ABSTRACT

Context. Accretion and ejection are tightly connected and represent the fundamental mechanisms regulating star formation. However, the exact physical processes involved are not yet fully understood.

Aims. We present high angular and spectral resolution observations of the Bry emitting region in the Herbig Ae star HD 163296 (MWC 275) in order to probe the origin of this line and constrain the physical processes taking place at sub-AU scales in the circumstellar region.

Methods. By means of VLT/AMBER observations at high spectral resolution ($R \sim 12\,000$), we studied interferometric visibilities, wavelength-differential phases, and closure phases across the Bry line of HD 163296. To constrain the physical origin of the Bry line in Herbig Ae stars, all the interferometric observables were compared with the predictions of a line radiative transfer disc wind model.

Results. The measured visibilities clearly increase within the Bry line, indicating that the Bry emitting region is more compact than the continuum. By fitting a geometric Gaussian model to the continuum-corrected Bry visibilities, we derived a compact radius of the Bry emitting region of $\sim 0.07 \pm 0.02$ AU (Gaussian half width at half maximum; or a ring-fit radius of $\sim 0.08 \pm 0.02$ AU). To interpret the observations, we developed a magneto-centrifugally driven disc wind model. Our best disc wind model is able to reproduce, within the errors, all the interferometric observables and it predicts a launching region with an outer radius of ~ 0.04 AU. However, the intensity distribution of the entire disc wind emitting region extends up to ~ 0.16 AU.

Conclusions. Our observations, along with a detailed modelling of the Bry emitting region, suggest that most of the Bry emission in HD 163296 originates from a disc wind with a launching region that is over five times more compact than previous estimates of the continuum dust rim radius.

1. Introduction

As a general view, the accretion and ejection processes in young stellar objects (YSOs) proceed as part of the matter in the disc is lifted up along the magnetospheric accretion columns and accretes onto the stellar surface, whereas a small amount of the accreting matter is instead accelerated and collimated outwards in the form of protostellar winds or jets. Accretion and ejection are tightly connected and represent the fundamental mechanisms regulating the formation of a star. The first indications of such a connection were found in classical T Tauri stars (CTTSs) and Herbig AeBe stars through the discovery of a correlation between the luminosity of jet line tracers (such as the [O I] 6300 Å line) and the infrared excess luminosity (Hartigan et al. 1995; Corcoran & Ray 1998). The exact physical processes driving and connecting the accretion and ejection activity are, however, not fully understood. One of the main reasons is the complex

structure of the accretion-ejection region and the small angular scales involved: within less than 1 AU from the central source (i.e. <10 mas at a distance of 100 pc) emission from the hot gaseous disc, outflowing material, and the accretion columns is expected. In this context, near-infrared interferometry and, in particular, HI Bry spectro-interferometric observations, have become an essential tool with which to investigate the hot and dense gas at sub-AU scales. The first Bry spectro-interferometric observations of Herbig AeBe stars showed that in some sources the bulk of the Bry emission arises from an extended component (probably tracing a disc or stellar wind; e.g. Malbet et al. 2007; Eisner et al. 2007; Kraus et al. 2008; Weigelt et al. 2011), in contrast with the scenario in which the Bry line would be related with magnetospheric accretion, and so unresolved by current IR interferometers. Despite its unclear origin, the Bry line luminosity is directly correlated with the accretion luminosity through empirical relationships (Muzerolle et al. 1998; Calvet et al. 2004) and extensively used to estimate the mass accretion rates of YSOs with different masses ($0.1\text{--}10 M_{\odot}$) and at different evolutionary stages ($10^5\text{--}10^7$ yr; e.g. Garcia Lopez et al. 2006; Antonucci et al. 2011; Caratti o Garatti et al. 2012).

In order to further constrain the origin of the Bry line in Herbig AeBe stars and probe the accretion-ejection connection, we have started a detailed high spectral resolution (HR) VLTI/AMBER study of Herbig AeBe stars. We present our results on the Herbig Ae star HD 163296 (MWC275). This star is one of the best candidates with which to perform a high angular and spectral study of the accretion-ejection region: HD 163296 is located at just ~ 119 pc (van Leeuwen 2007), it is among the few Herbig Ae stars driving a well collimated bipolar jet (HH409; see e.g. Wassell et al. 2006), and it is very likely a single star (Swartz et al. 2005; Montesinos et al. 2009). The main HD 163296 stellar parameters are listed in Table 1.

