ABSTRACT

Aims. We present direct evidence of the detection of the main energy release site in a non-eruptive solar flare, SOL2013-11-09T06:38 UT. This GOES class C2.6 event was characterised by two flaring ribbons and a compact, bright coronal source located between them, which is the focus of our study.

Methods. We use imaging from SDO/AIA, and imaging spectroscopy from RHESSI to characterise the thermal and non-thermal emission from the coronal source, and EUV spectroscopy from the Hinode/Extreme ultraviolet Imaging Spectrometer, which scanned the coronal source during the impulsive peak, to analyse Doppler shifts in Fe XII (log $T = 6.2$) and Fe XXIV (log $T = 7.2$) emission lines, and determine the source density.

Results. The coronal source exhibited an impulsive emission lightcurve in all SDO/AIA filters during the impulsive phase. RHESSI hard X-ray images indicate both thermal and non-thermal emission at the coronal source, and its plasma temperature derived from RHESSI imaging spectroscopy shows an impulsive rise, reaching a maximum at 12–13 MK about 10 s prior to the hard X-ray peak. High red-shifts associated with this bright source indicate downflows of 40–250 km s$^{-1}$ at a broad range of temperatures, interpreted as loop shrinkage and/or outflows along the magnetic field. Outflows from the coronal source towards each ribbon are also observed by SDO/AIA images at 171, 193, 211, 304, and 1600 Å. The electron density of the source obtained from a Fe XIV line pair is $10^{11.5}$ cm$^{-3}$ which is collisionally thick to electrons with energy up to 45–65 keV, responsible for the source’s non-thermal X-ray emission.

Conclusions. Given the rich observational evidence, we conclude that the bright coronal source is the location of the main release of magnetic energy in this flare, with a geometry consistent with component reconnection between crossing, current-carrying loops. We argue that the energy that can be released via reconnection, based on observational estimates, can plausibly account for the non-thermal energetics of the flare.

Key words. Sun: flares – Sun: UV radiation – Sun: X-rays, gamma rays – magnetic reconnection – line: profiles – Sun: corona

1. Introduction

It is commonly accepted that the energy to power solar flares comes from the coronal magnetic field. The mechanisms for a transient release of magnetic energy, through magnetic reconnection, have been intensively investigated in both theoretical (e.g. Sweet 1958; Parker 1963; Petschek 1964; Syrovatskii 1966; Henoux & Somov 1987; Litvinenko & Somov 1993; Longcope 1996; Priest & Forbes 2000; Aulanier et al. 2006) and observational (e.g. Demoulin et al. 1993; Yokoyama et al. 2001; Grigs & Benz 2005; Su et al. 2013; Dudík et al. 2014; van Driel-Gesztelyi et al. 2014) aspects. The release of magnetic energy causes plasma heating and particle acceleration, sometimes with clear evidence of a fast re-organisation of the magnetic structure (Liu et al. 2012; Simões et al. 2013; Shen et al. 2014). Most of the published observational studies regarding detection of the magnetic reconnection or energy release sites are related to the standard model for eruptive flares (CSHKP, Carmichael 1964; Sturrock 1966; Hirayama 1974; Kopp & Pneuman 1976), and include observation of cusps above the flaring loops and inflows (Yokoyama et al. 2001; Liu et al. 2013), hot and fast flows above flaring arcades (Imada et al. 2013), flows due to gradual pre-flare evaporation and flare eruption (Harra et al. 2005), and slow bi-directional flows above the loop (Hara et al. 2006). Other works show indirect evidence of reconnection (Joshi et al. 2007) and electron acceleration at X-points (Narukage et al. 2014).

However, CME-less, weaker events are much more common on the Sun (Yashiro et al. 2006) than large eruptive events, and might be more relevant to total power output due to solar magnetic activity, although the matter is far from settled (Hudson 1991). For these smaller events, the CSHKP standard model is less applicable, as cusp-like structures and plasmoid ejections are not observed. Recently Su et al. (2013) reported remarkable SDO/AIA observations in the non-eruptive flare SOL2011-08-17 of cool inflowing loops and newly-forming hot outflowing loops, cited as strong evidence for magnetic reconnection.

