ABSTRACT

Context. The formation and evolution of the Milky Way bulge is still largely an unanswered question. Some of the most essential observations needed for its modelling are the metallicity distribution and the trends of the α elements, as measured in stars. While bulge regions beyond $R \gtrsim 50$ pc of the centre have been targeted in several surveys, the central part has escaped a detailed study due to the extreme extinction and crowding. The abundance gradients from the centre are, however, of large diagnostic value.

Aims. We aim at investigating the Galactic centre environment by probing M giants in the field by avoiding supergiants and cluster members.

Methods. For nine field M-giants in the Galactic centre region, we have obtained high- and low-resolution spectra observed simultaneously with CRIRES and ISAAC on UT1 and UT3 of the VLT. The low-resolution spectra provide a means of determining the effective temperatures, and the high-resolution spectra provide detailed abundances of Fe, Mg, Si, and Ca.

Results. We find a metal-rich population at $[\text{Fe}/\text{H}] = +0.11 \pm 0.15$ and a lack of the metal-poor population, which is found further out in the bulge, corroborating earlier studies. Our $[\alpha/\text{Fe}]$ element trends, however, show low values, by following the outer bulge trends. A possible exception of the $[\text{Ca}/\text{Fe}]$ trend is found and needs further investigation.

Conclusions. The results of the analysed field M-giants in the Galactic centre region exclude a scenario with rapid formation, in which SNIe played a dominated role in the chemical enrichment of the gas. The high metallicities with low α -enhancement seems to indicate a bar-like population that is, perhaps, related to the nuclear bar.

Key words. Galaxy: bulge – Galaxy: structure – Galaxy: stellar content – stars: fundamental parameters – stars: abundances – infrared: stars

1. Introduction

The formation of the Milky Way bulge remains a puzzle. Abundance ratios of key elements, as measured in bulge stars of different populations and at different locations, can set empirical constraints on the formation and evolution of the bulge (see e.g. Silk & Wyse 1993; Matteucci 2012). While more and more detailed¹ elemental abundance determinations of stars in the intermediate and outer bulge (such as Baade's window) have emerged, the study of detailed abundances in bulge regions within projected distances of $R \lesssim 50$ pc of the Galactic centre has been prevented until recently due to regions of high extinction (see e.g. Schultheis et al. 2009) and the lack of sensitive high-resolution IR spectrographs. Extinction of 10–30 magnitudes in the V band can, however, be overcome by investigating stars in the K band, where the extinction is a factor of 10 lower (Cardelli et al. 1989).

The abundance gradient with its latitude is an important diagnostic of the properties and formation history of the bulge (Grieco et al. 2012). While the outer bulge shows evidence for a metallicity gradient (see e.g. Hill et al. 2011), whether it is

due to a true gradient in a population or the relative change in proportion of two or more populations, only a few studies have investigated abundance gradients in the inner bulge. Rich et al. (2007) studied detailed abundances of M-giants in a field at $(l, b) = (0^\circ, -1^\circ)$, while Rich et al. (2012) studied fields located at lower latitudes, $(l, b) = (0^\circ, -1.75^\circ)$ and $(l, b) = (1^\circ, -2.65^\circ)$. They find a iron abundances of $[\text{Fe}/\text{H}] = -0.2 \pm 0.1$ for all three fields, indicating a lack of any major vertical abundance-gradient. A detailed abundance study in the Galactic centre region itself is missing. Until now, most of the chemical abundance studies were limited to luminous supergiants, which make the abundance analysis difficult due to their complex and extended stellar atmospheres. Carr et al. (2000), Ramírez et al. (2000), and Davies et al. (2009) analysed high-resolution spectra of supergiant stars in the Galactic centre region, indicating metallicities of near solar metallicity. A similar conclusion was obtained by Najarro et al. (2009) by analysing two luminous blue variables. Cunha et al. (2007) derived abundances of a few M giants in the Central Cluster and found a metallicity of $[\text{Fe}/\text{H}] = +0.14 \pm 0.06$ with enhanced $[\text{O}/\text{Fe}]$ and $[\text{Ca}/\text{Fe}]$ abundances of +0.2 and +0.3, respectively, indicating that SN II played a dominant role in the chemical enrichment of the gas for this cluster.