The protoplanetary disc around HD 163296 has been extensively studied (e.g. Isella et al. 2007; Benisty et al. 2010; Tilling et al. 2012; Rosenfeld et al. 2013). Recently, ALMA observations have revealed a vertical temperature gradient across the disc, suggesting dust settling and/or migration (see e.g. de Gregorio-Monsalvo et al. 2013; Mathews et al. 2013). Despite the evidence of dust growth, the disc still has enough gas content to drive a CO disc wind and a large-scale collimated bipolar jet (Wassell et al. 2006; Klaassen et al. 2013).

Previous, spectro-interferometric studies of HD 163296 successfully resolved the inner edge of the circumstellar disc, locating it at distance values from the star ranging from ~ 0.19 AU to ~ 0.45 AU (e.g. Renard et al. 2010; Benisty et al. 2010; Eisner et al. 2010, 2014; Tannirkulam et al. 2008a,b). It is within this region that the extended Bry emission is being emitted

(Kraus et al. 2008; Eisner et al. 2014), although, the exact origin of the line emission, and the nature of the innermost gaseous disc are still unclear.

In the following, we will present our VLTI/AMBER HR observations ($R \sim 12\,000$) across the Bry line of HD 163296. The observations, data reduction, and calibration, as well as the interferometric observables derived from our observations are presented in Sects. 2 and 3. In Sects. 4–6, a description of the models used to interpret our results and their comparison with the observations are shown. Finally, in Sect. 8, a summary of our results and the main conclusions are presented.

2. Interferometric VLTI/AMBER/FINITO observations with spectral resolution of 12000

We observed HD 163296 during three nights in May and June 2012 with the ESO Very Large Telescope Interferometer (VLTI) and its AMBER beam combiner instrument (Petrov et al. 2007). For these observations, we used the three 8 m Unit Telescopes UT2, UT3, and UT4 with AMBER in the high spectral resolution mode ($R = 12\,000$). The observation parameters are described in Table 2. To obtain interferograms with a high signal-to-noise ratio (S/N), we used the fringe tracker FINITO for cophasing and a detector integration time of 6.0 s per interferogram.

Fig. 1. AMBER observation of HD 163296 with three different baselines (45.0 m: red upper line, 57.5 m: green middle line, and 81.6 m: blue lower line) and spectral resolution $R = 12\,000$. From top to bottom: wavelength dependence of flux, visibilities, wavelength-differential phases, and closure phases. For clarity, the differential phases of the first and last baselines are shifted by $+30^\circ$ and -30° , respectively. The results shown correspond to the averaged value over three different observations (see Sect. 2 and Appendix for details). The wavelength scale is with respect to the local standard of rest (LSR) and corrected by a cloud velocity of $\sim 8\text{ km s}^{-1}$ (Isella et al. 2007).

For data reduction, we used our own data reduction software based on the P2VM algorithm (Tatulli et al. 2007) to derive wavelength-dependent visibilities, wavelength-differential phases, and closure phases. Along with the science observations of HD 163296, we observed the interferometric calibrator stars

HD 163955, HD 162255, and HD 160915, which were used to calibrate the transfer function. The fringe tracking performance of FINITO is usually different during the target and calibrator observations. Therefore, we used all published archival low-resolution AMBER observations of HD 163296 to calibrate the continuum visibilities. The errors of the K -band squared visibilities are approximately $\pm 5\%$ or slightly better during the best nights. Each of our three recorded datasets consists of 75 target and calibrator interferograms. Because all three observations were performed with very similar projected baseline lengths and position angles (PAs), we averaged the results of all three observations in order to get a better S/N per spectral channel (Fig. 1). The smaller errors of the averages of the three datasets were obtained from the errors of the individual results in the standard way. Because the absolute continuum visibilities were calibrated using the published archive low resolution (LR) observations, in the next step, we took the errors of these LR archival data into account and we calculated the total error in the standard way. The three individual results are shown in the Appendix (Fig. A.1). The wavelength calibration was accomplished using the numerous telluric lines present in the region $2.15\text{--}2.19\text{ }\mu\text{m}$ (see Weigelt et al. 2011, for more details on the wavelength calibration method). We estimate an uncertainty in the wavelength calibration of $\sim 3\text{ km s}^{-1}$.

