ABSTRACT

The secular evolution of an infinitely thin tepid isolated galactic disc made of a finite number of particles is described using the inhomogeneous Balescu-Lenard equation. Assuming that only tightly wound transient spirals are present in the disc, a WKB approximation provides a simple and tractable quadrature for the corresponding drift and diffusion coefficients. It provides insight into the physical processes at work during the secular diffusion of a self-gravitating discrete disc and makes quantitative predictions on the initial variations of the distribution function in action space. When applied to the secular evolution of an isolated stationary self-gravitating Mestel disc, this formalism predicts the initial importance of the corotation resonance in the inner regions of the disc leading to a regime involving radial migration and heating. It predicts in particular the formation of a ridge-like feature in action space, in agreement with simulations, but over-estimates the timescale involved in its appearance. Swing amplification is likely needed to resolve this discrepancy. In astrophysics, the inhomogeneous Balescu-Lenard equation and its WKB limit may also describe the secular diffusion of giant molecular clouds in galactic discs, the secular migration and segregation of planetesimals in proto-planetary discs, or even the long-term evolution of population of stars within the Galactic centre.

Key words. galaxies: evolution – galaxies: kinematics and dynamics – galaxies: spiral – diffusion – gravitation

1. Introduction

Understanding the dynamical evolution of galactic discs over cosmic times is a long-standing endeavour. Self-gravitating discs are cold dynamical systems, for which rotation represents an important reservoir of free energy. Fluctuations in the potential induced by discrete (possibly distant) encounters may be strongly amplified, while resonances tend to confine and localise their produced by discrete (possibly distant) encounters may be strongly amplified, while resonances tend to confine and localise their dissipation: such small stimuli can lead to the spontaneous production of a self-gravitating discrete disc and makes quantitative predictions on the initial variations of the distribution function in action space. When applied to the secular evolution of an isolated stationary self-gravitating Mestel disc, this formalism predicts the initial importance of the corotation resonance in the inner regions of the disc leading to a regime involving radial migration and heating. It predicts in particular the formation of a ridge-like feature in action space, in agreement with simulations, but over-estimates the timescale involved in its appearance. Swing amplification is likely needed to resolve this discrepancy. In astrophysics, the inhomogeneous Balescu-Lenard equation and its WKB limit may also describe the secular diffusion of giant molecular clouds in galactic discs, the secular migration and segregation of planetesimals in proto-planetary discs, or even the long-term evolution of population of stars within the Galactic centre.

The kinetic theory of stellar systems is an old, yet fundamental, topic in astrophysics1. It was initiated by Jeans (1929) and Chandrasekhar (1942) in the context of 3D stellar systems such as elliptical galaxies and globular clusters. The kinetic theory of Coulombian plasmas was developed in parallel by Landau (1936) and Vlasov (1938). When encounters between the particles (stars or electric charges) are neglected, one gets a purely mean field equation (Jeans 1915; Vlasov 1938) called the collisionless Boltzmann equation, or the Vlasov equation. When encounters are taken into account, one gets a kinetic equation that includes a collision term. In early works, the collision term was obtained by assuming that a particle experiences a succession of independent two-body encounters with the other particles. The corresponding kinetic equation can be derived either from the Boltzmann equation by considering a limit of weak deflections (Landau 1936), or directly from the general form of the Fokker-Planck equation by evaluating the drift and diffusion coefficients in a binary collisions approximation (Chandrasekhar 1949; Rosenbluth et al. 1957). In the case of neutral plasmas, the system is spatially homogeneous, so the distribution function depends only on the velocity, hence the name kinetic theory. By contrast, stellar systems are spatially inhomogeneous, so the distribution function depends on position and velocity. In early works on stellar dynamics, spatial inhomogeneity was taken into account in the advection term (Vlasov), but the collisional term was calculated by making a local approximation as if the system were homogeneous. In 3D, the collisional term displays a logarithmic divergence at large scales (Jeans 1929; Landau 1936; Chandrasekhar 1942). In the case of plasmas, this divergence is due to the neglect of collective effects that are responsible for Debye shielding. Landau (1936) phenomenologically introduced a cut-off at the Debye length to regularize the divergence.

Later on, Balescu (1960) and Lenard (1960) developed a rigorous kinetic theory of plasmas, taking collective effects into account, and obtained a kinetic equation, the so-called Balescu-Lenard equation, that does not present any divergence at large scales. The Debye shielding is taken naturally into account.

1 For a historical account of the development of kinetic theories in astrophysics, plasma physics, and for systems with long-range interactions, see the Introduction in Chavanis (2013a,b).
in their treatment through the dielectric function (which is absent from the Landau equation). In the case of stellar systems, the divergence at large scales is solved by the spatial inhomogeneity of the system and its finite extent. One can phenomenologically introduce a cut-off at the Jeans scale (Weinberg 1993), i.e. at the system’s size, which would correspond to the analogue of the Debye length in plasma physics, but this ad hoc treatment is not fully satisfactory. Furthermore, it cannot be applied to cold (centrifugally supported) stellar discs where spatial inhomogeneity is more crucial than in 3D.

A more fruitful procedure is to write the kinetic equation with angle-action variables that are the appropriate variables to describe spatially inhomogeneous multi-periodic systems. When collective effects are neglected, one obtains the inhomogeneous Landau equation (Chavanis 2007, 2013b). When collective effects are accounted for, one gets the inhomogeneous Balescu-Lenard equation (Heyvaerts 2010; Chavanis 2012a). The collision term in these equations describes the effect of (possibly distant) encounters between stars. For self-gravitating systems, where the interaction is attractive (instead of being repulsive as in Coulombian plasmas), collective effects are responsible for an anti-shielding which tends to increase the effective mass of the stars, hence reducing the relaxation time. The Balescu-Lenard equation is valid at the order 1/N in an expansion of the dynamics in terms of this small parameter, where \( N \gg 1 \) is the number of stars. Therefore, it takes finite-N effects (encounters between stars) into account and describes the evolution of the system on a timescale of the order \( N t_D \), where \( t_D \) is the dynamical time. For times \( t \ll N t_D \), or for \( N \to +\infty \), it reduces to the Vlasov equation which ignores encounters between stars. Although the kinetic theory was initially developed for 3D stellar systems, the final form of the inhomogeneous Balescu-Lenard equation also applies to stellar discs such as those considered in this paper.

The Balescu-Lenard non-linear equation accounts for self-driven orbital secular diffusion of a self-gravitating system induced by the intrinsic shot noise due to its discreteness and the corresponding long range correlations. Even though this kinetic equation was first written down more than fifty years ago, it has hardly ever been applied in its prime context, but only in various approximate long range correlations. Even though this kinetic theory was initially developed for 3D stellar systems, the final form of the inhomogeneous Balescu-Lenard equation also applies to stellar discs such as those considered in this paper.

2. The inhomogeneous Balescu-Lenard equation

We consider a system made of \( N \) particles. We suppose that the gravitational background, associated with the Hamiltonian \( H_0 \), is stationary and integrable, so that we may always remap the physical space-phase coordinates \( (x, v) \) to the angle-action coordinates \( (\theta, J) \) (Goldstein 1950; Born 1960; Binney & Tremaine 2008). We also introduce the intrinsic frequencies of the system \( \Omega \) defined as

\[
\Omega(J, \theta) = \frac{\partial H_0}{\partial J}.
\]