Here, we present an analysis based on near-IR, high-resolution spectra of nine M-giant stars located in the Galactic centre, which are only 2.5–5.5 arcmin north of the very centre of the Milky Way and correspond to a projected galactocentric distance of 5–10 pc. Our goal is to obtain the metallicity

¹ At spectral resolutions of $R = \lambda/\Delta\lambda \gtrsim 50\,000$.

Fig. 1. Dereddened $(H - K)_0$ vs. K_0 diagram of the Galactic centre field using the data of Nishiyama et al. (2009) and the extinction map of Schultheis et al. (2009). In red, we indicate our selected M giants. The blue lines show the Padova isochrones with $Z = 0.008$, $\tau = 1$ Gyr (solid line), and $\tau = 10$ Gyr (dashed line), while the green line is at $Z = 0.06$ and $\tau = 10$ Gyr. The arrow on the top right shows the extinction vector of $A_K = 1$ mag (Nishiyama et al. 2009).

distribution and the corresponding α -element abundances (Mg, Si, Ca) of Galactic centre stars.

2. Observations

When selecting our Galactic centre stars, we used the Nishiyama et al. (2009) dataset and dereddened our sources using the extinction map of Schultheis et al. (2009). Due to the high extinction, we selected field red giants (avoiding cluster and supergiant stars) based on the dereddened $(H - K)_0$ vs. K_0 diagram covering the full $(H - K)_0$ colour range to avoid any selection bias. Figure 1 shows the dereddened CMD together with our selected M giants superimposed by the Padova isochrones with $Z = 0.008$ and $Z = 0.06$ and ages of 1 Gyr and 10 Gyr. Unfortunately the $H - K$ colour is very insensitive to the age of population, making it impossible to constrain the age and the mass of our stars. In addition, to ensure that our sources are located in the Galactic centre itself, we used the high-resolution, 3D interstellar-extinction maps of the Galactic bulge of Schultheis et al. (2014), who used data set from the VISTA Variables in The Via Lactea (VVV) public survey, in distance bins of 500 pc. We placed our stars on these 3D extinction plots and found that our stars lie between 7–9 kpc, which rules out any possible foreground contamination. We are, therefore, confident that all our “bulge” stars presented in Table 1 belong to the Galactic centre. The six local thick-disk stars, the thin-disk star BD-012971, and the reference star α Boo, which we also analyse in the same way as for the Galactic centre stars, are also given in Table 1.

On 27–29 June 2012, we observed the M giants close to the Galactic centre and the disk stars given in Table 1 in the near-infrared with the Very Large Telescope (VLT). Every star was observed both using the low-resolution spectrometer ISAAC (Moorwood et al. 1998) and the high-resolution spectrometer

Fig. 2. An example of a finding chart from our observing run with CRIRES at the VLT. The target star, GC22, shown here, is one of our nine M giants in the Galactic centre field with stars only 2.5–5.5' north of the very centre of the Milky Way. The left panel is an image in the R band at 660 nm (which is observed with the ESO Schmidt telescope and is from the VO-Paris Data Centre in Paris), while the right one shows the very same field but at 2.2 μm (a UKIDSS K-band image from DR9, see Lawrence et al. 2013). The large difference in appearance is caused by the massive dust extinction towards this field, which prohibits optical spectroscopy. The inset shows our K band spectrum of GC22, from which we can derive the Fe, Mg, Si, and Ca abundances. The adaptive optics (AO) system works in the R band.