3. Interferometric observables

Our VLTI/AMBER observations provide four direct observables: Bry line profile, visibilities, differential phases, and closure phases. These observables allow us to retrieve information about the size and kinematics of the Bry emitting region.

Figure 1 shows (from top to bottom) the Bry line profile, wavelength visibilities, differential phases, and closure phase of our Bry spectro-interferometric observations of HD 163296. The wavelength-dependent visibilities (second panel from top) clearly increase within the Bry line in all our baselines. This indicates that the Bry emitting region is more compact than the continuum emitting region.

Previous spectro-interferometric studies of HD 163296 at medium resolution had also detected an increase of the visibility within the Bry line (Kraus et al. 2008; Eisner et al. 2014). Our HR mode AMBER observations have, however, allowed us to measure the visibilities and phases in ~ 30 different spectral channels across the Doppler-broadened Bry line, helping us to better distinguish the contribution of the line to that of the continuum. The measured differential and closure phases do not clearly show any significant deviation from zero within the error bars of $\pm 5^\circ$, and $\pm 15^\circ$, respectively (Fig. 1, bottom panel).

4. Geometric modelling: the characteristic size of the Bry line-emitting region

The high spectral resolution of the AMBER data allows us to measure the visibilities of the pure Bry line-emitting region for several spectral channels across the Bry emission line (see Fig. B.1). These continuum-compensated line visibilities (required for the size determination of the Bry line-emitting region) were calculated in the following way. Within the wavelength region of the Bry line emission, the measured visibility has two constituents: the pure line-emitting component and the continuum-emitting component, which includes continuum emission from both the circumstellar environment and the

Table 3. Disc wind model parameters.

Parameters ^a	Range ^b	MW6 ^b	MW26	MW47
Temperature (K)	8000–10 000	10 000	10 000	10 000
Half opening angle (θ)	30°–45°	45°	30°	20°
Inner radius ($\omega_1(R_*)$)	2–3	2.0 (0.02 AU)	2.0 (0.02 AU)	5.0 (0.05 AU)
Outer radius ($\omega_N(R_*)$)	4–30	4.0 (0.04 AU)	15.0 (0.16 AU)	15.0 (0.16 AU)
Acceleration parameter (β)	1–7	5	3	4
Mass load parameter (γ)	1–5	3	3	3
Mass loss rate ($\dot{M}_w(M_\odot/\text{yr})$)	10^{-8} – 10^{-7}	5×10^{-8}	5×10^{-8}	5×10^{-8}

Notes. ^(a) The definition of the listed disc wind model parameters is described in detail in Weigelt et al. (2011). ^(b) Disc inclination and position angle (major axis) of $\sim 38^\circ$ and $\sim 138^\circ$, respectively, were assumed (gaseous ALMA disc; de Gregorio-Monsalvo et al. 2013), as well as the stellar parameters listed in Table 1.

unresolved central star. The emission line visibility V_{Bry} in each spectral channel can be written as

$$F_{\text{Bry}} V_{\text{Bry}} = \sqrt{|F_{\text{tot}} V_{\text{tot}}|^2 + |F_c V_c|^2 - 2 F_{\text{tot}} V_{\text{tot}} F_c V_c \cdot \cos \Phi} \quad (1)$$

$$= |F_{\text{tot}} V_{\text{tot}} - F_c V_c|, \quad (2)$$

if the differential phase ϕ is zero (Weigelt et al. 2007). The value F_{Bry} is the wavelength-dependent line flux, V_{tot} (F_{tot}) denotes the measured total visibility (flux) in the Bry line, V_c (F_c) is the visibility (flux) in the continuum, and Φ is the measured wavelength-differential phase within the Bry line. The intrinsic Bry photospheric absorption feature was taken into account in this analysis by considering a synthetic spectrum with the same spectral type and surface gravity of HD 163296 (Eisner et al. 2010; Mendigutía et al. 2013).

