABOCA 870  $\mu\text{m}$  flux ratios in apertures of 36'' (the angular resolution of the BLAST 250  $\mu\text{m}$  data). The color temperature can be derived using the following expression:

$$\frac{S_{250}}{S_{870}} = \frac{\nu_{250}^\beta B_{250}(T)}{\nu_{870}^\beta B_{870}(T)}, \quad (3)$$

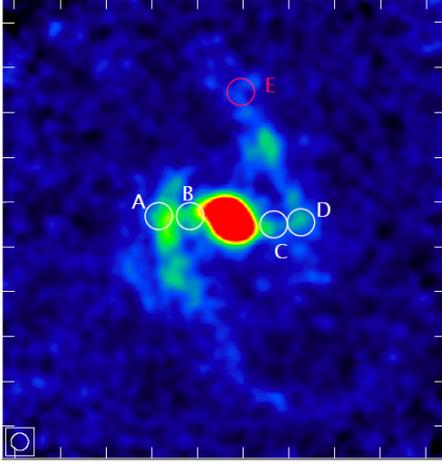

where  $S_{250}$  and  $S_{870}$  denote the measured flux at 250  $\mu\text{m}$  and 870  $\mu\text{m}$ , respectively. We used  $\beta = 2$  as derived based on the SED studies and that the dust is optically thin, which is valid at the wavelengths considered. The corresponding dust mass is then given by

$$M_d = S_{870} D^2 \kappa_{870}^{-1} B_{870}(T)^{-1}. \quad (4)$$

Measurements of  $S_{250}$  and  $S_{870}$  in apertures shown in Fig. 7 lead to  $T$  and  $M_d$  values listed in Table 4. Along the bar,  $T$  changes

**Table 4.** Dust temperature and mass along the bar in apertures shown in Fig. 7.

Aperture	RA [ <sup>h</sup> <sup>m</sup> <sup>s</sup> ]	Dec [ <sup>°</sup> <sup>'</sup> <sup>''</sup> ]	$T_c$ [K]	$M_d$ [ $10^6 M_\odot$ ]	$M_G$ [ $10^8 M_\odot$ ]
A	3 33 44.10	-36 08 16.59	$21 \pm 3$	$3.2 \pm 0.8$	$4.9 \pm 0.8$
B	3 33 40.59	-36 08 23.16	$23 \pm 4$	$6.8 \pm 1.8$	$10.2 \pm 1.8$
C	3 33 31.67	-36 08 39.54	$42 \pm 5$	$1.4 \pm 0.3$	$2.1 \pm 0.3$
D	3 33 27.75	-36 08 29.70	$36 \pm 4$	$0.8 \pm 0.2$	$1.2 \pm 0.2$
E	3 33 36.53	-36 05 21.40	$20 \pm 3$	$0.8 \pm 0.2$	$1.3 \pm 0.2$

**Fig. 7.** Selected apertures with  $36''$  diameter along the bar and northern spiral arm superimposed on the  $870 \mu\text{m}$  map of NGC 1365.

between  $21 \pm 3$  K to  $42 \pm 5$  K with errors determined based on calibration uncertainties of the integrated flux densities ( $\sim 20\%$  and  $15\%$  at  $250 \mu\text{m}$  and  $870 \mu\text{m}$ , respectively). The dust mass  $M_d$  changes between  $(0.8 \pm 0.2) \times 10^6 M_\odot$  to  $(6.8 \pm 1.8) \times 10^6 M_\odot$  in the selected apertures along the bar. The dust temperature in apertures A and B (in the eastern bar) is similar to that of the spiral arms (e.g. aperture E) and also similar to that of the cold dust in the disk ( $\approx 20$  K) obtained based on the SED analysis. On the other hand, the dust is warm in the western apertures C and D (the average equilibrium temperature in these two apertures is  $\approx 40$  K, the same as  $T_w$  for the disk). This together with the fact that the eastern bar is brighter than the western bar (Sect. 3.1) implies that the bar contains more dust in the east than in the west. Table 4 shows that the east/west ratio in  $M_d$  amounts to more than a factor of 4.