CRIRES (Käufl et al. 2004), mounted on UT3 and UT1, respectively, of the VLT. The ISAAC spectrometer with a spectral resolution of $R \sim 1000$ and a wavelength range between 2.00–2.53 μm was used to determine the effective temperature of our stars (for details, see Schultheis & Ryde, in prep.). Following standard procedures (Smoker 2007), CRIRES uses nodding on the slit and jittering to reduce the sky background and the adaptive optics (AO) MACAO system to enhance the amount of light captured by the slit. Due to the large crowding in our field (see Fig. 2), special care had to be taken of the orientation of the 40'' long slit. For the CRIRES observations, we used a 0'.4 wide slit ($R \sim 50\,000$), and a standard setting ($\lambda_{\text{vac}}^{\text{ref}} = 2105.5$, order = 27) with an unvignetted spectral range covering 20 818–21 444 \AA with three gaps (20 \AA) between the four detector arrays. We aimed at a signal-to-noise ratio per pixel of 50–100 depending on the brightness of the stars. When selecting our stars, an instrumental constraint was set by the requirements that the wavefront sensing is done in the R band. For optimal AO performance, the guide star has preferably to be brighter than $R = 14$ and within 15'' of the science object. The reductions of the CRIRES observations were done by following standard recipes (Smoker et al. 2012) using Gasgano (Klein Gebbinck et al. 2007). Subsequently, we used IRAF (Tody 1993) to normalise the continuum, eliminate obvious cosmic hits, and correct for telluric lines (with telluric standard stars). Two examples of CRIRES spectra are shown in Fig. 3.

3. Analysis

The derived stellar parameters of our stars are given in Table 1. Ramirez et al. (1997), Ivanov et al. (2004), and Blum et al. (2003) studied the behaviour of the ^{12}CO band-head situated at 2.3 μm with low-resolution K-band spectra and found a

Notes. ^a K magnitude of the Galactic centre stars from Nishiyama (priv. comm.) and of the disk stars from 2MASS. ^b The fundamental parameters of α Boo are taken from Ramírez & Allende Prieto (2011). ^c Identification number from the Southern Proper-Motion Program (SPM III Girard et al. 2004), as given in Monaco et al. (2011).

Fig. 3. Spectra of wavelength regions covering a few of the lines used for the abundance determination. Other features not marked are mostly due to CN. The top spectrum is from the Arcturus atlas (Hinkle et al. 1995), the middle one is of the thick disk star HD 787, and the bottom spectrum is of the Galactic centre star GC44. The flat regions of the HD 787 spectrum at 2.0955 and 2.0963 μm are due to the elimination of cosmic hits.

remarkably tight relation between the equivalent width and the effective temperature for M giants. We therefore analysed our ISAAC spectra guided by their work. The analysis of our observations of additional calibration stars with known effective temperatures leads to a tight relation between T_{eff} and the CO band intensity for $3200 < T_{\text{eff}} < 4000$ (Schultheis & Ryde, in prep.). The typical root-mean-square error is on the order of 100 K. We

were able to apply this method for all but three of our stars. For the three warmer thick-disk stars, which have temperatures beyond the bound of our temperature calibration (the reason being that the CO-band strength weakens and is virtually unmeasurable), we had to resort to the temperature determination of Monaco et al. (2011), which also was the source of our thick disk stars. These authors determined the effective temperatures

by imposing a common Fe abundance from Fe I lines of different excitation energies.

The surface gravities of our Galactic centre stars were determined in a similar way as [Zoccali et al. \(2008\)](#) by adopting a mean distance of 8 kpc to the Galactic centre, $T_{\odot} = 5770$ K, $\log g_{\odot} = 4.44$, $M_{\text{bol},\odot} = 4.75$, and $M_{\star} = 1.0 M_{\odot}$. The H and K s band photometry from the VVV survey ([Minniti et al. 2010](#)), extinction values from [Schultheis et al. \(2009\)](#), and the bolometric corrections from [Houk et al. \(2000\)](#) have been used. The surface gravity of all our disk stars are taken from the [Monaco et al. \(2011\)](#) determination, except the thin disk star BD-012971, whose surface gravity was taken from [Rich & Origlia \(2005\)](#).

