ABSTRACT

Aims. Type III radio bursts are intense radio emissions triggered by beams of energetic electrons often associated with solar flares. These exciter beams propagate outwards from the Sun along an open magnetic field line in the corona and in the interplanetary (IP) medium.

Methods. We performed a statistical survey of 29 simple and isolated IP type III bursts observed by STEREO/Waves instruments between January 2013 and September 2014. We investigated their time-frequency profiles in order to derive the speed and acceleration of exciter electron beams.

Results. We show these beams noticeably decelerate in the IP medium. Obtained speeds range from $\sim 0.02c$ up to $\sim 0.35c$ depending on initial assumptions. It corresponds to electron energies between tens of eV and hundreds of keV, and in order to explain the characteristic energies or speeds of type III electrons ($\sim 0.1c$) observed simultaneously with Langmuir waves at 1 au, the emission of type III bursts near the peak should be predominately at double plasma frequency. Derived properties of electron beams can be used as input parameters for computer simulations of interactions between the beam and the plasma in the IP medium.

Key words. Sun: radio radiation – Sun: particle emission – plasmas – methods: data analysis

1. Introduction

Type III radio bursts are produced by beams of suprathermal electrons accelerated near the Sun's surface during solar flares (Wild 1950). These exciter beams propagate outwards from the Sun along an open magnetic field line in the corona and in the interplanetary (IP) medium at large distances beyond 1 au, where suprathermal electrons can be detected in situ by spacecraft. They locally produce a bump-on-tail instability that leads to a generation of electrostatic Langmuir waves near the local plasma frequency f_{pe} . The conversion of Langmuir waves into escaping electromagnetic emission is believed to be due to nonlinear interactions involving electromagnetic waves: type III radio bursts near f_{pe} (the fundamental, F -component) or near $2f_{pe}$ (the harmonic, H -component), which can be observed remotely (Lin 1970; Gurnett & Anderson 1976). This conversion involves the wave-wave interactions of Langmuir, ion acoustic and electromagnetic waves (Ginzburg & Zhelezniakov 1958). Since electron beams propagate away from the Sun, the characteristic emission frequency decreases to consecutively lower frequencies corresponding to a decrease in f_{pe} .

Although we can distinguish the F - and H -components from metric to decametric wavelengths (i.e. of coronal origin), it is difficult to determine the observed component of type III bursts at longer wavelengths, which are generated in the IP medium. However, we can recognize the F - and H -components for cases where type III triggering electron beams intersect the spacecraft, those associated with Langmuir waves observed in situ

(Kellogg 1980). Nonetheless, such events occur rather seldom. Although IP type III bursts are generally assumed to be emitted at the harmonic of the electron plasma frequency (Reiner et al. 1992; Mann et al. 1999), we will discuss presence of both components separately.

Since early observations, the characteristic exciter speeds associated with type III bursts have normally been found in the range 0.1–0.6c. Dulk et al. (1987) investigated both onset and peak times of type III bursts associated with measurements of Langmuir waves and suprathermal electrons by the ISEE-3 spacecraft assuming presence of the F -component alone (Scarf et al. 1978; Anderson et al. 1978). They showed the exciter beam speed of 0.14c and 0.07c using onset and peak times, respectively. Hoang et al. (1994) have studied onset times of the type III bursts observed by the URAP instrument onboard the Ulysses spacecraft (Stone et al. 1992) using the same approach as Dulk et al. (1987). Hoang et al. (1994) concluded that the exciter beam speed ranges from 0.04c to 0.13c. However, the variation in these speeds proved to be more challenging. Fainberg & Stone (1970) have suggested that the beams are propagating over 1 au with little deceleration. Later, Poquérousse et al. (1996) suggest that deceleration occurs before about 0.1 au, and that there is no significant correlation between the initial and final speeds. The STEREO provides radio data with significantly better resolution than used in the above-mentioned studies.

In this paper, we present statistical results on speed and acceleration of exciter beams of IP type III radio bursts observed by the Solar TERrestrial Relations Observatory (STEREO). In Sect. 2.1 we focus on the instrumentation. In Sect. 2.2 we describe our data set. Then we show a detailed analysis of one IP

[★] Appendix A is available in electronic form at <http://www.aanda.org>

type III radio burst to illustrate the methods we used (Sect. 2.3). We present statistical results for exciter speeds and acceleration in Sect. 2.4.