## 4. Discussion

### 4.1. Molecular gas mass and $X_{\text{CO}}$ conversion factor

The total dust mass determined from fitting to the SED of the disk ( $R \leq 220''$ ) leads to a total gas mass  $M_G$  of  $1.5 \times 10^{10} M_\odot$  for a hydrogen gas-to-dust mass ratio of 150 (e.g. Krügel 2003; Young & Scoville 1991, and references therein). The total gas surface density ( $\sim 17 M_\odot \text{pc}^{-2}$ ) is about three times higher than the local gas surface density in the Milky Way ( $\sim 6 M_\odot \text{pc}^{-2}$ , Dame 1993).

To compare the gas mass estimate from the dust mass with that derived from the existing HI and CO observations, the same integration area must be taken into account. Hence, we obtained the dust mass for the same restricted area for which CO data are available ( $204'' \times 164''$ , Sandqvist et al. 1995). The integrated  $870 \mu\text{m}$  flux,  $S_{870} \approx 1.52$  Jy, results in a dust mass of  $M_d \approx 7.12 \times 10^7 M_\odot$  using Eq. (4) for the 20 K dust. The

corresponding total hydrogen gas mass is then  $M_G = 1.07 \times 10^{10} M_\odot$ .

Integrating the HI map in the same area results in an HI flux of  $S_{\text{HI}} = 2.1 \times 10^4$  Jy m s<sup>-1</sup>. Using the calibration relation

$$M_{\text{HI}} = 2.356 \times 10^5 S_{\text{HI}} D^2 M_\odot,$$

with  $S_{\text{HI}}$  in Jy km s<sup>-1</sup> and  $D$  in Mpc (e.g. Jorsater & van Moorsel 1995), we obtain the HI mass of  $M_{\text{HI}} = 1.72 \times 10^9 M_\odot$ . Thus, the mass of the molecular gas is  $M_{\text{H}_2} = M_G - M_{\text{HI}} = 8.95 \times 10^9 M_\odot$ . This is about 48% lower (relative difference) than the  $\text{H}_2$  mass estimate using the CO data and assuming a CO-to- $\text{H}_2$  conversion factor of  $X_{\text{CO}} = 2.3 \times 10^{20} \text{ mol cm}^{-2} (\text{K km s}^{-1})^{-1}$  ( $M_{\text{H}_2} = 1.73 \times 10^{10} M_\odot$ , Sandqvist et al. 1995). The two  $M_{\text{H}_2}$  estimates would be the same if a lower  $X_{\text{CO}}$  of  $1.2 \times 10^{20} \text{ mol cm}^{-2} (\text{K km s}^{-1})^{-1}$  were used. We stress that this value, which is an upper limit derived using the lowest possible dust temperature and hence highest possible dust and gas mass, is lower than the default Galactic value of  $2 \times 10^{20} \text{ mol cm}^{-2} (\text{K km s}^{-1})^{-1}$ .

For a similar comparison in the core, we first derived  $M_{\text{H}_2}$  using the CO data and assuming a CO-to- $\text{H}_2$  conversion factor of  $X_{\text{CO}} = 2.3 \times 10^{20} \text{ mol cm}^{-2} (\text{K km s}^{-1})^{-1}$  as used in Sandqvist et al. (1995). The intensity ( $I_{\text{CO}} = \int T_{\text{mb}} dv$ ) of the CO(1–0) line averaged over the central  $80''$  area, taking into account the SEST's beam width of  $44''$  at 110 GHz is  $\bar{I}_{\text{CO}} = 41.5$  K km s<sup>-1</sup>. Following Sandqvist et al. (1995),  $M_{\text{H}_2} = 3.7 \times 10^6 L_{\text{CO}}$  with the CO luminosity given by  $L_{\text{CO}} = A \bar{I}_{\text{CO}}$  ( $A$  is the integrated area in kpc<sup>2</sup>). Thus, the molecular gas mass in the bulge is  $M_{\text{H}_2} = 6.28 \times 10^9 M_\odot$  using the CO data. On the other hand, based on the dust mass (see Table 3) and taking into account the HI mass, the molecular gas mass is  $M_{\text{H}_2} = 4.33 \times 10^9 M_\odot$ , implying an  $X_{\text{CO}}$  conversion factor of  $1.6 \times 10^{20} \text{ mol cm}^{-2} (\text{K km s}^{-1})^{-1}$ .