Although the overall origin of the flare energy is known and the effects of the energy release are very well observed (heating, accelerated particles, plasma eruptions, etc.) the precise location of the energy release site and its physical properties are largely unknown and difficult to detect. In this paper we present observational evidence of both direct heating and acceleration of particles in a localised coronal source, which we interpret as the main energy release site for the event SOL2013-11-09T06:38 UT, a GOES class C2.6 two-ribbon flare.

2. Observations and data analysis

The flare SOL2013-11-09T06:38 UT, a GOES class C2.6 on AR 11890, located at S11W03 near the disk centre,
was observed simultaneously by several space-based instruments: Reuven Ramaty High Energy Solar Spectroscopic Imager (RHESSI, Lin et al. 2002), Atmospheric Imaging Assembly (AIA, Lemen et al. 2012) on board of the Solar Dynamics Observatory (SDO) and Hinode/Extreme ultraviolet Imaging Spectrometer (EIS, Culhane et al. 2007). There is a gradual rise in the extreme ultraviolet (EUV), soft X-ray (SXR) and hard X-ray (HXR) emissions starting about 06:24 UT, and the non-thermal HXRs peak at 06:25:46 UT. At all wavelengths imaged the flare has two short ribbons and a compact source between them, which – as we will argue – we identify as a coronal source. We show in the following sections that this coronal source is characterised by impulsive time evolution, sudden plasma heating reaching 12–13 MK, high electron density, and fast red-shifts measured by Doppler shifts of Fe xii and Fe xxi emission lines.

2.1. Characterisation of the coronal source

The SDO/AIA provides images at filter wavelengths of 94, 131, 171, 193, 211, 304, 335, 1600, and 1700 Å every 12 s for the EUV filters and 24 s for the UV filters, with a pixel size of 0.6 arcsec. We use it to characterise the spatial evolution of the sources and flows in the event. The flare has two bright ribbons about 50 arcsec apart, on opposite sides of the magnetic polarity inversion line. During the impulsive phase a remarkably bright and compact central source appears, located halfway between the ribbons: the same impulsive-phase morphology is observed in all nine EUV/UV SDO/AIA channels. Figure 1a shows the SDO/AIA image at 94 Å near the peak of the impulsive phase, overlaid with 1600 Å contours at the level 690 DN s⁻¹ pixel⁻¹, where we identify the east and west ribbons and this central source. Initial inspection suggested that the central source was a third footpoint, however using SDO/Helioseismic and Magnetic Imager (HMI, Scherrer et al. 2012) magnetograms, we verified that the photospheric magnetic field directly at the source location is very weak (±13 ± 10 G) and featureless, looking rather like supergranular cell-centre field (Fig. 1d). It was not clear how a third chromospheric footpoint could be magnetically connected by the observed EUV loops to both of the other ribbons. In fact the post-flare loops do not connect at the location of the central source, as shown by SDO/AIA images after the main impulsive phase, overlaid with 1600 Å contours at the level 690 DN s⁻¹ pixel⁻¹, where we identify the east and west ribbons and this central source. In Fig. 1a (see also Fig. 4), suggests a section of thin loops
P. J. A. Simões et al.: Direct observation of energy release site of a flare

Fig. 2. SDO/AIA images after the main impulsive phase, overlaid with 1600 Å contours (690 DN s$^{-1}$ pixel$^{-1}$, with different colours in each panel for better contrast) at the peak of the impulsive phase 06:25:52 UT.

connecting the two ribbons. Superposed contours in a colour-coded time sequence of SDO/AIA 211 Å images in Fig. 1b show bi-directional flows away from the source. These flows are also observed at SDO/AIA filters 171, 193, 304, 1600, and 1700 Å. Later on we also show strong red-shifts in both high and low-temperature lines, much faster than are normally seen in red-shifted footpoint emission (e.g. Milligan & Dennis 2009). We also point out the presence of dark filaments connecting the ribbon regions prior to the flare, as seen in SDO/AIA 171 (Fig. 4), 193, 211, and 304 Å, indicating that the already cool and dense coronal region is heated during the flare (e.g. Chifor et al. 2006), explaining both the EUV/UV emission and the high density inferred from Hinode/EIS density diagnostic (Sect. 3.2). Taken all together, these observations lead us to identify the central source as coronal rather than chromospheric. We obtained lightcurves of the coronal source taking the sum of the pixel values inside the box shown in Fig. 1a, for each AIA channel. As shown in Fig. 3a, it had impulsive EUV/UV emission, in all AIA filters (we show 94, 131, and 1600 Å), with a stronger peak reaching a maximum at around 06:25:50 UT and a second one, peaking around 06:27:30 UT, then fading after about 06:30 UT, as can be seen in Fig. 2.