Along the unperturbed trajectories, the angles \( \theta \) are \( 2\pi \)-periodic evolving with the frequency \( \Omega \), whereas the actions \( J \) are conserved. To describe the long-term evolution of such a system, one assumes that there are two decoupled timescales: a short dynamical timescale and a secular timescale of collisional evolution. We assume that the system is always in a virialized stable state (i.e. is a stable stationary solution of the Vlasov equation), so that the distribution function can be written as a quasi-stationary distribution \( F = F(J, t) \), which satisfies the normalization constraint \( \int d\theta dJ F = M_{tot} \), where \( M_{tot} \) is the total mass of the system. This is a function of the actions only and that slowly evolves in time due to stellar encounters (finite-\( N \) effects)\(^2\). From Heyvaerts (2010) and Chavanis (2012a; see also Appendix A for a short sketch of the derivation), the secular evolution, induced by collisional finite-\( N \) effects, of such a quasi-stationary distribution function \( F(J, t) \) is given by the inhomogeneous Balescu-Lenard equation which reads

\[
\frac{\partial F}{\partial t} = \pi(2\pi)^\mu \frac{\partial}{\partial J} \left[ \sum_{m_1 \cdots m_N} \int dJ_2 \frac{\delta_0(m_1, \Omega_1 - m_2 \cdot \Omega_2)}{|D_{m_1, m_2}(J_1, J_2, \Omega_1)|^2} \times \left( m_1 \cdot \frac{\partial}{\partial J_1} - m_2 \cdot \frac{\partial}{\partial J_2} \right) F(J_1, t) F(J_2, t) \right],
\]

where \( d \) is the dimension of the physical space, \( \mu = M_{tot}/N \) is the mass of the individual particles, and where we used the shortened notation \( \Omega_i = \Omega(J_i) \). The r.h.s. of Eq. (2) is the Balescu-Lenard operator which encompasses the secular diffusion due to collisional effects, see Fig. 1. Because it is the divergence of a flux, this writing ensures that the total number of stars is exactly conserved during the secular diffusion. The Dirac delta function \( \delta_0(m_1, \Omega_1 - m_2 \cdot \Omega_2) \) is the sharp resonance condition. One must remark that this condition allows us to describe non-trivial gravitational interactions. Indeed, it can cause non-local resonances by coupling different regions of action-space \( J_1 \) and \( J_2 \). Even for local resonances (i.e. \( J_1 = J_2 \)), it can allow for non-trivial coupling of oscillations, as soon as \( m_1 \) and \( m_2 \) have non-zero components. The coefficients \( 1/|D_{m_1, m_2}(J_1, J_2, \omega)|^2 \) represent the dressed susceptibilities of the system, for which collective effects have been taken into account\(^3\). To deal with the resolution of the non-local Poisson equation, following Kalnajs’ matrix method (Kalnajs 1976), one has to introduce a complete biorthonormal basis of potentials and densities \( \psi^{(p)}(x) \) and \( \rho^{(p)}(x) \) such that

\[
\Delta \psi^{(p)} = 4\pi G \rho^{(p)}, \quad \int dx \left[ \psi^{(p)}(x) \right] \rho^{(q)}(x) = -\delta^{pq}_r.
\]

\(^2\) In this paper, we are not interested in the initial complex mechanism of violent relaxation (Lynden-Bell 1967), during which the system gets virialized, since we intend to describe the long-term evolution of an already and continuously virialized system.

\(^3\) In the secular timescale limit, the amplification through the propagation of waves between resonances is assumed to be instantaneous, see Appendix A.
Thanks to this basis, the susceptibility coefficients are given by
\[
\frac{1}{D_{m_1, m_2}(J_1, J_2, \omega)} = \sum_{pq} \psi^{(pq)}_{m_1}(J_1) \left[ I - \hat{M}(\omega) \right]^{-1} \psi^{(pq)}_{m_2}(J_2),
\] (4)
where \( I \) is the identity matrix and \( \hat{M} \) is the response matrix given by
\[
\hat{M}_{pq}(\omega) = (2\pi)^d \sum_{m} \int dJ \frac{m \cdot \partial F}{\omega - m \cdot \Omega} \psi^{(p)}_{m}(J) \psi^{(q)}_{m}(J).
\] (5)

In this expression, \( \psi^{(p)}_{m}(J) \) corresponds to the Fourier transform in angles of the basis elements \( \psi^{(p)}(x) \), where we used the convention that the Fourier transform of a function \( X(\theta, J) \) is given by
\[
\begin{align*}
X(\theta, J) &= \sum_{m \in \mathbb{Z}^d} X_m(J) e^{im \cdot \theta}, \\
X_m(J) &= \frac{1}{(2\pi)^d} \int d\theta X(\theta, J) e^{-im \cdot \theta}.
\end{align*}
\] (6)

One should note that Eq. (2) is therefore a non-linear function of \( F \), both explicitly via the products of \( F \) on the r.h.s., describing the effects of the binary collisions (as in the Boltzmann or Landau equations), but also implicitly via Eq. (5), which encompasses the collective effects and is specific to the Balescu-Lenard equation. We also importantly note that – in contrast to its counterpart in plasma physics – Eq. (2) does not assume that local encounters drive secular evolution; resonant interactions of correlated possibly distant dressed orbits are sourcing long term orbital distortions.

2.1. Content of the diffusion equation

One may also rewrite the Balescu-Lenard Eq. (2) as an anisotropic Fokker-Planck equation introducing the associated drift and diffusion coefficients. It then reads
\[
\frac{\partial F}{\partial t} = \sum_{m_1} \frac{\partial}{\partial J_1} \left[ A_{m_1}(J_1) F(J_1) + D_{m_1}(J_1) m_1 \cdot \frac{\partial F}{\partial J_1} \right],
\] (7)
where \( A_{m_1}(J_1) \) and \( D_{m_1}(J_1) \) are respectively the anisotropic drift and diffusion coefficients associated with a given resonance \( m_1 \), i.e. with a given Fourier mode \( m_1 \) in angles. They both secularly depend on the distribution function \( F \), but this dependence has not been explicitly written out to shorten the notations. The drift coefficients are given by
\[
A_{m_1}(J_1) = -2\pi \sum_{m_2} \int dJ_2 \frac{\partial \psi^{(m_1 \cdot \Omega_1 - m_2 \cdot \Omega_2)}_{m_1, m_2}(J_1, J_2, \omega)}{|D_{m_1, m_2}(J_1, J_2, m_1 \cdot \Omega_1)|^2} m_2 \cdot \frac{\partial F}{\partial J_2},
\] (8)
while the diffusion coefficients are given by
\[
D_{m_1}(J_1) = \pi \sum_{m_2} \int dJ_2 \frac{\partial \psi^{(m_1 \cdot \Omega_1 - m_2 \cdot \Omega_2)}_{m_1, m_2}(J_1, J_2, \omega)}{|D_{m_1, m_2}(J_1, J_2, m_1 \cdot \Omega_1)|^2} F(J_2).\] (9)

The rewriting from Eq. (7) allows us to discuss some important properties of such anisotropic diffusion equation. We introduce the total flux, \( \mathcal{F}_{\text{tot}} \), associated with this diffusion, which reads
\[
\mathcal{F}_{\text{tot}} = \sum_m m \left( A_{m_1}(J_1) F(J_1) + D_{m_1}(J_1) m \cdot \frac{\partial F}{\partial J} \right) = \sum_m \mathcal{F}_m.
\] (10)

As a consequence, the Balescu-Lenard diffusion equation given by the expressions (2) and (7) takes the shortened form
\[
\frac{\partial F}{\partial t} = \text{div} \left( \mathcal{F}_{\text{tot}} \right).
\] (11)

We then define as \( M(t) \) the mass contained in a volume \( \mathcal{V} \) of the action-space at time \( t \), so that we have
\[
M(t) = \int_{\mathcal{V}} \mathcal{F}(J, t).
\] (12)