In the above estimate, it is assumed that the gas-to-dust ratio in the core is the same as for the disk. However, the gas-to-dust ratio or metallicity usually shows a radial gradient in galaxies (e.g. Muñoz-Mateos et al. 2009; Tabatabaei & Berkhuisen 2010; Magrini et al. 2007; Smith et al. 2012). These variations should be considered to estimate the  $X_{\text{CO}}$  conversion factor using the dust emission (FIR/submm) surveys across a galaxy (e.g. Cox et al. 1986). Based on optical observations of 53 HII regions, Pilyugin et al. (2004) obtained a radial gradient in metallicity or oxygen abundance in NGC 1365 as follows:

$$\begin{aligned} Z &\equiv 12 + \log(\text{O}/\text{H}) \\ &= -(0.023 \pm 0.005) R(\text{kpc}) + (8.74 \pm 0.06). \end{aligned} \quad (5)$$

Generally, the relative amount of dust and gas is expected to be correlated with the abundance of the heavy elements (e.g. Draine et al. 2007). Using a linear correlation between  $Z$  and the dust-to-gas mass ratio  $D$  (James et al. 2002), Eq. (5) leads to a gas-to-dust mass ratio of  $\approx 117$  in the core (assuming that it is 150 in the disk). This decreases the estimated molecular gas mass to  $M_{\text{H}_2} = 3.36 \times 10^9 M_\odot$  and the conversion factor to  $X_{\text{CO}} = 1.2 \times 10^{20} \text{ mol cm}^{-2} (\text{K km s}^{-1})^{-1}$ , which is the same as in the central disk (the  $204'' \times 164''$  region).

On the other hand, it has been shown that  $Z$  and  $D$  could be correlated nonlinearly in galaxies (e.g. Issa et al. 1990; Schmidt & Bolter 1993; Lisenfeld & Ferrara 1998). The correlation given by Schmidt & Bolter (1993) agrees with that given by Issa et al. (1990) (which includes few large galaxies like the Milky Way, M31, M51, and M101) but has a better statistics. Schmidt & Bolter (1993) found that  $Z$  is related to the logarithm of the dust-to-gas mass ratio  $D$  through  $Z \sim D^{0.63 \pm 0.25}$ . Assuming that the same proportionality applies in NGC 1365, we find a gas-to-dust mass ratio of  $\approx 100$  in the core, leading to a molecular gas mass of  $M_{\text{H}_2} = 2.86 \times 10^9 M_\odot$  and a conversion factor of  $X_{\text{CO}} = 1.0 \times 10^{20} \text{ mol cm}^{-2} (\text{K km s}^{-1})^{-1}$ . Therefore, the  $X_{\text{CO}}$  conversion factor is lower in the core than in the central disk by 20%.

Taking into account the metallicity gradient, the central gas mass concentration defined as the ratio of the total gas mass in the core to that in the entire disk is  $M_{\text{core}}/M_{\text{disk}} \approx 0.2$ .

#### 4.2. Star formation rate

Integrating the modeled SED for  $40 \mu\text{m} < \lambda < 1000 \mu\text{m}$ , the FIR luminosity is derived as  $L_{\text{FIR}} = 8.33 \times 10^{10} L_\odot$ . Following the FIR definition by Rice et al. (1988), the obtained luminosity in the range  $42.5 \mu\text{m} < \lambda < 122.5 \mu\text{m}$  is  $L_{42.5-122.5} = 5.46 \times 10^{10} L_\odot$ . This agrees with Rice et al. (1988), giving  $L_{42.5-122.5} = 5.49 \times 10^{10} L_\odot$  considering the different distance they used. Using the SED-based luminosity in the range  $40 \mu\text{m} < \lambda < 500 \mu\text{m}$ ,  $L_{40-500} = 8.31 \times 10^{10} L_\odot$  together with the FIR to total infrared luminosity TIR ( $8 \mu\text{m} < \lambda < 1000 \mu\text{m}$ ) luminosity calibration given by Chary & Elbaz (2001) for a sample of luminous infrared galaxies (LIRGs) and starburst galaxies, we derive  $L_{\text{TIR}} = 9.8 \times 10^{10} L_\odot$  (in agreement with Sanders et al. 2003, giving  $L_{\text{TIR}} \approx 10^{11} L_\odot$ ).

