ABSTRACT

Context. Balmer absorption is a rare phenomenon in active galactic nuclei (AGNs). So far, only seven Balmer-absorption AGNs have been reported in the literature.

Aims. We here report the identification of SDSS J112611.63+425246 as a new Balmer-absorption AGN through our spectral analysis and study the kinematics of its narrow emission-line region (NLR).

Methods. We modeled the continuum by a linear combination of a starlight component, a power law from the central AGN, and the emission from the FeII complex. After subtracting the modeled continuum, each emission or absorption line profile is a sum of multi-Gaussian functions. All the line shifts were determined with respect to the modeled starlight component.

Results. By using the host starlight as a reference for the local system, both Hα and Hβ show AGN absorptions with a blueshift of ∼300 km s\(^{-1}\). We identify a strong anticorrelation between the inferred velocity shifts and the ionization potential for various narrow emission lines, which suggests a stratified NLR kinematics. A de-accelerated outflow is implied for the inner NLR gas, an accelerated inflow for the outer NLR gas. This complicated NLR kinematics additionally implies that AGN narrow emission lines, even for the low-ionized lines, might not be a reliable substitute for the velocity of the local system.

Key words. galaxies: active – galaxies: peculiar – galaxies: individual: SDSS J112611.63+425246.4

1. Introduction

The feedback from a central active galactic nucleus (AGN) is now believed to be a potential key ingredient in understanding the coevolution of the AGN and its host galaxy. A widely accepted scenario is that the growth of a supermassive black hole (SMBH) regulates host star formation by sweeping out circumnuclear gas (e.g., Silk & Rees 1998; Somerville et al. 2008; Hirschmann et al. 2013; Di Matteo et al. 2006; Granato et al. 2004; Croton et al. 2006).

The evidence of outflow from an AGN on various scales has been identified in multiwavelength bands from radio to X-ray (see Veilleux et al. 2005 and Fabian 2012 for reviews). AGN outflow has been diagnosed by the blueshifted absorption lines. Although the narrow absorption lines with width ≤500 km s\(^{-1}\) are frequently identified in type I AGNs in UV and X-ray (∼50%, e.g., Hamann & Sabra 2004), Balmer-absorption AGNs are still rare cases. So far, only seven Balmer-absorption AGNs are reported in the literature. They are NGC 4151 (Hutching et al. 2002), SDSS J0839+3805 (Aoki et al. 2006), SDSS J1259+1213 (Hall 2007), SDSS J1024+4500 (Wang et al. 2008), SDSS 1723+5553 (Aoki 2010), LBQS 1206+1052 (Ji et al. 2012), and SDSS J2220+0109 (Ji et al. 2013). Because of their rarity, the identification of more Balmer-absorption AGNs is essential for subsequently studying the nature of the AGN Balmer absorption-line region (BAR).

First, recent studies pointed out that rigorous conditions with a high hydrogen column density of ∼10\(^{11-22}\) cm\(^{-2}\) are required to excite neutral hydrogen atoms to \(n = 2\) shell by Ly\(\alpha\) resonant pumping (e.g., Ji et al. 2012). Second, the Balmer absorption lines can be used as a diagnostic for the kinematics of the natural gas around central AGNs.

In this paper, we report a detailed spectroscopic analysis for SDSS J112611.63+425246.4 (hereafter SDSS J1126+4252 for short\(^1\)), which allows us to identify the object as a new Balmer-absorption AGN and to identify a stratified kinematics in its narrow emission-line region (NLR) with respect to the systematic velocity determined from the host galaxy.

2. Spectral analysis

The optical spectrum of SDSS J1126+4252 was extracted when we carried out a systematic X-ray and optical spectral analysis on the XMM-Newton 2XMMi/SDSS-DR7 catalog that was originally cross-matched by Pineau et al. (2011). The catalog contains a total of more than 30,000 X-ray point-like sources (with an X-ray position accuracy ≤5\(\prime\)\(\prime\)) that have an SDSS-DR7 optical counterpart with an identification probability higher than 90%. The spectrum of the object was taken by the SDSS dedicated 2.5 m wide-field telescope on February 27, 2004.