Thanks to the divergence theorem, the variation of mass in \( \mathcal{V} \) due to secular diffusion corresponds to the flux of particles through the boundary \( S \) of this volume so that
\[
\frac{dM}{dt} = \int_S \mathcal{F}_{\text{tot}} \cdot dS = \int_S \sum_m \int dS(m \cdot n) \left[ A_{m_1}(J_1) F(J_1) + D_{m_1}(J_1) m \cdot \frac{\partial F}{\partial J} \right],
\] (13)
where \( n \) is the exterior pointing normal vector. One can note in Eq. (13) that the contribution from a given resonance \( m \) takes the form of a preferential diffusion in the direction \( m \). This diffusion is therefore anisotropic because it is maximum for \( n \parallel m \) and equal to 0 for \( n \cdot m = 0 \). To emphasize the anisotropy of the diffusion, one may use the formalism of the slow and fast actions (Lynden-Bell 1979; Earn & Lynden-Bell 1996). For simplicity, we consider the 2D case. For a given resonance \( m = (m_1, m_2) \), we consider the change of coordinates
\[
J_s^m = \frac{J \cdot m}{|m|}, \quad J_t^m = \frac{J \cdot m^*}{|m|},
\] (14)
where \( J_s^m \) and \( J_t^m \) are respectively the slow and fast actions associated with the resonance \( m \). Here \( m^* \) corresponds to the direction perpendicular to the resonance so that \( m^* = (m_2, -m_1) \), and
\[ |m| = \sqrt{m \cdot m}. \text{ Thanks to the chain rule, for any function } X(J), \text{ one has} \]
\[ \frac{\partial X}{\partial J} = \frac{|m|}{\partial X} \frac{\partial |m|}{\partial J} |m|_{m=\text{const}}. \quad (15) \]
Introducing the natural vector basis elements \( \mathbf{e}_m^\alpha = m/|m| \) and \( \mathbf{e}_m^\beta = m^\perp/|m| \) associated with this change of coordinates, the diffusion flux \( \mathbf{F}_m \) associated with a resonance \( m \) and defined in Eq. (10) takes the form
\[ \mathbf{F}_m(J_m^*, J_m^*) = |m| \left[ A_m(J)F(J) + |m| D_m(J) \frac{\partial F}{\partial J_m} \right] \mathbf{e}_m^\alpha. \quad (16) \]
Such a rewriting illustrates the fact that as soon as only one resonance \( m \) dominates the secular evolution, the diffusion flux will be aligned with this resonance. Hence one will observe a narrow diffusion from \( J_m^* \) to \( J_m^* \) which can therefore be seen as an adiabatic invariant, whereas their slow action \( J_m^* \) gets to change. This strong anisotropy in the diffusion is an essential property of the Balescu-Lenard Eq. (7).

### 3. Thin tepid discs and their WKB limit

When implementing the inhomogeneous Balescu-Lenard equation, one encounters two main difficulties. The first one is the explicit construction of a mapping \( (\mathbf{r}, \mathbf{v}) \rightarrow (\theta, J) \) since the Balescu-Lenard drift and diffusion coefficients must be computed using angle-action coordinates. Assuming the disc to be tepid, one may rely on the epicyclic approximation to construct such a mapping. The second difficulty arises from the non-locality of Poisson’s equation which requires us to introduce potential basis elements \( \Psi(0) \) as in Eq. (3). One can then compute the response matrix from Eq. (5), which must subsequently be inverted. The following step is to compute the drift and diffusion coefficients from Eqs. (8) and (9) which requires us to explicitly deal with the resonance constraint \( m_1 \cdot \mathbf{\Omega}_1 - m_2 \cdot \mathbf{\Omega}_2 = 0 \).

In the case of a 2D axisymmetric disc, one may implement a WKB approximation (Lovelace 1837; Toomre 1964; Kalnajs 1965; Lin & Shu 1966; Palmer et al. 1989) which assumes that the diffusion of the system is made through tightly wound spirals. Such an assumption has two main consequences. First of all, Poisson’s equation becomes local, resulting in a diagonal response matrix. Moreover, it also entails that all the resonances becomes exactly local, allowing an explicit calculation of the resonant constraint \( \delta_{12}(m_1 \cdot \mathbf{\Omega}_1 - m_2 \cdot \mathbf{\Omega}_2) \). We now detail these two elements: epicyclic approximation and WKB assumption.

#### 3.1. Epicyclic approximation

For a sufficiently cold disc (i.e. a disc where the radial excursions of the stars are small), one can explicitly build up a mapping \( (\mathbf{r}, \mathbf{v}) \rightarrow (\theta, J) \) thanks to the epicyclic approximation. We introduce the polar coordinates \( (R, \phi) \) to describe the infinitely thin galactic disc, and introduce their associated momenta \((p_R, p_\phi)\). As the disc at equilibrium is axisymmetric, the stationary Hamiltonian of the system reads
\[ H_0(R, \phi, p_R, p_\phi) = \frac{1}{2} \left( \frac{p_R^2}{R^2} + \frac{p_\phi^2}{R^2} \right) + \psi_0(R), \quad (17) \]
where \( \psi_0 \) is the stationary background potential within the disc. Because \( \psi_0 \) is axisymmetric, it does not depend on \( \phi \), so that \( p_\phi \)
is a conserved quantity. We may then define the first action of the system, the angular momentum \( J_\phi \), as
\[ J_\phi = \frac{1}{2p_\phi} \oint d\phi p_\phi = p_\phi = R^2 \phi. \quad (18) \]
For a given value of \( J_\phi \), the equation of evolution of \( R \) is then given by
\[ \dot{R} = -\frac{\partial \phi_{\text{eff}}}{\partial R}, \quad (19) \]
where \( \phi_{\text{eff}} \) is an effective potential defined as
\[ \phi_{\text{eff}}(R) = \psi_0(R) + \frac{J_\phi^2}{2R^2}. \quad (20) \]

The heart of the epicyclic approximation is to assume that small radial excursions can be approximated as harmonic librations. For a given value of \( J_\phi \), we implicitly introduce the guiding radius \( R_g \) as
\[ 0 = \frac{\partial \phi_{\text{eff}}}{\partial R} \bigg|_{R_g} \Rightarrow \frac{\partial \psi_0}{\partial R} - \frac{J_\phi^2}{R_g^3}. \quad (21) \]
Here \( R_g(J_\phi) \) is the radius for which stars with an angular momentum \( J_\phi \) are on exactly circular orbits. It is important to note that the mapping between \( R_g \) and \( J_\phi \) is bijective and unambiguous (up to the sign of \( J_\phi \)). We may then define the two frequencies of evolution: \( \Omega_0(R_0) \) the azimuthal frequency and \( \kappa(R_0) \) the epicyclic frequency as follows
\[ \begin{cases} \Omega_0^2(R_0) = \frac{1}{R_g} \frac{\partial \psi_0}{\partial R} \bigg|_{R_g} = \frac{J_\phi^2}{R_g^3}, \\ \kappa^2(R_0) = \frac{\partial^2 \phi_{\text{eff}}}{\partial R^2} \bigg|_{R_g} = \frac{\partial^2 \psi_0}{\partial R^2} \bigg|_{R_g} + \frac{3J_\phi^2}{R_g^5} \end{cases} \quad (22) \]
As the radial oscillations are supposed to be small, one may perform a Taylor expansion at first order of the evolution Eq. (19) in the neighbourhood of the minimum \( R = R_g \) so that \( R \) satisfies the differential equation \( \dot{R} = -\kappa^2(R - R_g) \). Hence one can notice that in this limit the evolution of the radius of a star is the one of a harmonic oscillator centred on \( R_g \). Up to an initial phase, one has therefore \( R(t) = R_g + A \cos(\kappa t) \), where \( A \) is the amplitude of the radial oscillations. The associated radial action \( J_r \) is then given by
\[ J_r = \frac{1}{2\kappa} \oint dR p_R = \frac{1}{2} \kappa A^2. \quad (23) \]
For \( J_r = 0 \), the orbit is circular. Within the epicyclic approximation, the frequencies of motion along the action-tori, introduced in Eq. (1) are given by \( \Omega(J) = (\Omega_0(J_\phi), \kappa(J_\phi)) \). An important dynamical consequence of this approximation is that these two frequencies are only function of \( J_\phi \) and do not depend on \( J_r \), so that the resonance constraint \( m_1 \cdot \mathbf{\Omega}_1 - m_2 \cdot \mathbf{\Omega}_2 = 0 \) becomes simpler. Finally, one can explicitly construct the mapping between \( (R, \phi, p_R, p_\phi) \) and \((\theta_0, J_r, J_\phi, J_\phi)\) (Lynden-Bell & Kalnajs 1972; Palmer 1994; Binney & Tremaine 2008), which takes at first order the form
\[ \begin{cases} R = R_g + A \cos(\theta_0), \\ \phi = \theta_0 - \frac{2\Omega_0 A}{\kappa R_g} \sin(\theta_0). \end{cases} \quad (24) \]
Thanks to this mapping and the definitions of the actions from Eqs. (18) and (23), the epicyclic approximation allows us to
build up an explicit mapping between the physical phase-space coordinates and the angle-action ones.