Several authors have used the  $L_{\text{TIR}}/L_{\text{FUV}}$  ratio to measure the extinction (e.g. Calzetti 2001; Verley et al. 2009; Montalto et al. 2009). Here we calculated the extinction in the core and in the disk using this method. Calzetti (2001) and Calzetti et al. (2005) found the following relation between the visual extinction and  $L_{\text{TIR}}/L_{\text{FUV}}$  for starburst condition:

$$A_V = C \times 1.76 \times \log_{10} \left( \frac{1}{1.68} \times \frac{L_{\text{TIR}}}{L_{\text{FUV}}} + 1 \right), \quad (6)$$

with  $C = 1$  for emission from diffuse ionized gas and  $C = 0.44$  for emission from stars. Using the GALEX data, we derive  $L_{\text{FUV}} = 1.02 \times 10^9 L_\odot$  for the corresponding region in the disk. Assuming that the extinction is mainly caused by emission from stars,  $A_V \approx 1.4$  is obtained. This is equivalent to an FUV extinction  $A_{\text{FUV}} \approx 3.5$ , resulting in a de-reddened FUV luminosity of

$$L_{\text{FUV}}^0 = L_{\text{FUV}} e^{A_{\text{FUV}}/1.086} \approx 2.59 \times 10^{10} L_\odot.$$

The star formation rate based on the FUV emission is given by

$$SFR_{\text{FUV}}(M_\odot/\text{yr}) = 1.40 \times 10^{-28} L_{\text{FUV}}^0,$$

with  $L_{\text{FUV}}^0$  in  $\text{erg}^{-1} \text{s}^{-1} \text{Hz}^{-1}$  (Kennicutt 1998). This leads to  $SFR_{\text{FUV}} \approx 7 M_\odot \text{yr}^{-1}$  for the disk of NGC 1365. On the other hand, assuming that the energy source of the TIR emission is provided by massive stars, the so-called dust-enshrouded star formation rate can be derived using the TIR luminosity following Kennicutt (1998),

$$SFR_{\text{TIR}}(M_\odot/\text{yr}) = 1.71 \times 10^{-10} L_{\text{TIR}},$$

**Table 5.** Properties of the disk and core in NGC 1365.

Parameter	Unit	Disk	Core
$L_{\text{TIR}}$	$[10^{10} L_\odot]$	9.8	8.7
$L_{\text{FUV}}^0$	$[10^{10} L_\odot]$	2.5	1.4
$M_G^1$	$[10^9 M_\odot]$	15.1	2.9 (3.4) <sup>2</sup>
$X_{\text{CO}}$	$X_0^3$	1.2 <sup>4</sup>	1.0 (1.2) <sup>2</sup>
$A_V$	[mag]	1.4	2.1
$A_{\text{FUV}}$	[mag]	3.5	5.3
$SFR_{\text{TIR}}$	$[M_\odot \text{yr}^{-1}]$	16.7	15.0
$SFR_{\text{FUV}}$	$[M_\odot \text{yr}^{-1}]$	7.0	3.9

**Notes.** <sup>(1)</sup> The total gas mass. <sup>(2)</sup> For a nonlinear (linear)  $Z$ - $D$  correlation. <sup>(3)</sup>  $X_0 = 10^{20} \text{ mol cm}^{-2} (\text{K km s}^{-1})^{-1}$ . <sup>(4)</sup> Calculated for the central  $204'' \times 164''$  area in the disk.

with  $L_{\text{TIR}}$  in  $L_\odot$ . The corresponding value for NGC 1365 is  $SFR_{\text{TIR}} \approx 16.7 M_\odot \text{yr}^{-1}$ .

Table 5 shows similar calculations for the core (central  $80''$ ). The extinction value agrees with Kristen et al. (1997), who derived  $A_V \sim 2$ – $2.5$  by means of the Balmer-decrement-ratio method.

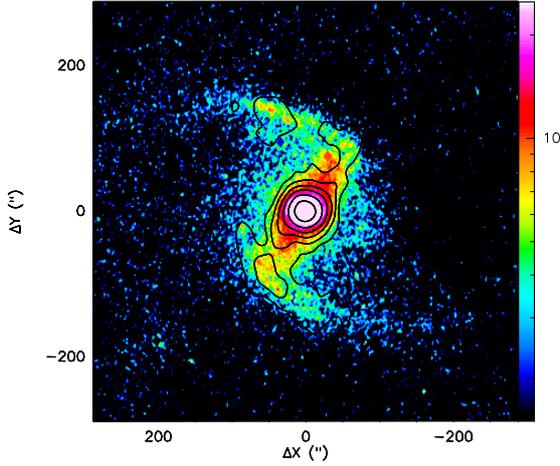

The molecular depletion timescale, defined as the molecular gas mass per star formation rate ( $M_{\text{H}_2}/SFR_{\text{FUV}}$ ), is about 1.2 Gyr in the central disk (the  $204'' \times 164''$  area). However, in the core, it is  $\approx 0.7$  Gyr and 0.9 Gyr for the nonlinear and linear  $Z$ - $D$  correlations, respectively. This is due to a more efficient star formation in the core than in the disk in NGC 1365.