We have derived the pure line visibility only in spectral regions where the line flux is higher than $\sim 10\%$ of the continuum flux. The results are shown in Fig. B.1. The average line visibility is ~ 1 at the shortest baselines (45 m), ~ 0.9 at medium baselines (57.5 m), and ~ 0.8 at the longest baselines (81.6 m). The approximate size of the line-emitting region was obtained by fitting a circular symmetric Gaussian model to the line visibilities presented in Fig. B.1. We obtained a Gaussian half width at half maximum (HWHM) radius of 0.6 ± 0.2 mas or $\sim 0.07 \pm 0.02$ AU. Similarly, by fitting a ring model with a ring width of 20% of the inner ring radius, an inner radius of 0.7 ± 0.2 mas or $\sim 0.08 \pm 0.02$ AU, is found. This radius is smaller than the inner continuum dust rim radius of $R_{\text{rim}} \sim 0.19$ – 0.45 AU reported in the literature (Tannirkulam et al. 2008a,b; Benisty et al. 2010; Eisner et al. 2014).

5. Disc and wind model

Following our previous work on the Herbig Be star MWC 297, we developed a disc wind model to explain the observed Bry line profile, line visibilities, differential phases, and closure phase (Weigelt et al. 2011; Grinin & Tarnovtseva 2011; Tarnovtseva et al. 2014). A detailed description of the disc wind model, the complete algorithm for the model computation, and a detailed description on how the disc wind model solution depends on the kinematic and physical parameters can be found in these papers. In the following, we will briefly summarise the main characteristics of our disc wind model.

The disc wind model employed here is based on the magneto-centrifugal disc wind model of Blandford & Payne (1982), adapted for the particular case of Herbig AeBe stars. For simplicity, the disc wind consists only of hydrogen atoms with constant temperature ($\sim 10\,000$ K) along the wind streamlines.

This approximation is in agreement with the so-called warm disc wind models (Safier 1993; Garcia et al. 2001), in which the wind is rapidly heated by ambipolar diffusion to a temperature of $\sim 10\,000$ K. In these models, the wind electron temperature in the acceleration zone near the disc surface is not high enough to excite the Bry line emission. Therefore, in our model, the low-temperature region below a certain height value does not contribute to the Bry disc wind emission.

For the calculations of the model images of the emitting region in the line frequencies and their corresponding interferometric quantities (i.e. visibilities and phases), we used the same approach as in Weigelt et al. (2011). For the calculations of the ionization state and the number densities of the atomic levels, we adopted the numerical codes developed by Grinin & Mitskevich (1990) and Tarnovtseva et al. (2001) for moving media. These codes are based on the Sobolev approximation (Sobolev 1960) in combination with the exact integration of the line intensities (see Appendix A in Weigelt et al. 2011). This method takes into account the radiative coupling in the local environment of each point caused by multiple scattering. The calculations were made for the 15-level model of the hydrogen atom plus continuum, taking into account both collision and radiative processes of excitation and ionization (see Grinin & Mitskevich 1990 for more details).

Very briefly, our disc wind model considers a wind launched from an inner radius ω_1 to an outer radius ω_N (wind footpoints). The disc wind half opening angle (θ) is defined as the angle between the innermost wind streamline and the system axis. The angle range (30°–45°) in Table 3 is consistent with the Blandford & Payne (1982) disc wind solution. The local mass-loss rate per unit area on the disc surface is defined as $\dot{m}(\omega) \sim \omega^{-\gamma}$, where γ is the so-called mass-loading parameter that controls the ejection efficiency. Thus, the total mass-loss rate is given by

$$\dot{M}_w = 2 \int_{\omega_1}^{\omega_N} \dot{m}_w(\omega) 2\pi \omega d\omega. \quad (3)$$

In all our disc wind models, the accretion disc is assumed to be transparent to radiation at radii up to the dust sublimation radius. At larger radii, the disc is an opaque screen that shields a large fraction of the wind emission because the observer cannot see the disc wind emission on the back side of the disc. It should be noted that this assumption (i.e. opaque disc with an inner gap) is only valid if the mass accretion rate ($\dot{M}_{\text{acc}}$) does not exceed a value of $\sim 10^{-6} M_\odot \text{ yr}^{-1}$ (Muzerolle et al. 2004).