The one-dimensional spectrum of the object was analyzed with the IRAF\(^2\) package, including Galactic extinction

\(^1\) This object has been analyzed by Hu et al. (2008) in their large type I AGN sample. The Balmer absorptions and starlight component were, however, not taken into account in their spectral modeling.

\(^2\) IRAF is distributed by the National Optical Astronomy Observatory, which is operated by the Association of Universities for Research in Astronomy, Inc., under cooperative agreement with the National Science Foundation.
predetermined through cross-correlation method before each intercept for the regions with strong emission lines. The line width of over the rest-frame wavelength range from 3700 to 7000 Å, except for the two narrow Balmer absorptions which are displayed in ordinals below the observed spectrum. All the spectra are shifted vertically by an arbitrary amount for visibility.

The total light spectrum at the rest frame is displayed in Fig. 1. It shows that there is significant contamination from its host galaxy. To isolate the AGN emission-line spectrum, we modeled the continuum by a linear combination of a power law continuum, an FeII complex template, and the seven eigenvalues of the host galaxy. To isolate the AGN emission-line spectrum, we modeled the continuum by a linear combination of a power law continuum, a starlight component, and the seven eigenspectra of the host galaxy. The adopted FeII template was taken from the Galactic reddening map of Schlegel, Finkbeiner, and Davies (Schlegel et al. 1998), by assuming an $R_V = 3.1$ extinction law of the Milky Way (Cardelli et al. 1989). The spectrum was then de-redshifted to its rest frame, along with the flux correction due to the relative effect basing upon the measured redshift provided by the SDSS pipelines. The object has a nominal redshift of $z = 0.15592 \pm 0.00121$, which corresponds to a velocity uncertainty of 363 km s$^{-1}$.

The object has a nominal redshift of $z = 0.15592 \pm 0.00121$, which corresponds to a velocity uncertainty of 363 km s$^{-1}$.

The continuum-subtracted emission-line spectrum is shown by the top curve. Below the emission-line spectrum, the modeled continuum is overplotted by the red curve on the observed spectrum. The modeled continuum is obtained by a linear combination of a starlight component, a power law continuum from the AGN, and the emission from the FeII complex, which are displayed in ordinals below the observed spectrum. All the spectra are shifted vertically by an arbitrary amount for visibility.

3. Results and discussions

The measured line properties are tabulated in Table 1. The reported flux of the H$\alpha$ broad emission (and the [OIII] λ5007 line emission) is the sum of the two fitted components. The quoted line width and velocity shift is based on the fitted narrow peak for the [OIII] line. The flux of the FeII blends (FeII λ4570) was measured in the rest-frame wavelength range from 4434 to 4684 Å, which results in a parameter of RF of 0.64 ± 0.20. RF is defined as the flux ratio between the FeII λ4570 and H$\beta$ broad component. All the reported line widths were not corrected for the intrinsic instrument resolution of $7.0_{{\text{inst}}} \approx 65$ km s$^{-1}$. Because of the evident contamination of the starlight in the integrated spectrum, we calculated the reported line shifts with respect to the modeled starlight component$^1$: $\Delta \nu = \Delta \nu_{\text{line}} - \Delta \nu_{\text{host}}$, where $\Delta \nu_{\text{line}}$ and $\Delta \nu_{\text{host}}$ are the modeled velocity shifts with respect to the nominal redshift for a given emission or absorption line and for the host galaxy. A negative value of $\Delta \nu$ corresponds to a blueshift, a positive value to a redshift.

All the uncertainties reported in the table (except for the FWHM of H$\alpha$) only include the errors at 1σ significance level resulting from the $\chi^2$ minimizations. The error of the FWHM of H$\beta$ was obtained from a statistics on the multiple measurements.