3. Evidence for the energy release site

3.1. A compact, moving source of heating and particle acceleration

RHESSI imaging at non-thermal energies reveal three main sources shown in Fig. 1c at 23–27 keV, integrated for the entire main impulsive phase ($\approx$300 s), closely associated with both ribbons and the coronal source. At the peak of the impulsive phase however, the coronal source emission dominates at all energy ranges as shown by the 4.1–4.9 keV (red contours) and 12.8–15.0 keV (blue) in Fig. 1c. At the HXR peak, the west ribbon source is too faint to be detected by RHESSI owing to its low dynamic range. The high temperature of the plasma at the coronal source suggested by the impulsive emission at 94 and 131 Å is further confirmed by RHESSI imaging spectroscopic analysis. We constructed RHESSI CLEAN (Hurford et al. 2002) images at ten logarithmically-spaced energy bands between 3.0 and 15.0 keV throughout the impulsive phase, using front detectors 3 to 8. We employed OSPEX (Schwartz et al. 2002) to fit the spectra of the spatially unresolved spectra and of the coronal source source separately, giving basic imaging spectroscopy. The HXR spectra were fitted with a isothermal plus thick-target model. The plasma temperature $T$ and emission measure EM from the spectral fits are shown in Figs. 3b, c (in red) along with the values obtained from spatially unresolved spectroscopy. The most remarkable feature is that temperature peaks at $\sim$13 MK around 06:25:40 UT (also seen in the spatially unresolved data), about 10 s before the HXR peak (vertical dashed-lines in Fig. 3).

Inspecting the HXR spectra we note that photons above 10 keV are mostly associated with non-thermal emission. A series of 12–15 keV images constructed using overlapping time intervals of 64 s, centred 10 s apart, allows us to follow the time evolution of the source positions using images with high count statistics. The centroid of the coronal HXR source and 94 Å EUV source are tracked and the centroid X positions are plotted in Fig. 3d. The source barely moves in the Y direction, both in HXR and EUV, consistent with being situated along the loops extending in the east-west direction seen in Fig. 1a. We note that the HXR and EUV centroids are not in exactly the same location, possibly because of uncertainties in the AIA pointing$^1$, slight differences in alignment of different instruments (here, SDO/AIA and RHESSI) and centroid determination at both HXR and EUV images. Nevertheless, they show clear, and

$^1$ See Sect. 6.1 of Guide to SDO Data Analysis at http://www.lmsal.com/sdodocs
patches observed in the images (of a few arcseconds), suggests that the energy is released successively at different locations along the magnetic field, however still around a somewhat small region of around 10 arcsec. This perhaps indicates elementary regions of energy release, and thus heating and acceleration (Liu & Fletcher 2009; Liu et al. 2010).

3.2. EUV Spectroscopy

For the entire flare duration Hinode/EIS was running the HH_Flare+AR_180 × 152 sequence, rastering the region in Fig. 1 from west to east nine times, each scan lasting 318 s. The study used the 2′ slit with a exposure time of 9 s, stepping 6′′ between slit positions. The coronal source is clearly visible in the raster beginning at 06:23:34, as the spectrometer slit crossed the source at 06:26:02 and 06:26:13, 30 s after the non-thermal 12–25 keV HXR peak. The EIS spectra show complex, broadened profiles with a sharp intensity rise in all observed lines, of formation temperatures between log \( T_{\text{max}} \simeq 5.4 \) and log \( T_{\text{max}} = 7.2 \), in agreement with the enhancement in all AIA channels. No cooler temperature response was available in this raster set.

A density diagnostic was carried out using a FeXIV line pair \((\log T_{\text{max}} = 6.3)\) at 264.78 Å and 274.20 Å and gives \( n_e \approx 11.50 \pm 0.82 \) at the coronal source during the impulsive phase. The lower density foreground corona was removed from the diagnostic by subtracting the pre-flare spectra before calculating the diagnostic ratio. Furthermore, the density was obtained from an average of only the flare enhanced region (approx. 5′′ × 6′′) and some pixel locations have higher densities within the region. For comparison, we found that the pre-flare density is \( n_e = 9.26 \pm 0.75 \). The apparent density enhancement of the region can be explained by an already dense region being heated to FeXIV temperatures during the impulsive phase. As pointed out in Sect. 2.1 dark, filamentary loops connecting the ribbon regions prior to the flare are observed in SDO/AIA 171 and 304 Å indicating cool and dense material in the low coronal region. The filament and its evolution can be seen in 171 Å, shown in Fig. 4.