Finally, throughout our calculation, we will assume that the stationary distribution function of the disc is a Schwarzschild distribution function (or locally isothermal DF) given by

$$F(R_{\phi}, J_\phi) = \frac{\Omega_{\phi}(R_\phi) \Sigma(R_\phi)}{\pi k(R_\phi) \sigma^2(R_\phi)} \exp\left[\frac{\kappa(R_\phi) J_\phi}{\sigma^2(R_\phi)}\right],$$

where $\Sigma(R_\phi)$ is the surface density of the disc and $\sigma^2(R_\phi)$, which varies within the disc, represents the radial velocity dispersion of the stars at a given radius. Increasing values of $\sigma^2$ correspond to hotter discs that are therefore more stable.

### 3.2. The WKB basis

As we are considering a 2D case, the potential basis elements $\psi^{(p)}$ introduced in Eq. (3) must be written as $\psi^{(p)}(R, \phi)$ in the disc polar coordinates and must be orthonormal to the associated surface density $\Sigma^{(p)}(R, \phi)$. Using a WKB approximation amounts to building up local basis elements thanks to which the response matrix will become diagonal.

#### 3.2.1. Definition of the basis elements

We introduce the basis elements

$$\psi^{[k, \sigma, k_0]}(R, \phi, z) = \mathcal{A} e^{i(k_{\phi} \phi + k z)} \mathcal{B}_{k_0}(R),$$

where the window function $\mathcal{B}_{k_0}(R)$ is defined as

$$\mathcal{B}_{k_0}(R) = \frac{1}{(\pi \sigma^2)^{1/4}} \exp\left[-\frac{(R - R_0)^2}{2\sigma^2}\right].$$

The basis elements are indexed by three numbers: $k_\phi$ is an azimuthal number which parametrizes the angular component of the basis elements, $R_\phi$ is the radius position in the disc around which the Gaussian window $\mathcal{B}_{k_0}$ is centred, and $k_\sigma$ is the radial frequency of the basis element. We also introduced an additional parameter $\sigma$ of scale-separation, which will ensure the biorthogonality of the basis elements, as detailed later on. Finally, $\mathcal{A}$ is an amplitude which will be tuned in order to normalize correctly the basis elements. Thanks to a somewhat unusual normalization of $\mathcal{B}_{k_0}$, we will ensure that $\mathcal{A}$ is independent of $\sigma$. Figure 2 illustrates the radial dependence of the basis elements. Figure 3 illustrates the shape of these basis elements in the polar $(R, \phi)$-plane.

The next steps will be to ensure that these WKB basis elements have all the properties required to allow for the computation of the dressed susceptibility coefficients introduced in Eq. (4). Therefore, we will successively compute the associated surface density elements $\Sigma^{[k, \sigma, k_0]}$, ensure the biorthogonality of the basis elements and their correct normalization, and finally compute the Fourier transform in angles of the basis elements.

#### 3.2.2. Associated surface densities

In order to ensure the biorthogonality of the basis, we will first build up the surface densities associated with the potential elements introduced in Eq. (26). We extend the WKB potential in the $z$-direction using the Ansatz

$$\psi^{[k, \sigma, k_0]}(R, \phi, z) = \mathcal{A} e^{i(k_{\phi} \phi + k z)} \mathcal{B}_{k_0}(R) Z(z).$$

Poisson’s equation in vacuum $\Delta \psi^{[k, \sigma, k_0]} = 0$ leads to

$$\frac{Z''}{Z} = k_\sigma^2 \left[1 - \frac{i}{k_\sigma R} + 2i \frac{R - R_0}{\sigma^2} \frac{1}{k_\sigma} + \frac{R - R_0}{(\sigma k_\sigma)^2} \right].$$

We now explicitly introduce our WKB assumptions. We assume that the spirals are tightly wound so that

$$k_\phi R \gg 1.$$  

Introducing the typical size of the system $R_{\text{sys}}$, we also additionally suppose that we have

$$k_\phi \sigma \gg \frac{R_{\text{sys}}}{\sigma}.$$  

Assuming that $k_\phi$ is of the order of unity, Eq. (29) becomes

$$\frac{Z''}{Z} = k_\sigma^2,$$  

where $k_\sigma$ is the radial frequency of the basis element.
Hence within the WKB limit, the extended potential from Eq. (28) takes the form
\[
\psi_{[k_0, k, R_0]}(R, \phi, z) = \psi_{[k_0, k, R_0]}(R, \phi) e^{-ik_0 z},
\]  
(33)
where we ensured that for \( z \to \pm \infty \) the potential tends to 0, therefore introducing a discontinuity for \( \partial \psi / \partial z \) in \( z = 0 \). Thanks to Gauss theorem, the associated surface density satisfies
\[
\Sigma(R, \phi) = \frac{1}{4\pi G} \left[ \lim_{z \to 0^+} \frac{\partial \psi}{\partial z} - \lim_{z \to 0^-} \frac{\partial \psi}{\partial z} \right],
\]  
(34)
so that we have
\[
\Sigma_{[k_0, k, R_0]}(R, \phi) = - \frac{|k_0|}{2\pi G} \psi_{[k_0, k, R_0]}(R, \phi).
\]  
(35)

3.2.3. Biorthogonality condition and normalization

One must now ensure that the basis elements introduced in Eqs. (26) and (35) form a biorthogonal basis as assumed in Eq. (3). Indeed, it has to satisfy the property
\[
\delta_{k_0, k_0}^{|k_0|} G \delta_{k, k_0}^{|k_0|} R_0 = - \int dR d\phi \psi_{[k_0, k, R_0]}^* \Sigma_{[k_0, k, R_0]} \psi_{[k_0, k_0, R_0]}.
\]  
(36)
The r.h.s. of this expression takes the form
\[
\left( \frac{|k_0|}{2\pi G} \right)^* \int d\phi e^{i(k_0 - k_0)\phi} \times \int dR d\phi e^{i(k - k_0)R} \exp \left[ -\frac{(R - R_0)^2}{2\sigma^2} \right].
\]  
(37)
The integration on \( \phi \) is straightforward and is equal to \( 2\pi \sigma_\phi \). In order to perform the integration on \( R \), we have to introduce additional assumptions to ensure the biorthogonality of the basis. The peaks of the Gaussians in Eq. (37) can be considered as separated if \( \Delta R_0 \gg \sigma \) and \( R_0 = R_0^p = R_0^q \). Under this assumption, the term from Eq. (37) can be assumed to be non-zero only for \( R_0^p = R_0^q \). The r.h.s. of Eq. (36) then takes the form
\[
\delta_{k_0, k_0}^{|k_0|} G \delta_{k, k_0}^{|k_0|} R_0 = - \int dR d\phi \psi_{[k_0, k_0, R_0]}^* \Sigma_{[k_0, k_0, R_0]} \psi_{[k_0, k, R_0]}.
\]  
(39)
The integration on \( R \) takes the form of a radial Fourier transform of a Gaussian of spread \( \sigma \) at the frequency \( \Delta k = k_0 - k \). It is therefore proportional to \( \exp[-(\Delta k)^2/(4\sigma^2)] \). Hence we will suppose that the frequency spread \( \Delta k \) satisfies
\[
\Delta k \gg \frac{1}{\sigma} \quad \text{if} \quad k_0 \neq k_0^q.
\]  
(40)
Under this assumption, the term from Eq. (39) is non-zero only for \( k_0 = k_0^q \). In order to have a biorthogonal basis, one must therefore consider a spread \( \sigma \), central radii \( R_0 \), and radial frequencies \( k \), such that
\[
\Delta R_0 \gg \sigma \gg \frac{1}{\Delta k}.
\]  
(41)
With these constraints, one must necessarily have \( k_0^p = k_0^q, k_0^p = k_0^q \) and \( R_0^p = R_0^q \), in order to have a non-negligible term in Eq. (36). It then only remains to explicitly estimate the amplitude \( A \) of the basis elements. Equation (36) gives
\[
A = \sqrt{\frac{G}{|k_0|^2/2\pi G}} \int dR d\phi \exp \left[ -\frac{(R - R_0)^2}{2\sigma^2} \right] = 1.
\]  
(42)
Thanks to the WKB assumption from Eq. (41), the integration can be straightforwardly computed and leads to
\[
A = \sqrt{\frac{G}{|k_0|^2}}.
\]  
(43)