2. Observations and data analysis

2.1. The STEREO spacecraft

STEREO consists of two identical spacecraft orbiting the Sun and providing a unique stereoscopic view of the solar-terrestrial system (Kaiser et al. 2008). The STEREO/Waves instrument records electric field fluctuations by three monopole antennas (Bougeret et al. 2008; Bale et al. 2008). For analysis of type III radio bursts we use data recorded by the Low Frequency Receiver (LFR, 10 kHz–160 kHz in 32 logarithmically spaced frequency channels) and High Frequency Receiver (HFR, 125 kHz–16.025 MHz in 319 linearly spaced frequency channels). The time resolution of both receivers is 38 s. With LFR and HFR we can investigate radio emissions that originate somewhere from $2 R_S$ up to the 1 au of the Sun when assuming an average electron density model in the solar wind (Cecconi et al. 2008). However, we are unable to accurately calculate frequency drifts of type III radio bursts above 1 MHz owing to low time resolution of the STEREO/Waves instrument. Therefore we limit our analysis to below 1 MHz. Both receivers can operate either in the three-monopole mode or in the dipole-monopole mode. We analysed the data only in the three-monopole mode. The LFR and HFR have been operating in this mode since January 2013 and May 2007, respectively. We subtracted receiver background levels from the data to improve the signal-to-noise ratio. These levels were calculated as median values over a long period of 15 days for each channel–antenna configuration separately. More details on method used can be found in Krupar et al. (2010, 2012, 2014b).

2.2. Data set

We performed a statistical analysis of 29 type III radio bursts observed by STEREO/Waves between January 2013 and September 2014. Only intense, simple, and isolated cases (i.e. without overlapping) with a low frequency cutoff below 100 kHz have been included in our data set. These constraints resulted in relatively few suitable events for time – frequency investigation. However, this helped to select radio bursts with smooth monotone relation between peak time and frequency.

2.3. September 27, 2013 type III radio burst

We show an analysis of an IP type III radio burst on September 27, 2013 to illustrate the methods used. Figures 1a–d display the flux density S measured by LFR and HFR onboard STEREO-A and STEREO-B. Both spacecraft detected the simple and isolated type III radio burst with a starting time of about 14:20 UT. The low frequency cutoff is 60 kHz and 80 kHz for STEREO-A and STEREO-B, respectively. We excluded frequencies above 1 MHz because of the insufficient time resolution of the receiver. During this event STEREO-A was 140° west of a Sun–Earth line at 0.97 au from the Sun, whereas STEREO-B was 146° east and 1.05 au of the Sun.

We investigated times corresponding to peak fluxes since onset times are difficult to accurately identify owing to density variations that result in fluctuations of the quasi-thermal noise (Meyer-Vernet & Perche 1989). Frequency channels have been converted to radial distances from the Sun considering both

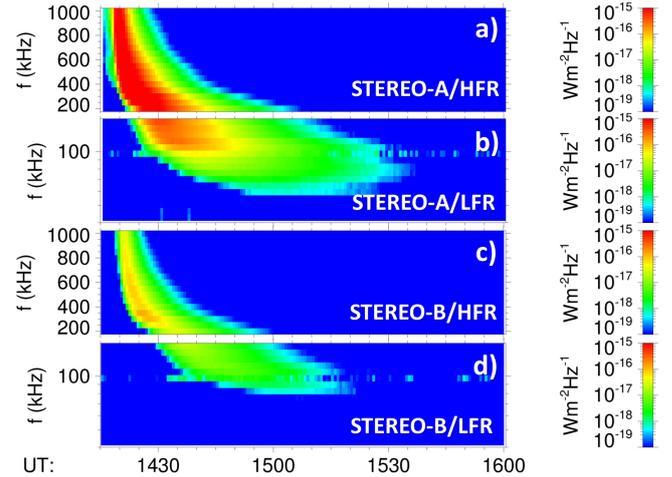

Fig. 1. Analysis of measurements recorded from 14:15 to 16:00 UT on September 27, 2013: the flux density S for STEREO-A (panels a), and b)) and STEREO-B (panels c), and d)).