$^3$ Hu et al. (2008) used the [OIII] λ5007 line as a reference and found that the [OII] emission line might be a more reliable reference than either [OIII] or H$\beta$. Our results are consistent with their measurements if the [OIII] line is used as a reference.
3. Balmer absorption lines

We argue that the observed blueshifted Balmer absorption lines most likely result from an outflow from the central engine, and not from the host galaxy. The starlight component was properly removed from the observed integral spectrum, as described above. Moreover, the lack of a strong Balmer break enabled us to conclude that the observed Balmer absorptions originate from a post-starburst galaxy with strong Balmer absorptions (e.g., Brotherton et al. 1999; Wang & Wei 2006). In interpreting of the Balmer absorptions in AGNs, the intrinsic equivalent width (EW) depends on whether the absorbing gas covers the BLR or not (e.g., de Kool et al. 2001). The latter scenario is favored for the XMM-Newton serendipitous source catalog (XMMSSC) and the X-ray bands. The object is a common source in the second optical Monitor serendipitous UV source survey above. Moreover, the lack of a strong Balmer break enabled us to exclude the observed Balmer absorptions from a post-starburst galaxy with strong Balmer absorptions (e.g., de Kool et al. 2001). The latter scenario is favored in the object from the measured Balmer absorption EW ratio with its theoretical value. In an absorption line without saturation, its EW could be related to its column density \( N \) as (Jenkins 1986)

\[
EW = \frac{\pi e f \lambda^2 N}{m_e c^2}, \quad (1)
\]

where \( f \) is the oscillator strength. A theoretical \( f \lambda \) value of 7.26 is therefore expected for the \( \text{H}\alpha-\text{H}\beta \) ratio, which is very close to the observed EW ratio of \( EW(\text{H}\alpha)/EW(\text{H}\beta) = 7.38 \pm 4.32 \) when both absorption lines are normalized with respect to the modeled AGN continuum. In contrast, the observed ratio is closer to 1 if both absorption lines are normalized to the corresponding broad emission line. This comparison therefore indicates that the absorbing gas responsible for the Balmer transitions is not saturated and fully covers the continuum source.

We furthermore estimated the neutral hydrogen column density from Eq. (1). The inferred column densities of hydrogen at \( n = 2 \) shell from the \( \text{H}\alpha \) and \( \text{H}\beta \) absorption lines are \( N_{\text{HI},2} = (1.2 \pm 0.5) \times 10^{14} \text{cm}^{-2} \) and \( (1.6 \pm 2.2) \times 10^{14} \text{cm}^{-2} \). The neutral hydrogen column density was derived from \( N_{\text{HI}} = N_{\text{HI},1} + N_{\text{HI},2} \), where \( N_{\text{HI},1} \) is the column density of hydrogen at \( n = 1 \) shell and is estimated by following Hall (2007):

\[
\frac{N_{\text{HI},1}}{N_{\text{HI},2}} = \frac{1}{4\tau_{\gamma,\text{Ly}}} e^{-\frac{\tau_{\gamma,\text{Ly}}}{4\tau_{\gamma,\text{Ly}}}}, \quad (2)
\]

where \( \tau_{\gamma,\text{Ly}} \) is the optical depth at the center of the \( \text{Ly}\alpha \) absorption. The depth \( \tau_{\gamma,\text{Ly}} \) was inferred from the relationship \( \tau_{\gamma,\text{Ly}} = 0.125 \tau_{\gamma,\text{H}\alpha}(N_{\text{HI},1}/N_{\text{HI},2}) \) (see Eq. (1) in Aoki 2010). Substituting this relationship into Eq. (2) results in a relation

\[
\frac{N_{\text{HI},1}}{N_{\text{HI},2}} = 1.44 \frac{e^{-\frac{\tau_{\gamma,\text{Ly}}}{4\tau_{\gamma,\text{Ly}}}}}{\sqrt{\tau_{\gamma,\text{H}\alpha}}}, \quad (3)
\]

Taking \( T = 7500 \text{ K} \) (Osterbrock & Ferland 2006) and \( \tau_{\gamma,\text{H}\alpha} = 1.69 \times 10^{14} E(W(\text{H}\alpha)/\lambda)/b = 8.66 \) (where \( b \) is the Doppler parameter of the absorption line after correcting for the intrinsic instrumental resolution), the inferred neutral hydrogen column density is \( \sim 1.5 \times 10^{17} \text{cm}^{-2} \).