3.2.4. Fourier transform in angles

In order to estimate the susceptibility coefficients and the response matrix from Eqs. (4) and (5), one has to be able to calculate \( \psi_m(k_0, J) \) for the WKB basis elements. Thanks to the explicit mapping from Eq. (24), we have to compute
\[
\psi_m(k_0, J) = \frac{A e^{ik_0 R_0}}{(2\pi)^2} \int d\theta \int dR e^{-im\theta} \exp \frac{i(\theta - \pi)}{2} \exp \left[ -\frac{R^2}{2\sigma^2} \right].
\]  
(44)
The integration on \( \theta_0 \) is straightforward and equal to \( 2\pi \delta_{m_0} \). Regarding the dependence on \( \theta_0 \) in the complex exponential, we may write
\[
k_0 A \cos(\theta_0) - \frac{2\Omega_0}{k_0} \sin(\theta_0) = H_{k_0}(k_0) \sin(\theta_0 + \theta_0^q),
\]  
(45)
where the amplitude \( H_{k_0}(k_0) \) and the phase shift \( \theta_0^q \) are given by
\[
H_{k_0}(k_0) = A |k_0| \sqrt{1 + \frac{\Omega_0}{k_0} 2k_0 R_0^2}, \quad \theta_0^q = \tan^{-1} \left( \frac{k_0 R_0}{\Omega_0} \frac{2k_0 R_0}{\Omega_0} \right).
\]  
(46)
For typical galaxies, we have \( 1/2 \leq \Omega_0 / k_0 \leq 1 \) (Binney & Tremaine 2008). Assuming that the azimuthal number \( k_0 \) is of the order of unity, one can use the WKB hypothesis introduced in Eq. (30), so that Eqs. (46) can be approximated as
\[
H_{k_0}(k_0) \approx A |k_0| \sqrt{\frac{2k_0 R_0}{k_0} |k_0|}, \quad \theta_0^q \approx -\frac{\pi}{2}.
\]  
(47)
Because we have assumed that the disc is tepid, the radial oscillations are small so that \( A \ll R_0 \). We may then get rid of the dependences on \( A \) in \( B_{R_0}(R_0 + A \cos(\theta_0)) \) by replacing it with \( B_{R_0}(R_0) \), so that the only remaining dependence on \( A \) will be in the complex exponentials. To be able to explicitly perform the remaining integration on \( \theta_0 \) in Eq. (44), we introduce the Bessel functions \( J_{\ell} \) of the first kind which satisfy the relation
\[
e^{i\phi \sin(\theta)} = \sum_{\ell \geq 2} J_{\ell}(|z|) e^{i\ell \phi}.
\]  
(48)
We then finally obtain the expression of the Fourier transform in angles of the WKB basis elements which reads
\[
\psi_m(k_0, J) = \delta_{m_0} e^{i\theta_0^q \phi} \int dR [H_{m_0}(k_0)] B_{R_0}(R_0).
\]  
(49)
3.3. Estimation of the response matrix

Thanks to the WKB basis introduced in Eq. (26), one can now compute the response matrix from Eq. (5). Indeed, we use the expression (49) of the Fourier transform of the basis elements, and after simplification of the phase-shift terms thanks to the approximation of Eq. (47), one has to evaluate

\[
\tilde{M}[κ^p_0, κ^q_0, κ^r_0; κ^p_0, κ^q_0, κ^r_0](ω) = (2π)^2 \sum \int J_0 \frac{m \cdot \partial F / \partial J}{ω - m \cdot Ω} Α_0 δ^p_0 δ^q_0 δ^r_0 \cdot Α_q \cdot Α_q \times \mathcal{F}_m \left[ \sqrt{\frac{2 I}{κ^p_0}} J_0 \right] \mathcal{F}_m \left[ \sqrt{\frac{2 I}{κ^q_0}} J_0 \right] \mathcal{F}_m \left[ \sqrt{\frac{2 I}{κ^r_0}} J_0 \right].
\]

The first step of the calculation is to show that in the WKB limit, the response matrix becomes diagonal. One should note that the previous expression (50) is similar to Eq. (37), where we discussed the biorthogonality of the WKB basis. In Eq. (50), the azimuthal Kronecker symbols ensure that $κ^p_0 = κ^q_0$. Moreover, because of our WKB assumptions from Eq. (41) on the step distances of the basis elements, the product of the two radial Gaussians in $R_q$ imposes that $R_q = R_q$ in order to have a non-zero contribution. In order to shorten the notations, we temporarily introduce the function $h(R_q)$ defined as

\[
h(R_q) = \frac{d J_0}{d R_q} \frac{m \cdot \partial F / \partial J}{ω - m \cdot Ω} Α_0 δ^p_0 δ^q_0 δ^r_0 \cdot Α_q \cdot Α_q \times \mathcal{F}_m \left[ \sqrt{\frac{2 I}{κ^p_0}} J_0 \right] \mathcal{F}_m \left[ \sqrt{\frac{2 I}{κ^q_0}} J_0 \right] \mathcal{F}_m \left[ \sqrt{\frac{2 I}{κ^r_0}} J_0 \right],
\]

which encompasses all the additional dependences appearing in Eq. (50). Thanks to the change of variables $J_0 \mapsto R_q$, the integral on $J_0$ which has to be evaluated in Eq. (50), when estimated for $R_q^0 = R_q^0$, is qualitatively of the form

\[
\int dR_q h(R_q) e^{i κ^p_0 Δk^p_0} \exp \left[ -\frac{(R_q - R_q^0)^2}{σ^2} \right].
\]

This expression corresponds to a radial Fourier transform $\mathcal{F}$ at the frequency $Δk$. It can be rewritten as a convolution of two radial Fourier transforms so that it becomes

\[
(51) \propto \int dk' \mathcal{F}[h](k') \exp \left[ \frac{(Δk - k')^2}{4σ^2} \right],
\]

where $Δk = k^p_0 - k^q_0$. We now rely on the WKB assumption from Eq. (40). If one has $Δk_0 \neq 0$, because of the Gaussian from Eq. (52), the contribution from $\mathcal{F}[h]$ will come from the region $k' \sim Δk_0 \gg 1/σ$. We assume that the function $h$ is such that its Fourier Transform is limited to the frequency region $|k'| \leq 1/σ$. This is consistent with assuming that the properties of the disc are radially slowly varying, and this implies that non-zero contributions to the response matrix can only be obtained when $Δk = k^p_0 - k^q_0 = 0$. Therefore, we have shown that within our WKB formalism, the response matrix from Eq. (5) is diagonal.

In order to shorten the notations, we will denote the matrix eigenvalues as

\[
λ[I_0; k_0, R_0](ω) = \tilde{M}[I_0; k_0, R_0, k_0, R_0](ω).
\]

For these diagonal coefficients, the last step is to explicitly compute the integrals over $J_0$ and $J_1$ in Eq. (50) to obtain the expression of the response matrix eigenvalues. We now detail this calculation. Thanks to our scale-decoupling approach, we may replace the radial Gaussian from Eq. (51) by a Dirac delta $δ_Ω(R_q - R_q^0)$ while paying a careful attention to the correct normalization of the Gaussian. Hence we have to evaluate

\[
λ[I_0; k_0, R_0](ω) = 2π^2 \exp \left[ -\frac{(R_q - R_q^0)^2}{σ^2} \right].
\]

Because of the presence of the azimuthal Kronecker symbol, we may drop the sum on $m$. The intrinsic frequencies from Eqs. (22) allow us to compute

\[
\frac{d J_0}{d R_q} = R_q κ^2.\]

Moreover, we assume that the galactic disc is tepid so that $|δF / δJ_0| \ll |δF / δJ_1|$. We may then only keep the term corresponding to a gradient with respect to the radial action $J_0$. Thanks to the expression of the Schwarzschild distribution function from Eq. (25) and the expression of the basis amplitude from Eq. (43), Eq. (54) becomes after some simple algebra

\[
λ[I_0; k_0, R_0](ω) = 2π^2 |Ω| κ^2 \frac{κ^4}{κ^2 |σ|^2} \times \sum m_0 \int d J_0 - m_0 \exp \left[ -κ^2 J_0 / |σ|^2 \right] \mathcal{F}_m \left[ \frac{2 I}{κ^2 J_0} \right].
\]