Significant Doppler shifts were visible in the wide 192 Å spectral window which included the strong lines of FeXII \((\log T_{\text{max}} = 6.2)\) at 192.394 Å and FeXXIV \((\log T_{\text{max}} = 7.2)\) at 192.0285 Å. The EIS wavelength scale was calibrated using the standard SolarSoft routines to correct for drifts due to temperature changes from the orbital motion of the spacecraft, and for the slit tilt relative to the CCD. A rest wavelength for the FeXII line was obtained from a quiet region of a pre-flare raster which was used to measure relative Doppler velocities. Here we find a value of 192.391 Å, which is a deviation of 3 mÅ blue-ward of the standard CHIANTI value. Unfortunately the FeXXIV line has no similar pre-flare signal to use as a zero-velocity reference so we use the same deviation measured for FeXII, assuming that it is systematic between lines. Nevertheless, the effect is small, of the order of 5 km s\(^{-1}\), when compared to the measured velocities.

Figures 5a–c show multiple-component fitting for these lines at three slit positions across the source which are both fitted with two components; one corresponding to a stationary or slightly red-shifted component (referred to as left in Fig. 5), and a second highly red-shifted component (right). A blend of FeXII 192.021 Å is observed in the FeXXIV profile which will be significant in hot and dense regions. The standard EIS line FeXII 188.213, nominally used to estimate such blends, was not observed in this raster. In order to remove the FeXII contribution we first created a synthetic...
spectrum from the CHIANTI v7.1.3 atomic database (Dere et al. 1997; Landi et al. 2013) using the default CHIANTI ionisation equilibrium, a density of $10^{11}$ cm$^{-3}$. We also assume a differential emission measure (DEM) obtained by Graham et al. (2013) for flare footpoints—i.e. hot, dense and compact sources, cooling by conduction (see Sect. 4.1) – which we expect to be very similar at least in terms of DEM shape, to the DEM of this coronal source. Obtaining DEMs of the coronal source and ribbons will be the subject of a future study. With these assumptions the intensity ratio of Fe xii 192.021 to Fe xi 192.480 Å transition between the temperature peak and the HXR peak. Interpolating gives similar results as Eq. (2). The heating rate in this phase exceeds the heating rate before the peak particle acceleration. We can estimate the cooling time $\tau$ of the source as the thermal energy $E_{th}$ divided by the conductive ($L_s$) and radiative ($L_r$) loss rates. RHESSI imaging spectroscopic analysis of the coronal source at the temperature peak (06:25:41 UT) gives $EM = 4.5 \pm 1.4 \times 10^{46}$ cm$^{-5}$ and $T = 13 \pm 1$ MK. The thermal energy content $E_{th} = 3k_{b}T(EM \times V)^{1/2} = 1.6 \sim 3.5 \times 10^{29}$ erg, and the volume of the coronal source is estimated as $V = L\pi(D/2)^{2}$, where the length $L = 9 \sim 18$ arcsec and cross-section diameter $D \approx 6$ arcsec were measured from AIA 94 Å images. The conductive energy loss rate is

$$L_c = \frac{k_0}{\Delta s} \frac{\partial T}{\partial s} A = \frac{\kappa_0 T^{5/2} \Delta T}{\Delta s} A, \quad (1)$$

where $k_0 = 10^{-6}$ erg s$^{-1}$ cm$^{-1}$ K$^{-7/2}$ is the Spitzer conductive coefficient, $\Delta s = L/2$ is half the length of the coronal source, $A = \pi(D/2)^{2}$ is the cross-section area of the source, and $\Delta T = 3$ MK, assuming that the loop temperature outside the coronal source is 10 MK. The radiative loss rate can be estimated by (Rosner et al. 1978)

$$L_r = 10^{-17.73} EM \frac{T^{2}}{3} \left( 10^{6.3} < T < 10^{7} \right) \quad (2).$$

We found that $L_c \gg L_r$, thus the cooling time is $\tau = E_{th}/(L_c + L_r) = E_{th}/L_c \approx 14 \sim 38$ s, consistent with the time between the temperature peak and the HXR peak. Interpolating the CHIANTI 7.1 table for the radiative losses (for a density of $log n = 10$ and coronal abundances) for the given EM and $T$ gives similar results as Eq. (2). The heating rate in this phase must be lower than the total cooling rate of $L_t + L_c \approx 4 \sim 8 \times 10^{26}$ erg s$^{-1}$, and the energy input (heating) rate to the thermal plasma must occur before the maximum of particle acceleration.