3.2. UV and X-ray observations

SDSS J1126+4252 is particularly weak and hard in UV and X-ray bands. The object is a common source in the second XMM-Newton serendipitous source catalog (XMMSSC) and the XMM-Newton optical Monitor serendipitous UV source catalog (XMMOMSUSS). Vagnetti et al. (2010) showed that the inferred specific luminosities at 2500 Å and 2 keV are \( 4.8 \times 10^{38} \text{ erg s}^{-1} \text{ Hz}^{-1} \) and \( 6.6 \times 10^{33} \text{ erg s}^{-1} \text{ Hz}^{-1} \). Its very hard X-ray spectrum can additionally be derived from the very high hardness ratios\(^4\): HR3 = 0.52 and HR4 = 0.63. Ji et al. (2012, 2013) recently pointed out that a rigorous condition is required for the formation of Balmer absorptions. The absorptions are likely caused by Ly\( \alpha \) resonant pumping in a partially ionized region with a high column density of \( N_{\text{HI}} \sim 10^{21} \text{ cm}^{-2} \). A heavy obscuration as a result of the required high column density is a possible explanation of the observed extremely weak and hard emission in both UV and X-ray.

3.3. Eddington ratio and SMBH mass

We estimated the SMBH mass \( M_{\text{BH}} \) in terms of its \( \text{H}\alpha \) broad component according to the calibration in Greene & Ho (2007):

\[
M_{\text{BH}} = 3.0 \times 10^{6} \frac{L_{\text{H}\alpha}}{10^{42} \text{ erg s}^{-1}} \times \frac{FWHM_{\text{H}\alpha}}{1000 \text{ km s}^{-1}} M_{\odot}, \quad (4)
\]

where \( L_{\text{H}\alpha} \) is the intrinsic luminosity of the \( \text{H}\alpha \) broad component corrected for the local extinction. The extinction was inferred from the narrow-line ratio \( \text{H}\beta/\text{H}\alpha \), assuming the Balmer decrement for standard case B recombination and a Galactic extinction curve with \( R_V = 3.1 \). With the estimated \( M_{\text{BH}} \), the Eddington ratio \( L/L_{\text{Edd}} \) (where \( L_{\text{Edd}} = 1.26 \times 10^{38} M_{\odot} \) is the Eddington luminosity) was obtained from a combination of the bolometric correction of \( L_{\text{bol}} = 9.4 L_{\text{H}\alpha}(5100 \text{ Å}) \) (Kaspi et al. 2000) and the \( L_{\text{H}\alpha}(5100 \text{ Å}) - L_{\text{H}\alpha} \) relation reported in Greene & Ho (2005),

\[
\alpha L_{\text{H}\alpha}(5100 \text{ Å}) = 2.4 \times 10^{43} \left( \frac{L_{\text{H}\alpha}}{10^{42} \text{ erg s}^{-1}} \right)^{0.86} \text{ erg s}^{-1}. \quad (5)
\]

This luminosity relation has an RMS scatter of 0.2 dex around the best-fit line. The calculated \( M_{\text{BH}} \) and \( L/L_{\text{Edd}} \) are \( \sim 1.8 \times 10^{6} M_{\odot} \) and \( \sim 0.06 \). By combining the intrinsic scattered of the relationships and the uncertainties derived from our line modelings, a proper error propagation returns 1\( \sigma \) uncertainties of 0.40 dex and 0.45 dex for the calculated \( M_{\text{BH}} \) and \( L/L_{\text{Edd}} \).