We may now use the following integration formula (see formula (6.615) from Gradshteyn & Ryzhik 2007)

\[
\int_0^∞ d J_0 e^{-κ J_0} \mathcal{F}_m \left[ \beta / J_0 \right] = \frac{e^{-β^2 / 2σ^2}}{σ^2},
\]

where $α > 0$, $β > 0$, $m_0 \in \mathbb{Z}$ and $I_{m_0}$ are the modified Bessel functions of the first kind. We apply this formula with $α = κ / |σ|^2$ and $β = \sqrt{2κ^2 / κ^2}$. We also introduce the notation

\[
χ = \frac{κ^2 |σ|^2}{κ^2},
\]

so that Eq. (56) becomes

\[
λ[I_0; k_0, R_0](ω) = \frac{2π^2 |Ω| κ^2}{κ^2} \chi \sum m_0 \frac{m_0 e^{-χ I_{m_0} / |σ|^2}}{ω - k_0 Ω_0 - m_0 κ}.
\]

We now define the dimensionless shifted frequency $s$ as

\[
s = \frac{ω - k_0 Ω_0}{κ}.
\]

Because we have $I_{m_0}[χ] = I_{m_0}[χ]$, we may rewrite Eq. (59) using the reduction factor (Kahlajns 1965; Lin & Shu 1966) defined as

\[
\mathcal{F}(s, χ) = 2(1 - s^2)^χ^{e^{-χ}} \sum_{m=-∞}^∞ I_{m_0}[χ] \chi^{(1 - s^2)^χ}.
\]

As a conclusion, we obtain that within our WKB formalism the response matrix $M$ becomes diagonal and in the limit of tepid discs reads

\[
M[I_0; k_0, R_0, k_0, R_0](ω) = \frac{2π^2 |Ω| κ^2}{κ^2 (1 - s^2)^χ} \mathcal{F}(s, χ).
\]

This eigenvalue recovered using the WKB basis introduced in Eq. (26) is in full agreement with the seminal results.
from Kalnajs (1965) and Lin & Shu (1966). In order to handle the singularity of the eigenvalue appearing for \( s = n \in \mathbb{Z} \), one adds a small imaginary part to the frequency of evaluation, so that \( s = n + \imath \eta \). Indeed, as long as \( \eta \) is small compared to the imaginary part of the least damped mode of the disc, adding this complex part makes a negligible contribution to the expression of \( \mathcal{R}(\lambda) \).

### 3.4. Estimation of the susceptibility coefficients

One can now estimate the dressed susceptibility coefficients from Eq. (4). In order to shorten the notations, we will write the WKB basis elements introduced in Eq. (26) as

\[
\psi^{(p)} = \psi^{(p)} \cdot \delta \phi^{(p)} R^{(p)}
\]  

(63)

We have shown previously in Eq. (62) that within our WKB basis, the response matrix \( \mathbf{M} \) is diagonal. Its eigenvalues will be noted as \( \lambda_p \) so that we have \( \mathbf{M}_{\lambda p} = \delta_{\lambda p} \lambda_p \). Hence the expression (4) of the susceptibility coefficients takes the form

\[
\frac{1}{D_{m_m}(J_1, J_2, \omega)} = \sum_p \psi^{(p)}_{m_m}(J_1) \left( \frac{1}{1 - \lambda_p(\omega)} \right) \psi^{(p)}_{m_m}(J_2).
\]

Using the expression of the Fourier transformed basis elements obtained in Eq. (49), we obtain

\[
\frac{1}{D_{m_m}(J_1, J_2, \omega)} = \sum_{p, e, R} \left[ \frac{\partial^{(p)}_{h_e \phi}}{\partial_{h_e \phi} \delta J} \right] \left[ \frac{\partial^{(p)}_{h_e \phi}}{\partial_{h_e \phi} \delta J} \right] \frac{G_{m_m}}{1 - \lambda_p}
\]

\[
\times J_{\phi} \left[ \frac{\partial^{(p)}_{h_e \phi}}{\partial_{h_e \phi} \delta J} \right] \left[ \frac{\partial^{(p)}_{h_e \phi}}{\partial_{h_e \phi} \delta J} \right] e^{i \phi(x) \lambda_p} \frac{1}{\sqrt{2 \pi}} \exp \left[ -\frac{(R_1 - R_p^0)^2}{2 \sigma^2} \right],
\]

(64)

where we used the shortened notations \( \phi = \phi(J) \), and \( R_1 = R_1(J) \). We also used the approximation introduced in Eq. (47) for the values at which the Bessel functions have to be evaluated. Thanks to the Kronecker symbols in \( n_0 \) and \( n_0' \), we necessarily have

\[
m_0 = m_0' = k_0^p,
\]

(65)

so that the sum on \( k_0^p \) can be dropped.

### 3.5. Restriction on the loci of resonance

Before proceeding with the evaluation of the susceptibility coefficients obtained in Eq. (64), one may first emphasize a crucial consequence of the WKB basis from Eq. (26), which is the restriction to only exactly local resonances. Indeed, one can note that the expressions (8) and (9) of the drift and diffusion coefficients all involve an integration over the mute variable \( J_2 \). For a given value of \( J_1, m_1, \) and \( m_2 \), this integration should be seen as a scan of the entire action-space, searching for resonant regions where the constraint \( m_1 \cdot \Omega_1 - m_2 \cdot \Omega_2 = 0 \) is satisfied. We first recall the rule for the composition of a Dirac delta and a function which reads

\[
\delta_p(f(x)) = \sum_{y \in Z_f} \frac{\delta_p(x - y)}{|f'(y)|},
\]

(66)

where \( Z_f = \{ y | f(y) = 0 \} \), and we have supposed that all the poles of \( f \) are simple. As noted in Eq. (22), within the epicyclic approximation, the intrinsic frequencies \( \Omega = (\Omega_0, \kappa) \) only depend on \( R_2 = R_2(J_0) \) and are independent of \( J_1 \). Hence, the resonance condition \( m_1 \cdot \Omega_1 - m_2 \cdot \Omega_2 = 0 \) only depends on \( J_2 \) and is independent of \( J_1 \). Hence if we consider fixed \( J_1, m_1, \) and \( m_2, \) the resonant Dirac delta which has to be studied takes the form

\[
\delta_p(m_1 \cdot \Omega_1 - m_2 \cdot \Omega_2) = \sum_{J_2(\Omega_1 - \Omega_2)} \frac{\delta_p(R_2 - R_2^*)}{|\Omega_2|^2}.
\]

(67)

where the resonance condition \( f(R_2^*) = 0 \) is given by

\[
f(R_2^*) = m_1 \cdot \Omega_1(J_1) - m_2 \cdot \Omega_2(J_2).
\]

(68)

The radii \( R_2^* \) therefore correspond to the resonant radii for which the resonance condition is satisfied. When writing Eq. (67), we assumed that the zeros of the resonance function are simple, which corresponds to the assumption that for any resonant radius \( R_2^* \), we have \( f'(R_2^*) \neq 0 \). Assuming that \( m_2^* \neq 0, \) this condition can be rewritten as

\[
\frac{\partial \Omega_2}{\partial k} \neq \frac{m_2^*}{m_1^*}.
\]

(69)

Resonance poles are therefore simple as long as the rates of change of the two intrinsic frequencies are not in a rational ratio. One can note that the Keplerian case for which \( \kappa = \Omega_0 \) and the harmonic case for which \( \kappa = 2 \Omega_0 \) are in this sense degenerate. They can lead to resonant poles of higher multiplicity and would therefore require a more involved evaluation of the Balescu-Lenard collision operator. In what follows we assume that the potential is non-degenerate.