Our CRIRES spectra were analysed using the software Spectroscopy Made Easy (SME, [Valenti & Piskunov 1996, 2012](#)) with a grid of MARCS spherical-symmetric, local thermodynamic equilibrium model atmospheres ([Gustafsson et al. 2008](#)). The SME is a spectral synthesis program that uses a grid of model atmospheres in which it interpolates for a given set of fundamental parameters. The program then derives an abundance from an observed spectral line by iteratively synthesising spectra, which are compared to the observations by calculating the χ^2 . The program then finds the best fit with the abundance as a free parameter by minimising the χ^2 . For details, see [Valenti & Piskunov \(1996\)](#)

An atomic-line list based on an extraction from the VALD database ([Piskunov et al. 1995](#)) is used. Due to inaccurate atomic data, atomic lines were fitted to the solar intensity spectrum of [Livingston & Wallace \(1991\)](#) by our determination of astrophysical $\log gf$ values for, most importantly, Fe, and Si lines. The metallicity and Si abundance we derive for α Boo are within 0.05 dex of the values determined by [Ramírez & Allende Prieto \(2011\)](#). However, since the Ca lines are very weak in the solar spectrum and the Mg lines are impossible to fit, we have determined their line strengths, such that they fit the Arcturus flux spectrum of [Hinkle et al. \(1995\)](#) with a Mg and Ca abundance from [Ramírez & Allende Prieto \(2011\)](#). These values include $[\text{Mg}/\text{Fe}] = 0.37$ and $[\text{Ca}/\text{Fe}] = 0.11$. In the syntheses, we have also included a line list of the only molecule affecting this wavelength range, namely CN ([Jørgensen & Larsson 1990](#)).

The microturbulence, χ_{micro} , is difficult to determine empirically but is nevertheless important for the spectral syntheses, affecting saturated lines. We have chosen to use a typical value found in detailed investigations of red giant spectra in the near-IR by [Tsuji \(2008\)](#). The microturbulence is more than a km s^{-1} larger when determined from near-IR spectra compared to optical ones. We have, therefore, chosen a generic value of $\chi_{\text{micro}} = 2.0 \text{ km s}^{-1}$, as seen in [Cunha et al. \(2007\)](#). Furthermore, to match our synthetic spectra with the observed ones, we also convolve the synthetic spectra with a “macroturbulent” broadening, χ_{macro} , which takes the macroturbulence of the stellar atmosphere and instrumental broadening into account. These were determined by matching the prominent Si line at 20917.1 \AA and the two Al lines at 21093.08 \AA and 21163.82 \AA .

The iron (giving the metallicity), Mg, Si, and Ca abundances were then determined by χ^2 minimisation between the observed and synthetic spectra for six to nine Fe, two to six Si, one to four Ca, two Mg, and typically ten CN lines, depending on star. These abundances are presented in [Table 2](#), and the synthesised spectra are shown with the observed ones for a few typical stars in [Fig. 3](#) and for all our spectra in [Figs. 8 and 9](#).

The uncertainties in the determination of the abundance ratios for typical uncertainties in the stellar parameters are all

Fig. 4. Sensitivity of typical spectral lines for a change of the abundance of Fe, Si, Ca, and Mg, respectively. The red spectrum shows the best fit and the blue ones show the spectra for a change of ± 0.2 dex in abundance. The star in this case is GC28.

modest within 0.1 dex (see [Schultheis & Ryde, in prep.](#)), as seen in [Table 3](#). We note, specifically the relative small uncertainty in the abundance ratio due to a variation of the microturbulence parameter, ξ_{micro} . This demonstrates that the lines are not badly saturated, and therefore, they should be sensitive to the abundances. In [Fig. 4](#) the sensitivity of the spectral lines to a change of 0.2 dex in abundance is shown. The lines are obviously useful for an abundance determination for these stars.

Fig. 5. Abundances trends of $[Mg/Fe]$, $[Si/Fe]$, and $[Ca/Fe]$, as well as the mean of these. Red dots mark our Galactic centre stars; blue dots our local disk star measurements, and magenta triangles mark the $[Ca/Fe]$ measurements (with uncertainties of ± 0.15 dex) of M giants (with $M_{\text{bol}} > -5.5$) in the Galactic centre by Cunha et al. (2007). The black small dots are the abundances determinations based on micro-lensed dwarfs by Bensby et al. (2013).