4. Discussion

4.1. Thermal properties of the coronal source

The coronal source is impulsively heated, reaching 12–13 MK (from HXR data), up to 16 MK (Fe xiv emission line) and cools fast. The temperature peak is reached about 10 s before the HXR peak which indicates that the plasma cooling rate exceeds the heating rate before the peak particle acceleration. To determine the density $n$ of the coronal source we use the DEM given by Graham et al. (2013) in values of $EM$ and $T$. Interpolating from the CHIANTI 7.1 table for the radiative losses (for a density of $log n = 10$ and coronal abundances) for the given EM and $T$ gives similar results as Eq. (2). The heating rate in this phase must be lower than the total cooling rate of $L_t + L_c \approx 4 \sim 8 \times 10^{26}$ erg s$^{-1}$, and the energy input (heating) rate to the thermal plasma must occur before the maximum of particle acceleration.

Fig. 4. Time sequence of SDO/AIA 171 Å images showing the pre-flare filament, the evolution of the ribbons and coronal source during the flare.
where \( \mu \) is the electron pitch-angle cosine, \( e \) is the electron charge, and \( \ln A = 20 \) is the Coulomb logarithm. We then obtain the energy of an electron that is completely stopped in the coronal source:

\[
E_0[\text{keV}] = \frac{n_e L}{(\mu_0 10^{27})^2}.
\]

For \( \mu = 1 \) (a beam) the minimum kinetic energy that electrons need to leave the region is \( E_0 = 45 \sim 65 \text{ keV} \). If \( \mu < 1 \) higher energy electrons will be stopped in the corona – for example, for a semi-isotropic distribution, the average pitch-angle cosine is 0.5, and \( E_0 = 65 \sim 90 \text{ keV} \). Electrons with energies lower than \( E_0 \) will be stopped completely within the coronal source, heating the plasma. Particle trapping due to magnetic field convergence between corona and chromosphere will further enhance the coronal source intensity, as will any non-collisional pitch-angle scattering in the region, which enhances the trapping of electrons inside the coronal loops (e.g. Simões & Kontar 2013; Kontar et al. 2014). Overall the picture is consistent with the coronal HXR source being caused by a brief burst of non-thermal particle acceleration in a dense coronal accelerator, with the electrons then stopping predominantly within that region.

4.3. Flows in the coronal source

Fast plasma flows detected by spectroscopic observations have been reported as direct evidence of reconnection flows (Wang et al. 2007; Hara et al. 2011). Recently, Brosius (2012) reported observations of a sudden rise of the emission of the Fe XIX line, formed at 8 MK, without enhancements of line emission from ions formed at lower temperatures. In addition, significant non-thermal broadening of the Fe XIX line was attributed to reconnection outflow or turbulence, and led Brosius (2012) to the conclusion of direct coronal heating. A pressure gradient created by heating may additionally drive a flow. In the event studied here, flows are detected by EIS spectroscopy and by AIA imaging in the 171, 193, 211 (shown in Fig. 1b) and 1600 Å filters. Using 1600 Å images, we estimated the flow speed from the coronal source towards the west ribbon by verifying the brightness evolution along the arrow in Fig. 6c. The resulting time-position diagram is shown in Fig. 6d where two flows can be identified with their estimated speeds: \( v_1 = 149 \text{ km s}^{-1} \) and \( v_2 = 76 \text{ km s}^{-1} \). The onset of both flows seem to be well associated with the HXR peaks (Fig. 6f). Before the AIA outflows are observed, when the EIS slit first catches the coronal source at 06:26:02, the left components of Fe XII and Fe XXIV are at rest (\( \pm 5 \pm 4 \) and \( 15 \pm 6 \text{ km s}^{-1} \)) while the right components have \( v = 200 \sim 250 \text{ km s}^{-1} \) (see Fig. 5a). At the subsequent slit positions, still over the coronal source, at 06:26:13 and 06:26:24, both Fe lines are stronger by a factor of \( \approx 2 \) and show left redshift velocities of \( v = 40 \text{ km s}^{-1} \), at the time when of the AIA flow is first visible. For Fe XII, the right component gets weaker and slower (see Figs. 5b, c). Assuming that the plasma velocity is composed of the EIS left line-of-sight velocity, \( v_{\text{EIS}} = 40 \text{ km s}^{-1} \), and AIA plane-projected velocity \( v_{\text{AIA}} = 149 \text{ km s}^{-1} \), a simple triangular geometry yields \( v_0 = (v_{\text{EIS}}^2 + v_{\text{AIA}}^2)^{1/2} \approx 155 \text{ km s}^{-1} \).