the F -component (r_F) and the H -component (r_H) using the electron density model in the IP medium by Sittler & Guhathakurta (1999). It allows the obtained times to be corrected for a light travel time frequency by frequency from the source to the spacecraft with a radial distance from the Sun ($r_{S/C}$):

$$t_i(f) = t(f) - \frac{r_{S/C} - r_i(f)}{c}, \quad (1)$$

where f represents frequency, c is a speed of light, and i stands for the F - and H -components. This correction assumes that radio sources are located on the Sun-to-spacecraft line. The validity of this assumption has been tested using computer simulations in Appendix A.

Previous studies of exciter beam speed were dedicated to events associated Langmuir waves observed in situ (Dulk et al. 1987; Hoang et al. 1994; Robinson & Cairns 1994) resulting in different assumptions on radio source locations. Plasma parameters measured onboard were used to estimate the Parker spiral geometry together with the density profile along it (Parker 1958). However, this approach does not consider a propagation of plasma parameters between the Sun, so the spacecraft located at 1 au. It can take up to several days for the solar wind to travel between the corona and the spacecraft and both plasma speed and density, used for the Parker spiral reconstruction, may differ significantly from measurements in situ. Because of this drawback and since our events were not associated with Langmuir waves, we assume that the radio sources lies on the Sun-to-spacecraft line, so the average electron density model in the ecliptic was used.

A comparison between corrected times and frequencies converted into radial distances allows speed and acceleration of exciter beams to be derived. However, this simple method does not take several important ambiguities into account. The first is that we are unable to distinguish the F - and H -components of IP type III radio bursts. The distance r_H is typically twice greater than r_F resulting in about twice greater beam speed and acceleration for the H -component than for the F -component. Therefore we discuss our results considering the presence of both components throughout the paper. Moreover, triangulated radio sources of IP type III radio bursts lie at considerably (five times for the F -component and three times for the H -component) larger radial distances from the Sun than the electron density models predict (Steinberg et al. 1984; Krupar et al. 2014a). It indicates that we

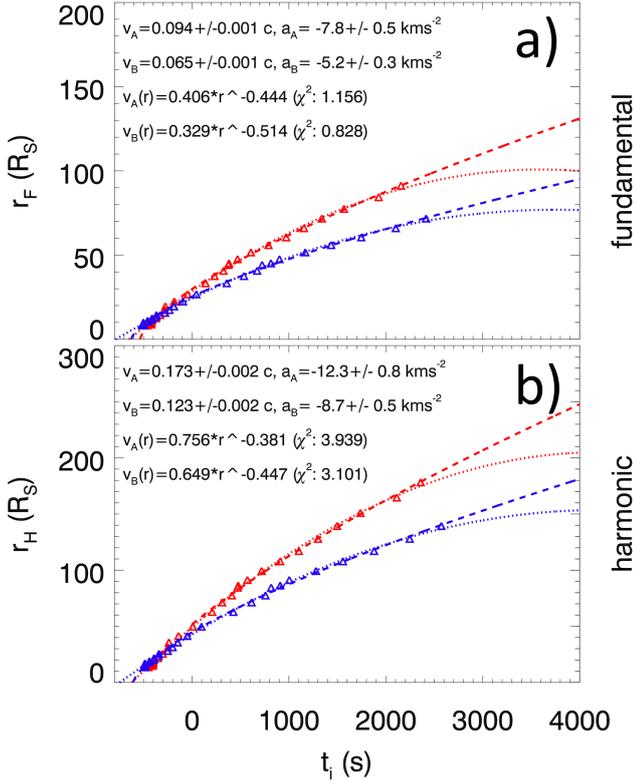

Fig. 2. Analysis of measurements recorded from 14:15 to 16:00 UT on September 27, 2013: radial distances from the Sun vs. corrected times for STEREO-A (in red) and STEREO-B (in blue) assuming the F - (panel a) and H -component (panel b)). Dotted lines represent results of the polynomial model (Eq. (3)). Dashed lines show the power law model (Eq. (6)). Obtained parameters of both models are shown on the top.

observed only scattered images of real sources that are apparently very extended. We thus conclude that the presented method provides us with a lower bound estimate of the exciter speed.