We argue that the inferred \( M_{\text{BH}} \) from the broad \( \text{H}\alpha \) emission agrees with the properties of the host galaxy. With the velocity dispersion of the host galaxy of \( \sigma_* \sim 270 \text{ km s}^{-1} \) obtained from our continuum modeling, \( M_{\text{BH}} - \sigma_* \) relation of \( \log(M_{\text{BH}}/M_{\odot}) = 8.13 + 4.02 \log(\sigma_*/200 \text{ km s}^{-1}) \) (Tremaine et al. 2004) yields a black hole mass of \( \log(M_{\text{BH}}/M_{\odot}) \sim 8.7 \), which is highly consistent with the value estimated from the broad \( \text{H}\alpha \) emission.

3.4. Stratified NLR kinematics

The spectral analysis allows us to study the line shifts in SDSS J1126+4252 by using its host starlight component as a reference of the systematic velocity. One can see from Table 2 that all the low-ionized narrow emission lines show a redshift with respect to its host galaxy, while a blueshift is identified in the high-ionized emission line [NeIII]λ3868. It is interesting
that the [OIII]λ5007 emission line has a marginal blueshift of $\Delta v = -10 \pm 30 \, \text{km s}^{-1}$.

A strong anticorrelation between the velocity shifts and ionization potential (IP) is shown in Fig. 3. The velocity shift of the emitting gas of neutral hydrogen atom is taken from the measurement of narrow Hα emission, both because the narrow Hα and Hβ emission show comparable velocity shifts and because of the higher signal-to-noise ratio of the narrow Hα line. An average value of velocity shift is adopted in the figure for the [SII] doublet. The best fit yields a relation of $\Delta v = (186.4 \pm 35.4) - (4.00 \pm 0.80)/\text{IP}$. Komossa et al. (2008) proposed a similar correlation between the line shift and IP in the narrow-line Seyfert 1 galaxies with a high [OIII] line blueshift over 150 km s$^{-1}$.

Because the AGN NLR gas is believed to be generally stratified in density and ionization potential (e.g., Filippenko & Halpern 1984; Filippenko 1985; De Robertis & Osterbrock 1986), our fitted relationship implies a complicated NLR kinematics in SDSS J1126+4252. A de-accelerated outflow is expected for the inner NLR gas, while an accelerated inflow for the outer NLR gas. The turnover of the radial velocity occurs at the [OIII]λ5007 emission-line gas, whose radial velocity shift with respect to the local system determined from the host starlight is very close to zero. Although the outflows from central AGNs on various scales have frequently been identified in AGNs (e.g., Komossa et al. 2008 and Fabian 2012 for a recent review), the inflows have already been revealed in a few of nearby AGNs through integrated field spectroscopic observations in both optical band and near-infrared (e.g., Fathi et al. 2005; Storchi-Bergmann et al. 2007; Riffel et al. 2008, 2013; Riffel & Storchi-Bergmann 2011). The observations reveal distinct kinematics for different emitting gas. The inflowing gas to the central active nucleus can be traced by the H2 emission, the outflowing gas by the [FeII] emission, which is similar to the kinematics revealed in SDSS J1126+4252.

The implications described above are based on the scenario in which the detected NLR lines are seen in front of the central AGN. We cannot exclude an alternative scenario here in which these NLR lines are seen behind the central source. In this scenario, the obtained relationship implies a de-accelerated inflow for the inner NLR gas, and an accelerated outflow for the outer NLR gas.

Our spectral analysis indicates that in SDSS J1126+4252 all the narrow emission lines, except for the OIII, show strong velocity shifts with respect to the local system determined from the host starlight. This causes concern that AGN narrow emission lines, even for the low-ionized lines, might not be a reliable substitute for the velocity of the local system. A large sample is needed to perform a more detailed examination of the relationship between the velocity shifts of various narrow emission lines and the local system determined from host starlight in the future.

4. Conclusions

We performed a detailed spectral analysis on SDSS J11261.63+425246.4, which allowed us to identify the object as a new Balmer-absorption AGN. By using the modeled host starlight as the reference of the local system, a stratified kinematics was identified in the NLR of the object, that is, a strong anticorrelation between the inferred velocity shifts and ionization potentials. The revealed relationship implies a de-accelerated outflow stream for its inner NLR gas, and an accelerated inflow stream for its outer NLR gas.