#### 4.3. Gas flow in the bar

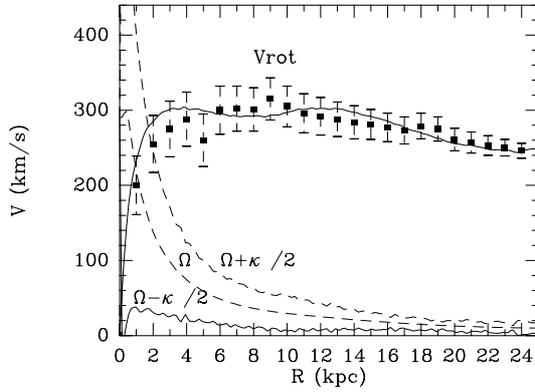

The central gas mass concentration obtained in Sect. 4.1 is evolving fast due to the gas flow in the bar. The correlation between the cold dust emission and a sum of the atomic and molecular gas emission (Sect. 3.1) already shows that the cold dust is a proxy for the gas in the disk. This additionally motivated us to investigate the gas flow in the bar based on the submm data as a tracer of the total gas. The strongly barred galaxy NGC 1365 is expected to experience gravity torques exerted by the bar on the gas disk, which could efficiently drive the gas toward the center through a reduction in its angular momentum.

We quantified the gas inflow in NGC 1365 by averaging the action of gravitational forces on the gas at different radii following Combes & Sanders (1981) and e.g. García-Burillo et al. (2005). The gravitational forces were computed to derive the underlying gravitational potential. It was assumed that the total mass budget is dominated by the stellar contribution and that the effect of gas self-gravity can be neglected. As a proxy of the stellar mass distribution, we used the  $H$ -band ( $1.5 \mu\text{m}$ ) image of the 2MASS data, which is only weakly affected by dust extinction or stellar population biases. After removing the foreground stars, the  $H$ -band image was deprojected (the position angle and inclination are listed in Table 1). The image was then resampled at  $1.5''$  per pixel. The deprojected  $H$ -band image is superposed on the dust contours in Fig. 8, showing a very good correspondence. This indicates that the molecular gas is well-aligned along the bar and spiral arms in NGC 1365. However, a slight phase shift can be noticed. The dust is shifted to the leading side of the bar: in Fig. 8, the contours of the dust in the bar are lemon-shaped elongated ellipsoids, whose extremities are shifted to smaller position angles with respect to the red-color bar on both sides, i.e., north and south of the center.

The deprojected  $H$ -band image was completed in the vertical dimension by assuming an isothermal plane model with

**Fig. 8.** Logarithmic contours of dust emission superposed on the near-infrared  $H$  image from 2MASS in logarithmic levels. Both images have been deprojected and rotated ( $50^\circ$  counterclockwise) such that the major axis is horizontal.

**Fig. 9.** Rotation curve and derived frequencies  $\Omega$ ,  $\Omega - \kappa/2$  and  $\Omega + \kappa/2$ , for NGC 1365, obtained from the  $H$ -band image, and a constant  $M/L$  ratio. The model rotation curve has been fitted to the data points compiled from  $H\alpha$  and HI data (see Zanmar Sanchez et al. 2008).

a constant scale height, equal to  $\sim 1/12$ th of the radial scale-length of the image. The potential was then derived by a Fourier transform method, assuming a constant mass-to-light ( $M/L$ ) ratio. The  $M/L$  value was selected to retrieve the observed rotation curve (given by Zánmar Sánchez et al. 2008, using  $H\alpha$  and HI data). Only a very light dark matter halo was added, of  $3 \times 10^{10} M_\odot$ , to better fit the rotation curve in the outer parts. The axisymmetric part of the model, fitted by parametric functions, was then derived to find the proper frequencies, as shown in Fig. 9.