All free model parameters are listed in Table 3. Some model parameters such as $\dot{M}_w$, the stellar parameters and the disc inclination angle were taken from the literature (see Tables 3 and 1).

The modelled total mass-loss rate ($\dot{M}_w^1$) was allowed to vary within ~ 0.1 – 1.0 times the $\dot{M}_{acc}$ observed average value (see Table 1). In addition, the estimated value of the corotation radius is set as a lower limit to the inner disc wind launching radius value ω_1 (see Sect. 6). These parameters, along with our interferometric observations further constrain our disc wind model solution. For instance, the measured visibilities constrain the size of the disc wind launching region, and the adopted $\dot{M}_w$ and measured line profile constrain the wind dynamics (see Tambovtseva et al. 2014, for a complete discussion).

Finally, in order to compute the model differential phases, a continuum model consisting of two components, an inner and an outer disc, was adopted (e.g. Tannirkulam et al. 2008a; Benisty et al. 2010). This model is able to reproduce both the observed continuum visibilities and continuum flux of HD 163296. The dominant outer disc is a temperature-gradient disc with a power law index of -0.50 , inner temperature of 1500 K, and a dust rim radius of $20 R_*$ (i.e. ~ 0.21 AU). The stellar flux is 0.14 of the observed flux in the K -band (Benisty et al. 2010). The additional optically thin inner disc has an inner radius of $5 R_*$, an outer radius equal to the inner radius of the outer disc (i.e. $20 R_*$), and a constant intensity distribution flux of 20% of the observed continuum flux.

6. Results

In order to find a disc wind model that is able to approximately reproduce all interferometric observables, we calculated more than 100 models within the parameter ranges listed in Table 3. All our models were computed assuming a disc inclination (angle between the line of sight and the system axis of the gaseous ALMA gas disc) of $\sim 38^\circ$ and a position angle of the major axis of the disc of $\sim 138^\circ$ (de Gregorio-Monsalvo et al. 2013). We computed the intensity distributions of the models for all the wavelength channels across the Bry line.

Because our observations do not provide us with wavelength-dependent images (as the modelling does), but only with the Bry line profile and information on visibilities and phases, we first had to derive the following interferometric quantities from the wavelength-dependent model intensity distributions: model line profiles, model visibilities, and differential and closure phases of the model. All the interferometric model quantities were computed for the same baseline lengths, baseline PAs, and spectral resolution as the observations. This method allowed us to compare the observed interferometric quantities (i.e. line profile, visibilities, differential phases, and closure phases) with the corresponding interferometric model quantities and to find out which of our models can best reproduce the observations.

Figures 2 and B.1 show a comparison of the observations with the interferometric quantities derived from our best disc wind model MW6 (see Table 3 for a list of the model parameters). The intensity distribution maps of this model at several radial velocities are presented in Fig. 3. All model parameters are listed in Table 3. As shown in the figures, model MW6 approximately agrees with the observed line profile (Fig. 2, upper panel), visibilities (Fig. 2, middle panel), and small differential phases and closure phases (Fig. 2; the measured differential and closure phases are approximately zero within our errors; the model closure phase is $\sim 1^\circ$). Moreover, this model is also able to approximately reproduce the visibilities and small

Fig. 2. Comparison of our interferometric observations with the interferometric quantities derived from our best disc wind model MW6. From top to bottom, observed Bry line profile (grey) and model line profile (pink), observed visibilities (grey dots with error bars) and model visibilities (coloured lines), observed and model wavelength-differential phases, and, observed and model closure phases.

differential phase of previous Keck interferometric observations of this source (Eisner et al. 2010, 2014). However, it slightly overpredicts the pure Bry line visibilities for the longest baseline (see Fig. B.1). This can also be seen in Fig. 2, where the model continuum visibility is slightly below the observed value for the longest baseline.