One can now use the properties of the WKB basis to restrict the range of resonant radii, \( R_2^* \). The expression (64) of the susceptibility coefficients, thanks to the two Gaussians, imposes that the relevant resonant radius \( R_2^* \) must necessarily be close to \( R_1 \). As noted in Eq. (65), in order to have a non-zero susceptibility, one also has to satisfy the constraint \( m_0^* = m_0^* \). The resonant condition which has to be satisfied is therefore given by

\[
m_0^* \Omega_0(R_1) + m_0^* \kappa(R_1) = m_0^* \Omega_0(R_2^*) + m_0^* \kappa(R_2^*),
\]

(70)

where the distance \( \Delta R = R_1 - R_2^* \) is such that \( |\Delta R| \leq (\text{few}) \sigma \). Because the scale-decoupling parameter \( \sigma \) is supposed to be small compared to the size of the system, we may approximate the previous resonant condition as

\[
\left[ m_2^* \frac{\partial \Omega_0}{\partial R} + m_2^* \frac{\partial \kappa}{\partial R} \right] \Delta R = m_2^* |m_1^* - m_2^*| \kappa(R_1).
\]

(71)

On the l.h.s. of Eq. (71), the term within bracket is non-zero because we assumed in Eq. (69) that the resonant poles are simple. Moreover, \( \Delta R \) is small because of our scale-decoupling approach. The r.h.s. of Eq. (71) is discrete: it is either zero or at least of the order of \( \kappa(R_1) \). Because the l.h.s. is necessarily small, we must have

\[
R_2^* = R_1, \quad m_2^* = m_1^*.
\]

(72)

This result is a crucial consequence of our WKB tightly wound spiral assumption because it implies that only local resonances are allowed. In particular this implies that the WKB limit does not allow for distant orbits to resonate (through e.g. propagation of swing amplified wave packets, see below). Then the sum \( \sum_{R_2^*} \) from Eq. (67) can be limited to the evaluation
in $R_2^2 = R_1$. Hence within this WKB limit, the susceptibility coefficients from Eq. (64) have to be evaluated only for $m_1 = m_2 = m_1$ and $R_2 = R_1$, so that we have to deal with the expression

$$\frac{1}{\mathcal{D}_{m_1,m_1}(R_1, J_1, R_1, J_1, \omega)} = \sum_{k, R_0} \frac{G}{k R_0} \frac{1}{1 - \lambda_k} \mathcal{F}_{m_1} \left[ \sqrt{\frac{2 \pi}{\lambda_k}} k_1^p \right] \mathcal{F}_{m_1} \left[ \sqrt{\frac{2 \pi}{\lambda_k}} k_1^p \right] \frac{1}{\sqrt{4 \pi \sigma^2}} \exp \left[ -\frac{(R_1 - R_0)^2}{\sigma^2} \right].$$

(73)

### 3.6. Asymptotic continuous limit

One can note that in Eq. (73) the susceptibility coefficients are still expressed as a discrete sum on the basis index $k_1^p$ and $R_0^p$. Our next step is to replace these sums by continuous integrals. The discrete basis elements are separated by the step distances $\Delta R_0$ and $\Delta \lambda_k$, which must satisfy the WKB hypothesis detailed in Eq. (41). We use the Riemann sum formula $\sum f(x) \Delta x \approx \int dx \ f(x)$, where $\Delta x$ controls the distance between the basis elements. This transformation is a subtle stage of the calculation because one has to consider step distances $\Delta R_0$ and $\Delta \lambda_k$, which have to simultaneously be large to comply with the WKB assumption from Eq. (41) and small to allow the use of the Riemann sum formula. As we are going to transform both the sums on $k_1^p$ and $R_0^p$, the exact value of the susceptibility coefficients will depend on our choice for $\Delta R_0 \Delta \lambda_k$. One has to consider the case

$$\Delta R_0 \Delta \lambda_k = 2\pi.$$  

(74)

This sampling corresponds to a critical sampling condition (Gabor 1946; Daubechies 1990; see also Fouvry et al. 2015b).

Equation (73) then takes the form

$$\frac{1}{\mathcal{D}_{m_1,m_1}(R_1, J_1, R_1, J_1, \omega)} = \frac{G}{2\pi R_1} \int dk \frac{1}{k R_0} \frac{1}{1 - \lambda_k} \mathcal{F}_{m_1} \left[ \sqrt{\frac{2 \pi}{\lambda_k}} k_1^p \right] \mathcal{F}_{m_1} \left[ \sqrt{\frac{2 \pi}{\lambda_k}} k_1^p \right] \frac{1}{\sqrt{4 \pi \sigma^2}} \exp \left[ -\frac{(R_1 - R_0)^2}{\sigma^2} \right].$$

(75)

One can now assume that the radial Gaussian present in Eq. (75) is sufficiently peaked. Because it is correctly normalized, we may in this limit replace it by $\delta(R_1 - R_0)$. The integration on $R_0$ can then be immediately performed to give

$$\frac{1}{\mathcal{D}_{m_1,m_1}(R_1, J_1, R_1, J_1, \omega)} = \frac{G}{2\pi R_1} \int dk \frac{1}{k} \frac{1}{1 - \lambda_k} \mathcal{F}_{m_1} \left[ \sqrt{\frac{2 \pi}{\lambda_k}} k_1^p \right] \mathcal{F}_{m_1} \left[ \sqrt{\frac{2 \pi}{\lambda_k}} k_1^p \right],$$

(76)

where only $\lambda_k$ depends on the frequency of evaluation $\omega$. One may note that in Eq. (76), all the dependencies in $\sigma$ have disappeared, so that the value of the susceptibility coefficients is independent of the precise choice of the WKB basis. The square of the susceptibility coefficients which is required to estimate the drift and diffusion coefficients from Eqs. (8) and (9) is therefore given by

$$\frac{1}{\mathcal{D}_{m_1,m_1}(R_1, J_1, R_1, J_1, \omega)}^2 = \frac{G^2}{4\pi^2 R_1} \mathcal{F}_{m_1} \left[ \sqrt{\frac{2 \pi}{\lambda_k}} k_1^p \right] \mathcal{F}_{m_1} \left[ \sqrt{\frac{2 \pi}{\lambda_k}} k_1^p \right].$$

(77)

where we introduced a cut-off at $1/\sigma_k$ for the integration on $k$. This bound is justified by the WKB constraint from Eq. (41), which imposes that the probed radial frequency region is bounded from below. It is also important to note that these susceptibility coefficients should be evaluated at $R_2 = R_1$, since we proved in Eq. (72) that, consistently with our WKB approximation, exactly local resonances are the only ones which have to be considered.

At this stage, there is an arbitration to make between two possible behaviours depending on the physical properties of the underlying disc. First of all, if the amplification function $k_r \rightarrow 1/(1 - \lambda_k)$ is asymptotically a sharp function reaching a maximum value $\lambda_{\text{max}}$ for $k_r = k_{\text{max}}$, one can assume that the susceptibility coefficients are dominated by the contribution from the peak in $\lambda_k$. In this situation, we can perform an approximation of the small denominators. The second possible behaviour arises if the function $k_r \rightarrow 1/(1 - \lambda_k)$ is asymptotically flat, so that there is no characteristic scale of blow-up of the amplification eigenvalues. In such a situation, the susceptibility coefficients are mostly dominated by the behaviour at the boundaries of integration from Eq. (77) where $k_r \rightarrow 1/\sigma_k$. The detailed response structure of the self-gravitating disc then does not play a significant role.