Figures 2a and 2b display radial distances from the Sun (r_F and r_H) as a function of corrected times (t_F and t_H). We used two models to fit the r_i vs. t_i dependence. Initially, we considered a constant acceleration, when the speed (v_i) is a linear function of time (t_i):

$$v_i(t_i) = v_{0i} + a_i t_i, \quad (2)$$

where v_{0i} is a beam speed at $t_i = 0$ (an initial speed in [km s^{-1}]), and a_i represents the beam acceleration in [km s^{-2}]. The corresponding relation between r_i and t_i is then

$$r_i(t_i) = r_{i0} + v_{0i} t_i + \frac{1}{2} a_i t_i^2, \quad (3)$$

where r_{i0} is an initial distance from the Sun at $t_i = 0$. We denote it as “the polynomial model” which represents the simplest approach for estimation of both initial speed and acceleration.

The second model assumes that a beam speed v_i has a power law dependence on the radial distance r_i from the Sun as

$$v_i(r_i) = \alpha_i (r_i/R_S)^{\beta_i}, \quad (4)$$

where α_i represents the beam speed at $1 R_S$ (a power law initial speed) and β_i denotes power-law index, so that positive values of β_i represent acceleration. Since we measure r_i vs. t_i we need to solve the first-order nonlinear differential equation:

$$\frac{dr_i}{dt_i} = \alpha_i (r_i/R_S)^{\beta_i}. \quad (5)$$

By separating variables we obtain the following relation between r_i and t_i :

$$r_i(t_i) = [(1 - \beta_i)(\alpha_i t_i + C_i) R_S^{-\beta_i}]^{\frac{1}{1-\beta_i}}, \quad (6)$$

where C_i is the constant of integration. Since both numerical simulations (Kontar 2001) and theoretical relationships suggest that the velocity should vary as a power of the distance of the source from the Sun (Robinson 1992), we denote it as “the power law model”. The acceleration a_i for this model can be obtained by differentiation of Eq. (4):

$$a_i(r_i) \equiv \frac{dv_i}{dt} = \beta_i \alpha_i \left(\frac{r_i}{R_S} \right)^{\beta_i - 1} \frac{1}{R_S} \frac{dr_i}{dt} = \frac{\beta_i \alpha_i^2}{R_S} \left(\frac{r_i}{R_S} \right)^{2\beta_i - 1}. \quad (7)$$

We performed a polynomial regression of the second order to estimate type III exciter beam parameters according to the polynomial model (Eq. (3)). Calculated initial speeds are greater at STEREO-A than at STEREO-B. This difference is probably related to the time correction method. The stronger signal at STEREO-A suggests that the electron beam propagates more towards STEREO-A than STEREO-B. The time correction method thus underestimates the calculated speed slightly at the latter (Appendix A). The F -component assumption (panel a) provides us with slower speeds when compared to the H -component as it can be expected. Our results indicate that the electron beam decelerates ($a_F \sim -7 \text{ km s}^{-2}$ and $a_H \sim -12 \text{ km s}^{-2}$) depending on an assumption on the observed component. For the power law model, we used a nonlinear least squares fit of the spacecraft data with Eq. (6). The parameters of the model obtained with a χ^2 goodness-of-fit statistic weighted by the measurement error are shown in Fig. 2. Negative values of β confirm that the electron beam decelerates.

Both models fit the data very well. We observe a discrepancy between the two models for larger distances from the Sun when the polynomial model predicts greater deceleration when compared to the power model. Since exciter beams typically travel far beyond 1 au, the exciter power law model seems to be more applicable for larger distances from the Sun. However, exciter speeds farther from the Sun, and the initial speeds (v_{i0} , α_i), where we do not have any data, are dubious since they represent an extrapolation of both models.

2.4. Statistical results

We performed the above described propagation analysis on 29 IP type III radio bursts observed by STEREO/Waves between January 2013 and September 2014 case by case (Sect. 2.2).