In order to obtain a lower value of the modelled pure line visibility at the longest baseline, it would be necessary to increase the size of the disc wind region (e.g. ω_N). Two examples

¹ From now on, we use $\dot{M}_w$ for the modelled total mass-loss rate and $\dot{M}_{out}$ for the observed value from the literature.

Fig. 3. Bry intensity distribution maps of our best disc wind model MW6 (see Table 3) at several radial velocities, as indicated by the white labels in units of km s^{-1} . Emission from the disc continuum and the central star is not shown. The colours represent the intensity in logarithmic scale in arbitrary units.

of such models (i.e. with $\omega_N > 4R_*$) can be found in Fig. C.1 (model MW26) and Fig. C.2 (model MW47). Model MW26 has the same ω_1 value as our best model MW6, but a ω_N value almost 4 times larger (0.16 AU). Model MW47 has larger values of ω_1 (0.05 AU) and ω_N (0.16 AU). The modelled interferometric results presented in Figs. C.1, C.2 show that these larger disc wind launching radii have little influence on the line visibility. Both new models have, however, large differential phases ($\gtrsim 34^\circ$) that disagree with the observed differential phases (approximately zero within the average error of $\sim \pm 5^\circ$). These large differential phases are caused by the larger radii, that produce larger photo centre shifts with respect to the continuum. It should be noted that the acceleration parameters of models MW6, MW27, and MW47, as well as the half opening angles, differ slightly from model to model ($\beta = 5, 3$, and 4, and $\theta = 45^\circ, 30^\circ$, and 20° , respectively). However, these model parameters mainly modify the Bry line profile (see e.g. [Tambovtseva et al. 2014](#)), and have little effect on the line visibilities and differential phases which mostly depend on the ω_1 and ω_N parameters. Therefore, a good match between our interferometric observables (line profile, visibilities, and differential and closure phases) and the modelled

results can only be achieved when combining lower values of the inner and outer disc wind footpoints, that is, when a compact disc wind is considered.

7. Discussion

The disc wind launching region of our best model MW6 is quite compact, extending from an inner radius of ~ 0.02 AU to an outer radius of ~ 0.04 AU. This latter value is not far from the lowest outer launching radius of 0.03 AU derived from [Ferreira et al. \(2006\)](#) from a comparison of optical jet observations of T Tauri stars (typical $R_{\text{cor}} \sim 0.1$ AU) and the predictions from extended disc wind models. Even if a direct comparison between T Tauri and Herbig AeBe stars is difficult, this result suggests that disc wind models with low ω_N values can explain some observations of extended emission in YSOs. However, Fig. 3 shows that the entire disc wind emitting region extends to an outer radius of $\sim 15 R_*$ or ~ 0.16 AU. As discussed in the previous section, this allows us to obtain approximately the required low visibilities at the longest baseline, as well as small differential phases, and to fit the Bry line profile.