4. Results and discussion

Figure 5 shows the abundance ratio trends for Mg, Si, and Ca, as derived from our Galactic centre stars in red and our local thick-disk stars in blue. In black we show the micro-lensed bulge dwarfs from the outer bulge ($|b| > -2^\circ$), as determined by Bensby et al. (2013). Within uncertainties, our thick disk trend and the Mg and Si trends follow the outer bulge trends with low values of $[\alpha/Fe]$ at $[Fe/H] > -0.2$, although the Galactic centre stars show a much more narrow spread in $[Fe/H]$. Our $[Ca/Fe]$ in the Galactic centre show a higher trend than the outer bulge stars, which actually agree with Cunha et al. (2007) and one of the outer bulge stars. With random uncertainties being of the order of 0.1 dex, this trend is significantly higher. This difference between Mg, Si, and Ca is not expected theoretically (Matteucci, priv. comm.), and systematic uncertainties could be important. To reduce random and systematic uncertainties, we therefore also plot a mean of the three trends in the lower right panel. From this plot, it is evident that we cannot claim that our $[\alpha/Fe]$ trend in the Galactic centre is particular compared to the outer bulge. However, more investigations on the $[Ca/Fe]$ trend is needed to verify its high trend in the Galactic centre.

Figure 6 shows the tight metallicity distribution with $[Fe/H] = +0.11 \pm 0.15$ and the total spread in metallicities of 0.41 dex. Our mean metallicity distribution is close to that found by Cunha et al. (2007), as indicated by the red histogram. However, our total spread is broader than theirs of 0.16, but it is much smaller than that found typically for giants in the Galactic bulge (see e.g. the metallicity distributions of Zoccali et al. 2003; Fulbright et al. 2006; Hill et al. 2011; and Ness et al. 2013). The most striking feature is clearly the absence of the metal-poor population with no stars below -0.1 dex in $[Fe/H]$ that agree with the work of Cunha et al. (2007). This strengthens the argument of a specific population different to those of the bulge. Fields in the inner bulge located at $b = -1^\circ$ (Rich et al. 2007) (magenta) and $b = -1.65^\circ$ (green), as well as $b = -2.65^\circ$ (blue)

Fig. 6. Histogram of our metallicities in black with a mean of $[Fe/H] = 0.11$ and a standard deviation of 0.15. The red histogram shows the metallicities of the Galactic centre giants of Cunha et al. (2007). For comparison we show the field of Rich et al. (2007) located at $(l, b) = (0^\circ, -1^\circ)$ in magenta, the field at $(0^\circ, -1.75^\circ)$ in green (Rich et al. 2012), and the field at $(1^\circ, -2.65^\circ)$ in blue (Rich et al. 2012).

(Rich et al. 2012) have mean metallicities at $[Fe/H] = -0.22$, $[Fe/H] = -0.16$, and $[Fe/H] = -0.21$, which are ~ 0.3 dex lower than our metallicities in the Galactic centre (see Fig. 6).

In Fig. 7, we show our abundance-ratio trends again but now with those of the inner bulge fields, as derived by Rich et al. (2007) and Rich et al. (2012), which are shifted to the solar scale

Fig. 7. Same abundance ratio trends as in Fig. 5 but with the addition of the trends derived from the M giants in the fields located at $(l, b) = (0^\circ, -1^\circ)$ of Rich et al. (2007) denoted by green asterisks, and at $(0^\circ, -1.75^\circ)$ and $(1^\circ, -2.65^\circ)$ of Rich et al. (2012), denoted by green pluses and crosses, respectively. Furthermore, the mean abundance ratios of the two populations of Terzan 5 at $(l, b) = (3.8^\circ, +1.7^\circ)$ from Origlia et al. (2011) are shown with green squares. For the inner globular cluster Liller 1 at $(l, b) = (354.8^\circ, -0.2^\circ)$, Origlia et al. (2002) find $[\text{Fe}/\text{H}] \sim -0.3$ and $[\alpha/\text{Fe}] \sim +0.3$, which fits nicely with the general trend of the Rich et al. (2007, 2012) field stars.