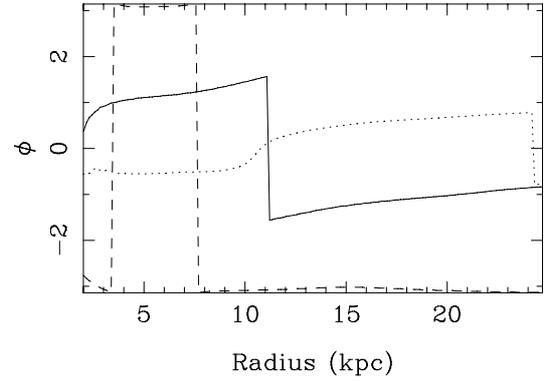

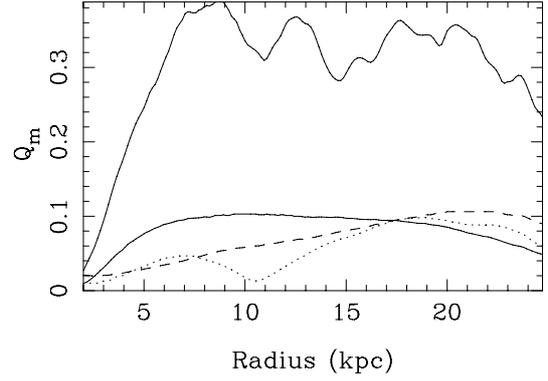

For the non-axisymmetric part, the potential  $\Phi(R, \theta)$  was then decomposed in the different  $m$ -modes,

$$\Phi(R, \theta) = \Phi_0(R) + \sum_m \Phi_m(R) \cos(m\theta - \phi_m(R)),$$

where  $\Phi_m(R)$  and  $\phi_m(R)$  represent the amplitude and phase of the  $m$ -mode.

Following Combes & Sanders (1981), we defined the strength of the  $m$ -Fourier component,  $Q_m(R)$ , as  $Q_m(R) = \frac{m\Phi_m}{R|F_0(R)|}$ , i.e., by the ratio between tangential and radial forces. The strength of the total non-axisymmetric perturbation is defined by

$$Q_T(R) = \frac{F_T^{\max}(R)}{F_0(R)},$$

**Fig. 10.** Strengths ( $Q_1$ ,  $Q_2$ ,  $Q_4$  and total  $Q_T$ ) and phases ( $\phi_1$ ,  $\phi_2$  and  $\phi_4$ ) of the  $m = 1$  (dash)  $m = 2$  (full line) and  $m = 4$  (dots) Fourier components of the stellar potential. The region of constant  $m = 2$  phase delineates the extent of the bar (note the phase jumps by  $2\pi/m$ ). The  $\phi$ -angles are measured from the  $+X$  axis in the counter-clockwise direction.

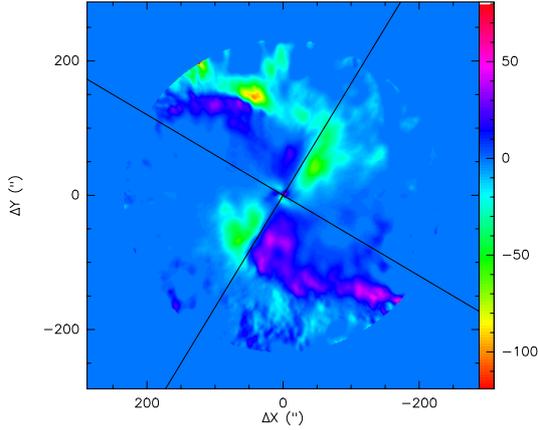

where  $F_T^{\max}(R)$  represents the maximum amplitude of the tangential force and  $F_0(R)$  is the mean axisymmetric radial force. This quantity is a measure of the strength of the bar. The variation of phase  $\phi_m$  with radius  $R$  distinguishes between bar and spiral arms. For example, the phase is constant for  $m = 2$  in the bar-like potential, hence the extent of the bar can be deduced where  $\phi_2(R) = \text{const.}$  (see Fig. 10). A main bar can be seen clearly, together with two spiral arms, with small pitch angle.