It should be noted that our modelling does not exclude that a fraction of the Bry flux might be emitted from a compact magnetosphere, a stellar wind, and/or an X-wind (see e.g. [Tambovtseva et al. 2014](#), for examples of hybrid models). Because of the small magnetic fields measured in Herbig AeBe stars, the distance at which the circumstellar disc of Herbig AeBe stars is truncated by the stellar magnetic field (the truncation radius) is expected to be much smaller than in CTTs and it is located within the corotation radius (R_{cor} ; [Shu et al. 1994](#); [Muzerolle et al. 2004](#)). For the case of HD 163296, the corotation radius, R_{cor} , is $\sim 1.6 R_*$ or ~ 0.02 AU². Therefore, the magnetosphere outer radius ($\lesssim 0.02$ AU) is much smaller than the outer radius of the whole disc wind emitting region (~ 0.16 AU; see Fig. 3), and comparable to the inner launching radius parameter ω_1 in our disc wind model MW6. As a consequence, any additional emission in our model located within the corotation radius (~ 0.02 AU) would increase the modelled Bry visibilities of the disc wind intensity distribution. To illustrate this effect, we employed a hybrid model (disc wind plus magnetosphere) as described in [Tambovtseva et al. \(2014\)](#), and add the contribution of a compact magnetosphere accounting for 40% of the total Bry flux to our best model MW6 (a brief description of the magnetosphere parameters and their values can be found in Appendix D). To account for the extra emission from the magnetosphere and obtain a good fit to the line profile, the Bry emitting region in model MW6 was reduced by increasing the size of the low-temperature region at the wind base where the gas does not produce Bry emission (see Sect. 5). In this way, the disc wind Bry emission was reduced to a 60% of the total Bry flux. Figure D.1 shows the result of this model overplotted on our observations: the pure Bry line visibilities are now ~ 1 at all baselines. To conclude, our hybrid model (i.e. disc wind plus magnetosphere) suggests that the observed low visibility values can only be achieved with larger disc wind footpoint radii than in model MW6, but this would in turn produce excessive values of the differential phase as well, contradicting our observations.

Nevertheless, we would like to point out that the aim of this paper is to investigate which mechanism is responsible for

² The corotation value of $1.6 R_*$ was derived from the stellar parameters presented in Table 1, assuming an inclination angle of 38° ([de Gregorio-Monsalvo et al. 2013](#), see Table 3), and a projected rotational velocity of $v \sin i = 133 \text{ km s}^{-1}$ ([Montesinos et al. 2009](#)).

most of the Bry emission in HD 163296. Therefore, our observations do not rule out that some of the Bry emission is produced in an X-wind and/or a magnetosphere in HD 163296, but they would probably have to act in combination with a more extended emission like the disc wind reported here in order to reproduce the observed Bry line visibilities and the line profile.

The presence of a disc wind in HD 163296 is also supported by ALMA observations which revealed an extended CO rotating disc wind emerging from this source (Klaassen et al. 2013). Our observations also indicate a compact disc wind component traced by the Bry line, and launched well within the dust sublimation radius. This, in turn, would explain why no dust has been detected along the long-scale optical/infrared bipolar jet (Ellerbroek et al. 2014), that is, the jet is launched from an inner disc region where none or only little dust is present.

8. Summary and conclusions

In this paper, we present AMBER high spectral resolution ($R = 12\,000$) observations of the young Herbig Ae star HD 163296. The high spectral resolution has allowed us to sample the interferometric observables (i.e. line profile, visibilities, differential phases, and closure phases) in many spectral channels across the Bry line. Our observations show that the visibility within the Bry line is higher than in the continuum (Fig. 1). Therefore, the Bry emitting region is less extended than the continuum emitting region. To characterise the size of the Bry emitting region, we fitted geometric Gaussian and ring models to the derived continuum-corrected Bry line visibilities (i.e. the pure Bry visibilities). We derived a FWHM Gaussian radius of 0.6 ± 0.2 mas or $\sim 0.07 \pm 0.02$ AU, and ring-fit radius of 0.7 ± 0.2 mas or $\sim 0.08 \pm 0.02$ AU for the Bry line-emitting region (for the adopted distance of 119 pc).

To obtain a more physical interpretation of our AMBER observations, we employed our own line radiative transfer disc wind model (Weigelt et al. 2011; Grinin & Tarnovtseva 2011). Using this approach, we computed a model that approximately agrees with all interferometric observables. Figures B.1 and 2 show that our best disc wind model MW6 (Table 3) agrees with (1) the Bry line profile; (2) the total visibilities across the Bry line; (3) the continuum-corrected Bry line visibilities; and (4) the small observed wavelength-differential phases and closure phases. Therefore, our AMBER HR spectro-interferometric observations of the Bry line, along with a detailed modelling of the line-emitting region suggest that the Bry line-emitting region in HD 163296 mainly originates from a disc wind with an inner launching radius of 0.02 AU and an outer launching radius of 0.04 AU. However, Fig. 3 shows that the entire disc wind emitting region extends to an outer radius of $\sim 15 R_*$ or ~ 0.16 AU. The modelled disc wind emitting region is more compact than the inner continuum dust rim radius reported in the literature ($R_{\text{rim}} \sim 0.19\text{--}0.45$ AU; Benisty et al. 2010; Eisner et al. 2010, 2014; Tannirkulam et al. 2008a,b). Our modelling does not exclude that some of the Bry emission is produced in the magnetosphere. However, in addition to the emission from the magnetosphere, emission from a more extended region, like the disc

wind presented here, would be required to explain the interferometric observations.