of Grevesse et al. (2007) and used in our analysis. It is clear again that our metallicities are generally higher with a small overlap. Although there are certainly systematic uncertainties that could make a comparison difficult, it is worth discussing; compared to the large difference in the metallicities of the stars, the $[\alpha/\text{Fe}]$ abundance ratios agree quite well, although our values tend to be of the order of 0.1 dex lower. It is interesting to note that the $[\text{Ca}/\text{Fe}]$ versus $[\text{Fe}/\text{H}]$ trend seem to show higher values from all the inner fields compared to the micro-lensed dwarf sample.

In Fig. 7, we also plot the mean abundances of the two populations in the complex globular cluster Terzan 5 located in the inner bulge, $(l, b) = (3.8^\circ, +1.7^\circ)$, as derived by Origlia et al. (2011, in green squares in Fig. 7). It is interesting that the metal-rich population at $[\text{Fe}/\text{H}] = +0.27$ shows a solar $[\alpha/\text{Fe}]$, which is similar to our Galactic centre population at that metallicity. However, in contrast to Terzan 5, we clearly miss a distinct metal-poor population. Origlia et al. (2011) suggest that there might be a common origin and evolution of field populations in the bulge and Terzan 5, the latter perhaps being a relic building block of the bulge.

Thus, we see a metal-rich but low α -enhanced population in the Galactic centre. This finding would rule out a scenario that SNIIE played the dominate role in the chemical enrichment of the gas associated with a rapid formation. Again, we find a significant difference compared to the high α -enhanced values of Rich et al. (2007, 2012), indicating that the Galactic centre population is different. The metal-rich population of Terzan 5 shows similarities to our Galactic centre population.

The presence of a double bar in our Galaxy, which can be observed in external galaxies (Laine et al. 2002; Erwin 2004) is still questioned. Alard (2001), Nishiyama et al. (2005), and Gonzalez et al. (2011) claim that there is an inner structure that is distinct to the large-scale Galactic bar with a different orientation angle, which could be associated with a secondary, inner bar. On the other hand, Gerhard & Martinez-Valpuesta (2012) can

explain this inner structure by dynamical instabilities from the disk without requiring a nuclear bar. The metal-rich metallicities with low α -enhancement that we derive for the Galactic centre stars in our study presented here seems to indicate a bar-like population (as seen by Babusiaux et al. 2010 for the main bar), which is most likely related to the nuclear bar.

Detailed chemical evolution models for the central 200 pc of the Galactic centre, which takes the increased star formation history, star formation efficiency, various gas-infall and gas outflow mechanisms, including the possible role of the nuclear bar, into account are unfortunately missing. Detailed chemical/dynamical modelling of this extreme part of our Galaxy is needed for a proper interpretation of the observables but also for bulge formation models in general.

Acknowledgements. The anonymous referee is thanked for valuable suggestions that improved the paper. Dr. Stefan Uttenhaller is acknowledged for assisting in the preparation of the CRIRES observations. Dr. Francesca Matteucci is thanked for enlightening discussions and Dr. David Nataf for commenting on the paper. Nils Ryde is a Royal Swedish Academy of Sciences Research Fellow supported by a grant from the Knut and Alice Wallenberg Foundation, and acknowledges support from the Swedish Research Council, VR (project number 621-2008-4245), Funds from Kungl. Fysiografiska Sällskapet i Lund. (Stiftelsen Walter Gyllenbergs fond and Märta och Erik Holmbergs donation). This publication makes use of data products from the Two Micron All Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Center/California Institute of Technology, funded by the National Aeronautics and Space Administration and the National Science Foundation. This work has made use of the VALD database, operated at Uppsala University, the Institute of Astronomy RAS in Moscow, and the University of Vienna.