Figures 3a–d display histograms of the acceleration coefficient a_i and β_i . Median values of the acceleration for the F -component a_F are $\sim -4 \text{ km s}^{-2}$ while the acceleration for the H -component a_H is about 50% larger than a_F . However, both β_F and β_H are comparable for the power law model (~ -0.35). Figures 3e and f show the relation between the acceleration and the radial distance from the Sun for both models using median values from panels above. While the acceleration is obviously constant for the polynomial model (Fig. 3e), it decreases for the power law model with a radial distance (Fig. 3f). The acceleration for both models are comparable between $5 R_S$ and $20 R_S$.

Figure 4 shows results on exciter beam speeds v_i vs. radial distance r_i for all events. Curves represent only the data that have been measured by STEREO (i.e. above the low frequency cutoff case by case, Figs. 4a–d). Calculated speeds range from $\sim 0.02c$ to $\sim 0.22c$ and from $\sim 0.03c$ to $\sim 0.35c$ for the F - and

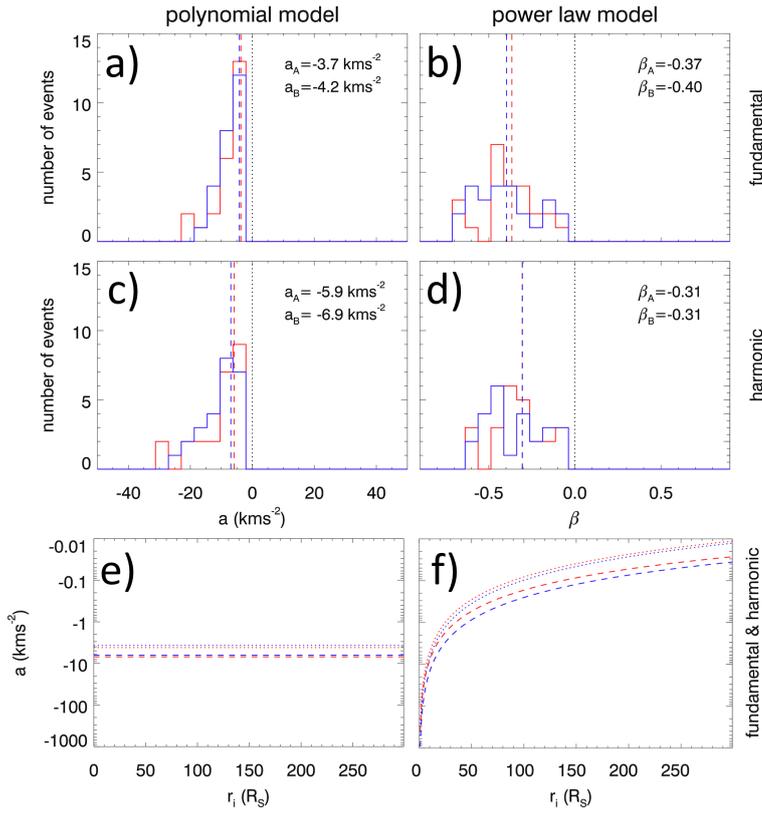

Fig. 3. Panels **a)–d)**: histograms of the acceleration coefficient a (the polynomial model, Eq. (3)) and the acceleration coefficient β (the power law model, Eq. (6)) assuming the F - and H -component for STEREO-A (in red) and STEREO-B (in blue). Dashed lines indicate median values. Black dotted lines show zero values. Panels **e)** and **f)**: acceleration vs. distances for the polynomial and power-law models for STEREO-A (in red) and STEREO-B (in blue). Dotted and dashed lines represent F - and H -components, respectively.