Acknowledgements. The authors thank the Paranal science operation team for carrying out these observations in service mode. Appendix A: Individual set of observations

Fig. A.1. All three AMBER observations of HD 163296 with spectral resolution of 12 000. The three columns show the observed interferometric results from 2012 May 11 (*left*), 2012 May 12 (*middle*), and 2012 June 04 (*right*). Shown *from top to bottom* are wavelength dependence of flux, visibilities, wavelength-differential phases (for better visibility, the differential phases of the first and last baselines are shifted by $+50^\circ$ and -50° , respectively), and closure phase observed at projected baselines as shown in the plot. The wavelength scale at the bottom is corrected to the local standard of rest. The typical visibilities, differential, and closure phases errors are $\pm 5\%$, 5° , and 15° .

Appendix B: Pure line visibilities

Fig. B.1. Comparison of the observed and modelled pure Bry line visibilities of our AMBER observation of HD 163296. *From top to bottom:* wavelength dependence of flux, visibilities of the first, second, and third baseline. In each visibility panel: (1) the observed total visibilities (red, green, blue, as in Fig. 1); (2) the observed continuum-compensated pure Bry line visibilities (pink), and the modelled pure Bry line visibilities (black; model MW6, Table 3) are shown.

Appendix C: Examples of computed disc wind models

Fig. C.1. Same as Fig. B.1 (left panel) and Fig. 2 (right panel) but for model MW26 (see Table 3).

Fig. C.2. Same as Fig. B.1 (left panel) and Fig. 2 (right panel) but for model MW47 (see Table 3).

Appendix D: Examples of computed hybrid models: disc wind plus magnetosphere

D.1. The magnetosphere

A full description of the model employed here can be found in [Tambovtseva et al. \(2014\)](#). Here, only a brief description of the main model parameters is presented.

Our model considers a compact, disc-like rotating magnetosphere of height h_m through which free-falling gas reaches the stellar surface at some altitude near the magnetic pole. The gas rotational velocity component (u) is described by

$$u(r) = U_0(r/R_*)^p, \quad (\text{D.1})$$

where U_0 is the rotational velocity of the gas at the magnetic poles, r is the distance from the star, and p is a parameter. Finally, we assume a dependence of the electron temperature (T_e) of

$$T_e(r) = T_e(R_*) \exp(-r1), \quad (\text{D.2})$$

where $r1 = ((r - R_*)/R_*)^q$, $T_e(R_*)$ is the temperature of the gas near the stellar surface, and q is a parameter.

Table D.1. Magnetosphere model parameters

Parameters	MS6a
$T_e(R_*)$ (K)	10 000
q	0.4
U_* (km s ⁻¹)	10
$U(r_T)/U_K$	1
r_c (R_*)	2.0 (0.02 AU)
h_m (R_*)	1.5
$\dot{M}_{\text{acc}}$ ($M_\odot/\text{yr}$)	1×10^{-7}

In our hybrid model, the magnetosphere is equivalent to a point source at our interferometer baselines. Thus, it accounts for the compact and unresolved Br γ emission, whereas the disc wind component is responsible of the resolved Br γ emission.

Because of the spread on the measured $\dot{M}_{\text{acc}}$ values, and the large uncertainties in measuring this quantity ($\sim 20\%$), an average value of $1 \times 10^{-7} M_\odot \text{ yr}^{-1}$ was assumed in our magnetosphere model.

Fig. D.1. Same as Fig. B.1 (left panel) and Fig. 2 (right panel) but for the hybrid model MW6+MS6a (see Tables 3 and D.1).