4.4. Interpretation of flows as pressure-driven

The high pressure in the coronal source may drive plasma outflows along the field. Assuming that the observed flows are field-aligned, the mean angle between the magnetic field

---

**Fig. 5.** Fitted EIS spectra at three positions (and times) across the coronal source, as indicated in Fig. 6a. The specific intensity is shown in the solid black line, with the associated data uncertainty, and the dotted black line shows the total fit to the data. Two fitted Gaussian components for Fe XXIV are shown in green, for Fe XII in red, and the estimated blend of Fe XI in black (dash-dotted line). A vertical dash-dotted line marks the rest wavelength for the Fe XXIV 192.028 Å and Fe XII 192.394 Å lines, and Doppler velocities relative to these wavelengths for each fitted component are also shown.

**4.2. Non-thermal properties of the coronal source**

The coronal HXR source is compact and intense, dominating the footpoint emission (Fig. 1c). An obvious interpretation is of a localised acceleration site, and a high local density, so that a large fraction of the electrons are completely stopped in the region (Wheatland & Melrose 1995). The electron density measured by EIS is \( \log n_e \approx 11.50 \text{ cm}^{-3} \), and \( L \) is 9–18 arcsec. This gives a column depth in the coronal source of 2.1–4.1×10^{20} \text{ cm}^{-2}. From the relationship between stopping column depth \( N_{\text{stop}} = n_e L \) and energy \( E_0 \) of an electron that is collisionally stopped over column \( N \) (Emslie 1978; Tandberg-Hanssen & Emslie 2009)

\[
N_{\text{stop}} = \frac{\mu e^4}{6\pi \mu_0 \ln A} E_0^2 \approx 10^{17} \mu (E_0[\text{keV}])^2,
\]
at the coronal source and the line of sight would be \( \theta = \arctan\left(\frac{v_{\text{AIA}}}{v_{\text{EIS}}} \right) \approx 75^\circ \). Such pressure-driven flows would have speed approximately equal to the ion sound speed,

\[
c_s = \left(\frac{\gamma Z k T}{m_i}\right)^{1/2},
\]

where for ionised hydrogen \( Z = 1 \), \( \gamma = 5/3 \), and \( m_i \) is the proton mass. Taking the temperature of formation of the Fe XII line as \( T = 1.3 \, \text{MK} \), we find \( c_s = 132 \, \text{km s}^{-1} \) and for Fe XXIV (formed at \( T = 15.8 \, \text{MK} \)), \( c_s = 467 \, \text{km s}^{-1} \). Within the uncertainties, \( v_{\text{flow}} \approx c_s \) for \( T = 1.3 \, \text{MK} \) indicating that the observed AIA flows and EIS (left) red-shifts could be driven by the pressure gradient between the hot, compact coronal source, and its immediate surroundings.

### 4.5. Interpretation in terms of component magnetic reconnection

The loop geometry observed in this event cannot be explained by the CHSKP model, but may fit better with the scenario investigated by Melrose (1997, 2004) of reconnection between crossing, current-carrying loops, in which current and magnetic flux are exchanged between loops. This is usually described in terms of quadrupolar reconnection (Hardy et al. 1998; Aschwanden et al. 1999). The black lines sketched in Fig. 6e represent pre- and post-flare field lines in this configuration, which are consistent with the magnetic polarities of the footpoints, and also the role of the coronal source as a possible location of local plasma energisation. Since they cross at an angle, the reconnection is...
between the anti-parallel components of the field (we ignore for now any internal twist in the reconnecting pre-flare loops), with an outflow speed reduced compared to the Alfvén speed (Chae 1999), i.e. $v_{\text{outflow}} = v_A \sin(\theta/2) = B \sin(\theta/2) / (4 \pi n_e c)^{1/2}$ where $\theta$ is the angle between the crossing field. Chae (1999) also gives an expression for the maximum energy $\Delta E$ that can be released in the process as the loops shorten,