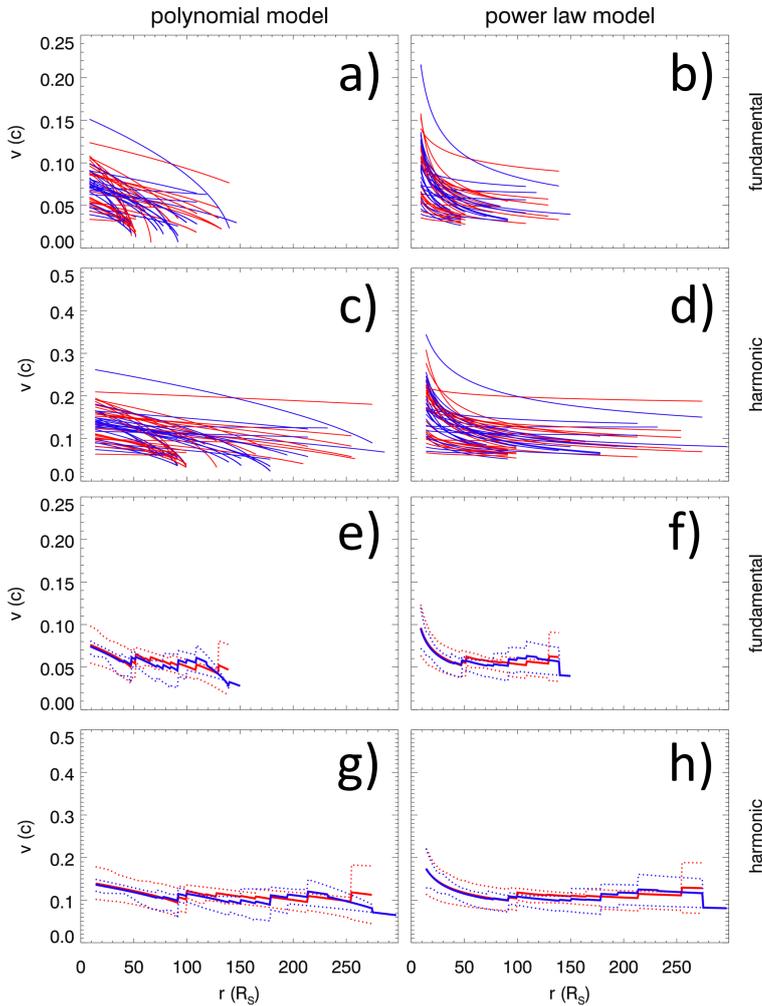

Fig. 4. Panels **a)–d)**: Exciter beam speeds v_1 vs. radial distance r_1 for all events considering the polynomial model (Eq. (3)) and the power law model (Eq. (6)) for STEREO-A (in red) and STEREO-B (in blue). Panels **e)–h)**: median values (solid lines) and 25th/75th percentiles (dotted lines) of data in panels **a)–d)**.

H-components, respectively. From individual kinematic curves, we calculated median beam speeds with the 25th and the 75th percentiles (Figs. 4e–h). The statistical curves we obtained contain jumps due to the termination of some bursts. Median values of the speeds decrease from $\sim 0.09c$ to $\sim 0.04c$ and from $\sim 0.16c$ to $\sim 0.09c$ for the *F*- and *H*-component, respectively. It suggests that the exciter beams of IP type III radio bursts decelerate in the solar wind. However, other interpretations of this statistical results can be proposed: the observed deceleration could be an apparent observational effect caused by stronger scattering and thus larger refractive index of radio waves at lower frequencies. The important role of scattering of IP type III bursts has been demonstrated via the Monte Carlo simulations by Thejappa et al. (2007). The power law model provides us with more reasonable beam speeds when extrapolated to 1 au, while the polynomial model predicts a beam halt before 1 au which is not generally observed.

3. Conclusions

We investigated the properties of 29 simple and isolated type III radio bursts observed by the two STEREO spacecraft. The *F*- and *H*-components have been considered using two different models for estimating the exciter beam speed and acceleration. We show a detailed analysis of one event from our data set as an example. The presented method provides us with a lower bound estimate of the exciter speed.

Our results suggest that exciter beams decelerate in the IP medium (Fig. 3). The collisional losses cannot account for this effect: the collisional mean free path of electron with kinetic energy ~ 10 keV in typical solar wind plasma is higher than 1 au and the cumulative effect of collisions on the beam energy is negligible. The deceleration can be explained by the energy loss of electron beams due to instabilities producing Langmuir waves and the effect of solar-wind inhomogeneities on these waves. This loss of the energy is a two-step process. First, Langmuir waves are generated by the front the beam. Second, these wave are refracted in decreasing plasma density towards high wave numbers (lower phase velocities), thereby reducing the level of waves that can be re-absorbed by the beam (e.g. Kontar 2001). Large scale simulations of electron transport show that a large part of the initial energetic electron energy is lost via Langmuir waves due to plasma inhomogeneity (Reid & Kontar 2013). The obtained acceleration a_i ranges from ~ -4 km s $^{-2}$ to ~ -7 km s $^{-2}$. Derived exciter speeds vary between $\sim 0.02c$ and $\sim 0.35c$, which corresponds to electron energies from tens of eV up to hundreds of keV (Fig. 4), where the higher speeds correspond to the *H*-component. A comparison with energies of electron beams detected in situ suggest that the *H*-component predominantly occur in our data set (Lin et al. 1996).