After calculating the 2D force field per unit mass ( $F_x$  and  $F_y$ ) from the derivatives of  $\Phi(R, \theta)$  on each pixel, the torques per unit mass were derived ( $t(x, y) = xF_y - yF_x$ ). This torque field, by definition, is independent of the present gas distribution in the plane.

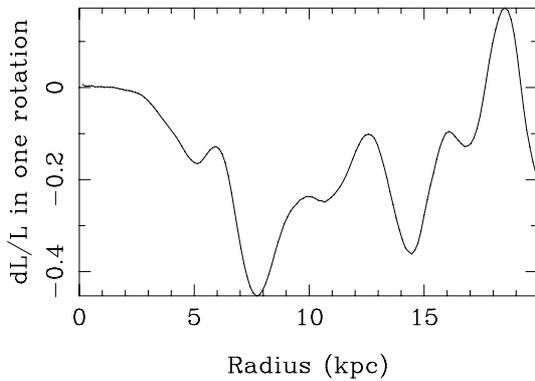

The next steps consist of using the torque field to derive the angular momentum variations and the associated flow timescales. We assume that the cold dust emission at each offset in the galaxy plane is a fair estimate of the probability of finding gas at this location at present. Hence, the gravitational torque map weighted by the gas surface density traced by the cold dust emission ( $t(x, y) \times \Sigma(x, y)$ , see Fig. 11) allows us to derive the net effect on the gas at each radius (the torque map is oriented according to the sense of rotation in the galactic plane).

To estimate the radial gas flow induced by the torques, we first computed the torque per unit mass averaged over the azimuth, using  $\Sigma(x, y)$  as the actual weighting function, i.e.,

$$t(R) = \frac{\int_\theta \Sigma(x, y) \times (x F_y - y F_x)}{\int_\theta \Sigma(x, y)}.$$

**Fig. 11.** Map of the gravitational torque ( $t(x,y) \times \Sigma(x,y)$ , as defined in text) in the center of NGC 1365. The derived torques change sign as expected, following a pattern of four quadrants. The orientation of quadrants follow the bar orientation in NGC 1365. In this deprojected picture, the major axis of the galaxy is oriented parallel to the horizontal axis.

**Fig. 12.** Radial variation of the torque, or more precisely, the fraction of the angular momentum transferred from/to the gas in one rotation.

By definition,  $t(R)$  represents the time derivative of the specific angular momentum  $L$  of the gas averaged azimuthally, i.e.,  $t(R) = dL/dt|_{\theta}$ . To derive non-dimensional quantities, we normalized this variation of angular momentum per unit time to the angular momentum at this radius and to the rotation period. We then estimated the efficiency of the gas flow with the average fraction of the gas specific angular momentum transferred in one rotation ( $T_{\text{rot}}$ ) by the stellar potential, as a function of radius, i.e., by the function  $\Delta L/L$  defined as

$$\frac{\Delta L}{L} = \frac{dL}{dt} \Big|_{\theta} \times \frac{1}{L} \Big|_{\theta} \times T_{\text{rot}} = \frac{t(R)}{L_{\theta}} \times T_{\text{rot}},$$

where  $L_{\theta}$  is assumed to be well-represented by its axisymmetric estimate, i.e.,  $L_{\theta} = R \times v_{\text{rot}}$ . The  $\Delta L/L$  radial distribution for NGC 1365 derived from the dust emission is displayed in Fig. 12.

Figure 11 shows that the derived torques change sign following a characteristic four-quadrant pattern. There is only one notable exception in the top quadrant of the diagram, where a patch of strong negative torque exists in the positive torque quadrant. These perturbations could be the consequence of infalling material, as noticed by Zánmar Sánchez et al. (2008). The gas location is mainly concentrated in the negative torque regions, as can be seen by comparison with Fig. 8, i.e., the majority of the gas in the bar is phase-shifted toward the leading edge, where the

torques are negative. The rotation sense in the galaxy is clockwise, and the spiral structure is trailing.

These results can be explained according to the classical scenario of angular momentum transfer in barred galaxies. The main bar of  $\sim 11$  kpc in radius ends slightly inside its co-rotation. This length obtained is longer than measurements using the I-band image of the galaxy ( $100'' \sim 9$  kpc Zánmar Sánchez et al. 2008). From Fig. 9, it is deduced that the bar pattern speed is  $\sim 26$  km/s/kpc. This value of the pattern speed indicates that there must be an inner Lindblad resonance (ILR) in the circum-nuclear region, which might correspond to the high gas concentration there, at  $r < 2$  kpc. In the central region, the stellar kinematics suggest the presence of a nuclear disk, as shown by Emsellem et al. (2001).