$$\Delta E = 2 \left(1 - \cos \frac{\theta}{2} \right) L A B^2 / 8 \pi,$$

for pre-reconnection loop length $L$ and cross-sectional area $A$. The value of $B$ can be deduced from the plasma flow. A 2D planar interpretation of the geometry in Fig. 6c would mean that $v_{\text{outflow}}$ would be oriented along the cut direction shown.

Time-slices of intensity along the cut in Fig. 6e are plotted in Fig. 6f, and the spreading of the two ridges corresponds to a speed of $\sim 14$ km s$^{-1}$. However, with the electron number density of $\sim 3.2 \times 10^{11}$ cm$^{-3}$ from the EIS diagnostics, and an angle 30° between the dashed lines in the 2D geometry, we obtain $B \sim 14$ G, which is a rather small value. This implies that the geometry is not 2D. Instead we take the measured EIS speed of around 200 km s$^{-1}$ tentatively associated with loop retraction, as a guide to the outflow speed, but we only have a lower limit to $\theta$, as the dashed lines in Fig. 6e would represent the field in projection. Using these values give $B \gtrsim 200$ G, more in line with expectation, as photospheric magnetic fields up to 1000 G associated with the position of the ribbons are observed by SDO/HMI. Using $L \sim 90$ arcsec, the maximum energy release

![Fig. 7. Fitted EIS spectra across the coronal source, as for the same positions in Figs. 5a–c, at various temperatures. The vertical dashed-dotted line marks the rest wavelength determined from the quiet background. The rest wavelength of each ion, formation temperature and velocity of the red-shifted components are indicated in each panel.](image)
is $\gtrsim 7.0 \times 10^{11}$ A erg. A nominal value of $A$, relative to the diameter of reconnecting loop strands of one arcsecond, would give $\Delta E \sim 2.9 \times 10^{25}$ erg per pair of strands. From RHESSI imaging spectroscopic analysis, we found the total non-thermal energy of the electrons in the coronal source $E_{\text{non-thermal}} = 3.5 \times 10^{29}$ erg, integrating the impulsive phase (06:23:34 to 06:28:42 UT), which yields an energy rate of $\approx 10^{28}$ erg s$^{-1}$. This would require the reconnection of about one pair of strands every three seconds on average, or about 120 strands through the main impulsive phase, corresponding to a bundle of strands around 11″ thick, about twice the estimated width of the coronal source. The spreading motion seen in Fig. 6f does still require an explanation; perhaps this is associated with the spreading of the reconnection site across a surface between two sheets of crossed magnetic field.

5. Conclusions
We present clear observational evidence of the direct energy release and heating and possibly acceleration site during a non-eruptive two-ribbon flare. Combined RHESSI, Hinode/EIS, and SDO/AIA observational data reveal a coronal source, located roughly between the flaring ribbons, being heated impulsively. The coronal source shows fast downflow plasma flows at 40–250 km s$^{-1}$ at two different temperatures, measured through Doppler shifts of emission lines Fe xii $(\log T = 6.2)$ and Fe xxiv $(\log T = 7.2)$ by Hinode/EIS. RHESSI imaging spectroscopy reveals that the coronal source is suddenly heated, reaching a temperature peak of 12–13 MK about 10 s before the main HXR peak. Its fast cooling time is consistent with conductive losses, and implies that heating at the site reaches a peak before the peak of particle acceleration. Moreover, RHESSI HXR imaging shows that the coronal source dominates the footpoint emission at the peak of the impulsive phase. This is consistent with a scenario where plasma is first heated, and then electrons are accelerated in a turbulent and dense coronal source, with newly accelerated electrons are collisionally stopped before leaving the region. The energy deposited further heats the plasma, which then flows from the region at speeds around the sound speed towards each ribbon. These flows are observed as red-shifted emission lines by EIS and plasma motions by AIA images. This event does not show any eruptions and it is not associated with a CME. It may be explained by component magnetic reconnection between current-carrying loops. In such a geometry, the energy that can be released seems to plausibly account for the flare energetics observed.