However, the deceleration could also be related to stronger scattering at lower frequencies. Presented properties of type III exciter beams can be used as input parameters for computer simulations of beam – plasma interactions in the IP medium.

Fig. A.1. Simulated beam speeds vs. deviation angle $\Delta\phi$. Colors denote beam speeds (red: $0.2c$, green: $0.14c$, and blue: $0.07c$). The fundamental and harmonic components are represented by solid and dashed lines, respectively. Horizontal lines indicate initial speeds. Dash-dotted lines show maximal and mean separation angles between the two STEREO in our data set.

Appendix A: Time correction method validation

We validated our time correction method via simulations of electron beams propagating away from the Sun (Fig. A.1). Simulated beams travel with a given constant speed along the X axis while emitting radio emissions at frequencies between 40 kHz and 1 MHz (i.e. at a frequency range of STEREO/Waves used in this study). We have considered the F - and H -components using the electron density model by Sittler & Guhathakurta (1999). A modeled spacecraft lies on a circle around the Sun with a radius of 1 au in the ecliptic ($Z = 0$), so its position can be parametrized by angle $\phi = \arctan \frac{y}{x}$. We applied the time correction method (Eq. (1)) to observed times by the modeled spacecraft. Our results show that differences between initial and derived beam speeds are negligible for small angles. For a mean separation angle between the two STEREO spacecraft

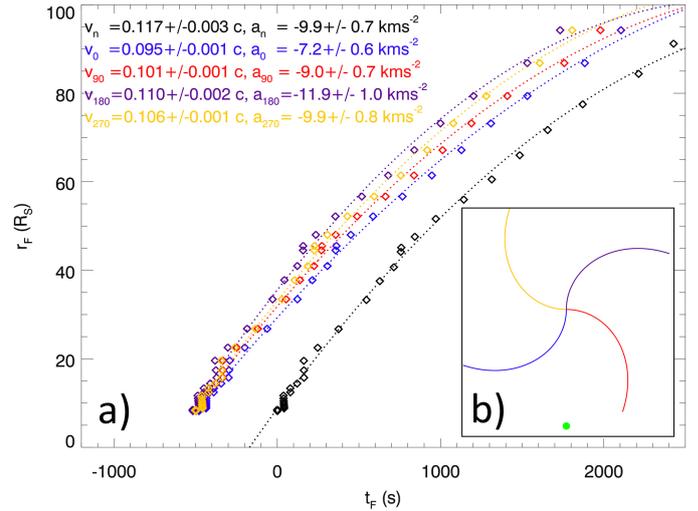

Fig. A.2. Analysis of measurements recorded by STEREO-A from 14:15 to 16:00 UT on September 27, 2013 assuming the F -component: panel a): radial distances from the Sun vs. uncorrected (in black) and corrected times assuming Parker-spiral propagation (in blue, red, purple, and orange); panel b): Parker-spiral paths and the spacecraft location (in green).

in our data set ($\phi = 50^\circ$), this difference ranges from 1% to 7%. The difference at $\phi = 100^\circ$ varies between 7% and 20%. Moreover, variations between the F - and H -components are minor.

We also investigated the role of Parker-spiral propagation on estimates of speed and acceleration (Fig. A.2). We analyzed the data from STEREO-A from September 27, 2013 assuming the F -component (Sect. 2.3). The emitting energetic electrons were assumed to travel along four Parker-spiral lines with respect to spacecraft position. The parameters obtained for various time corrections are not significantly different. For a comparison, results with no time correction are shown in black. We thus conclude that the time correction method is applicable to our data set and that it provides us with reasonable results for electron beam dynamics with typical speeds in the solar wind.