The gas flow toward the center is taken just in the act in NGC 1365 at the present epoch. Figure 12 shows that at 7 kpc radius, about 45% of the angular momentum is removed in one orbit, so the radial flow timescale is 300 Myr. Hence, the flow rate is relatively high due to the strong bar. This leads to a high concentration of molecular gas toward the center, which must be recent, since the center does currently not host a strong starburst.

These results indicate that the galaxy's AGN (Seyfert 1.5) is fueled by the present gas flow. However, it is not possible to conclude unambiguously whether the gas is stalled at the inner Lindblad resonance of the main bar or is still driven inward due to a nuclear bar, because of lack of spatial resolution.

There is a good correspondence between the regions of strongest (positive) torques (Fig. 11) and where ordered magnetic fields are strongest in NGC 1365 (Beck et al. 2005). This furthermore shows that ordered magnetic fields (traced by polarized radio emission) are signatures of non-axisymmetric gas flows and hence angular momentum transfer.

## 5. Summary

We produced the first large-scale map of the giant barred galaxy NGC 1365 at  $870 \mu\text{m}$  using the Large APEX Bolometer Camera at  $20''$  resolution. The submm map exhibits strong emission from the core and the bar, similar to molecular gas traced by CO emission, as well as the large-scale emission from the spiral arms, similar to HI emission. We investigated possible origins of this emission and performed a dust SED analysis, leading to estimates of the dust mass and total infrared luminosity. Assuming that the cold dust, presented by the submm emission, traces the total neutral gas in the galaxy, we also estimated the gas mass, the  $X_{\text{CO}}$  conversion factor (taking into account the variation in metallicity), and the star formation rate in the disk and the core (central  $80''$ ) of NGC 1365. The most important findings of this study are summarized as follows:

- The thermalized dust SED in NGC 1365 can be best fitted by a two-component modified black-body model, with temperatures of 20 K and 40 K for cold and warm dust, respectively. The cold dust represents about 98% of the total dust content in this galaxy.
- Comparing the gas mass obtained from the dust mass measurements with that based on the CO and HI observations, we derived an average CO-to- $\text{H}_2$  conversion factor of  $X_{\text{CO}} \approx 1.2 \times 10^{20} \text{ mol cm}^{-2} (\text{K km s}^{-1})^{-1}$  for the central disk (limited in a  $204'' \times 164''$  area). This value is the same (20% higher than) in the core, taking into account the metallicity variation and assuming a linear (nonlinear) correlation between the gas-to-dust mass ratio and the metallicity.

- The central gas mass concentration reduces from  $\sim 30\%$  to about  $20\%$  taking into account metallicity variations.
- Integrating the dust SED, the total IR luminosity is  $L_{\text{TIR}} = 9.8 \times 10^{10} L_{\odot}$ , leading to a dust-enshrouded star formation rate of  $SFR_{\text{TIR}} \approx 16.7 M_{\odot} \text{yr}^{-1}$  in NGC 1365. The star formation efficiency is found to be higher in the core than in the disk by  $\geq 50\%$ .
- The bar exhibits an east-west asymmetry in the  $870 \mu\text{m}$  emission similar to that in the  $6 \text{ cm}$  radio continuum emission. This leads to an asymmetry in the distributions of the dust properties: The eastern bar is colder and heavier than the western bar by more than a factor of 4.
- Apart from the similar distribution of the radio and submm emission along the bar and spiral arms, their correlation decreases by decreasing the spatial scale. This could indicate different origins of the cold dust emission (e.g., heating by a diffuse ISRF) and the radio continuum emission (e.g., CREs propagated along the magnetic fields) instead of massive star formation.
- Based on the cold dust map, we deduced that the gas in NGC 1365 flows toward the center on a timescale of  $300 \text{ Myr}$ . About  $45\%$  of the angular momentum is removed in one orbit at  $7 \text{ kpc}$  radius.

*Acknowledgements.* We are grateful to Aa. Sandqvist for kindly providing us with the CO(3–2) data. We thank A. Belloche for useful discussions on LABOCA data reduction. F.S.T. acknowledges the support by the DFG via the grant TA 801/1-1.