We place ourselves within the approximation of the small denominators, assuming that the biggest contribution to the susceptibility coefficients comes from waves which yield the largest $\lambda_k$. Therefore, one has to suppose that the function $k_r \rightarrow 1/(1 - \lambda_k)$ is a sharp function reaching a maximum value $\lambda_{\text{max}}(R_1, \omega)$, for $k_r = k_{\text{max}}(R_1, \omega)$, with a characteristic spread $\Delta \lambda_k(R_1, \omega)$. The expression (77) then becomes

$$\frac{1}{\mathcal{D}_{m_1,m_1}(R_1, J_1, R_1, J_1, \omega)}^2 = \frac{G^2 (\Delta \lambda_k)^2}{4\pi^2 R_1^2} \mathcal{F}_{m_1} \left[ \sqrt{\frac{2 \pi}{\lambda_k}} k_1^p \right] \mathcal{F}_{m_1} \left[ \sqrt{\frac{2 \pi}{\lambda_k}} k_1^p \right].$$

(78)

While still focusing on the contribution to the susceptibility coefficients due to the waves with the largest amplification $\lambda(k_r)$, one can improve the approximation of the small denominators from Eq. (78). Indeed, starting from Eq. (77), one can instead perform the $k_r$-integration for $k_r \in [k_{\text{inf}}, k_{\text{sup}}]$, where these bounds are given by $\lambda(k_{\text{inf(sup)}}) = \lambda_{\text{max}}/2$. This approach is numerically more demanding but does not alter the principal conclusions drawn in this paper, while allowing a more precise determination of the secular flux structure. All the calculations presented in Sect. 4 were performed with this improved approximation. Finally, in Appendix B, we detail how this same WKB formalism may be applied to the inhomogeneous Balescu-Lenard equation without collective effects (Chavanis 2013b).

### 3.7. Estimation of the drift and diffusion coefficients

The drift and diffusion coefficients are given by Eqs. (8) and (9). Within the WKB approximation, we have shown in Eqs. (65) and (72) that the susceptibility coefficients have to be evaluated only for $m_1 = m_2$, so that the sum on $m_1$ in the expressions of the drift and diffusion coefficients may be dropped. As the resonances are exactly local, using the formula from Eq. (67) adds a prefactor of the form $1/|\partial(m_1 \cdot \Omega)/\partial m_1|$ so that the drift
coefficients from Eq. (8) become
\[ A_m(J) = -\frac{4\pi^7\mu}{|\frac{\partial}{\partial \|J_m \|} \Omega_1|} \times \int dJ^2 \frac{m_1 \cdot \delta F/\delta J(J^1, J^2)}{|D_m,m(J^1, J^2, J^3, m_1 \cdot \Omega_1)|^2}. \] (79)

Similarly, the diffusion coefficients are given by
\[ D_m(J) = \frac{4\pi^7\mu}{|\frac{\partial}{\partial \|J_m \|} \Omega_1|} \times \int dJ^2 \frac{F(J^1, J^2)}{|D_m,m(J^1, J^2, J^3, m_1 \cdot \Omega_1)|^2}. \] (80)

In both Eqs. (79) and (80), the susceptibility coefficients are given by Eq. (77) or, within the approximation of the small denominators, by Eq. (78).

Such simple expressions of the drift and diffusion coefficients along with the required expression of the susceptibility coefficients constitute a main result of this paper. One should also note that this WKB formalism is self contained and is obtained without any ad hoc assumptions or fittings. Except for the explicit recovery of the amplification eigenvalues from Eq. (62), the calculations presented previously are not limited to the Schwarzschild distribution function from Eq. (25). Indeed, the drift and diffusion coefficients from Eqs. (79) and (80) are valid for any tepid disc, as long as the epicyclic angles-actions mapping from Eq. (24) may be used. In Appendix C, we show how the drift and diffusion coefficients from Eqs. (79) and (80) can be explicitly computed, when one considers a Schwarzschild distribution function as in Eq. (25) and when the susceptibility coefficients are estimated thanks to the approximation of the small denominators from Eq. (78). Finally, in Appendix D, we compare this 2D WKB Balescu-Lenard equation with other similar kinetic equations.

4. Application

We may now illustrate how this WKB approximation of the inhomogeneous Balescu-Lenard equation can be implemented to recover some results obtained via well-crafted numerical simulations. Indeed, Sellwood (2012; hereafter S12) using careful numerical simulations studied the long-term evolution of an isolated stable and stationary Mestel disc (Mestel 1963) sampled by pointwise particles. When evolved for hundreds of dynamical times, such a disc would secularly diffuse in action-space through the spontaneous generation of transient spiral structures. Figure 7 of S12 shows for instance the late time formation of resonant ridges along very specific resonant directions. Such features are possible signatures of secular evolution, which results in a long-term aperiodic evolution of a self-gravitating system, during which small resonant and cumulative effects can add up in a coherent way. These small effects, which are then amplified through the self-gravity of the system originate from finite-\(N\) effects. Indeed, the distribution function of the system is made of a finite number \(N\) of pointwise particles. Even with a perfect numerical integrator, the system would necessarily undergo encounters during which orbits feel the discreteness of the joint DF through its two point correlation. One should remark that these interactions need not be local but assume that the potential fluctuations are resonant so as to build up a secular evolution of the system. This effect, which is still present even in the absence of any numerical noise, is the effect captured by the Balescu-Lenard equation (see Fig. 1).

4.1. The disc model

The disc considered by S12 is an infinitely thin Mestel disc, for which the circular speed \(v_c\) is a constant \(V_0\) independent of the radius. Such a model represents fairly well the observed rotation curve of real galaxies. The stationary background potential \(\psi_m\) of such a disc and its associated surface density \(\Sigma_m\) are given by
\[ \psi_m(R) = V_0^2 \ln \left( \frac{R}{R_0} \right); \quad \Sigma_m(R) = \frac{V_0^2}{2\pi GR^2}. \] (81)

where \(R_0\) is a scale parameter. Because of this scale invariance, the relationship between the angular momentum \(J_0\) and the guiding radius \(R_0\) is straightforwardly given by
\[ J_0 = R_0 V_0. \] (82)

Within the epicyclic approximation, the intrinsic frequencies \(\Omega_0\) and \(\kappa\) can be computed thanks to Eqs. (22) and read
\[ \Omega_0(J) = \frac{V_0^2}{J_0}; \quad \kappa(J) = \sqrt{2} \Omega_0(J). \] (83)

We note that \(\kappa/\Omega_0 = \sqrt{2}\), so that the Mestel disc could be seen as an intermediate case between the Keplerian case for which \(\kappa/\Omega_0 = 1\) and the harmonic case for which \(\kappa/\Omega_0 = 2\). The ratio of the intrinsic frequencies is an important parameter for the system since it will determine the location of the resonances and a constant ratio may introduce dynamical degeneracies. This is the case for the Keplerian and harmonic discs for which \(\kappa/\Omega_0\) is a rational number, as discussed below Eq. (69). By contrast, for the Mestel disc, the non-rational ratio \(\kappa/\Omega_0 = \sqrt{2}\) ensures that the potential is non-degenerate. Using the epicyclic approximation, the DF considered by S12 takes, as in Eq. (25), the form of a Schwarzschild DF, where the intrinsic frequencies are given by Eq. (83), the velocity dispersion \(\sigma_r\) is constant throughout the entire disc, and the surface density is given by \(\Sigma\), i.e. the active surface density of the disc. Indeed, in order to accommodate the central singularity and the infinite extent of the Mestel disc, one introduces tapering functions \(T_{\text{inner}}\) and \(T_{\text{outer}}\) to damp out the inner and outer regions, which read
\[ \begin{aligned} T_{\text{inner}}(J_0) &= \frac{J_0^\nu}{(R_0 V_0)^\nu + J_0^\nu}, \\
T_{\text{outer}}(J_0) &= \left[ 1 + \frac{J_0}{R_0 V_0} \right]^{\mu_1 - 1}, \end{aligned} \] (84)

where \(\nu_1\) and \(\mu_1\) control the sharpness of the two tapers and \(R_0\) is an additional scalar parameter. The two tapers are physically motivated by the presence of a bulge and an outer truncation for the disc. Moreover, in order to reduce the susceptibility of the disc, we also suppose that only a fraction \(\xi\) of the disc is self-gravitating, with \(0 \leq \xi \leq 1\), so that the rest of the gravitational field is provided by the static halo. As a conclusion, the active surface density \(\Sigma\) is given by
\[ \Sigma(J) = \xi \Sigma_m(J) T_{\text{inner}}(J) T_{\text{outer}}(J). \] (85)

where \(\Sigma_m\) is the surface density of the Mestel disc from Eq. (81). We place ourselves in the same units system as in S12, so that we...
have \( V_0 = G = R = 1 \). The other numerical factors are given by \( \sigma_r = 0.284, v_1 = 4, \mu_1 = 5, \xi = 0.5 \) and \( R_0 = 11.5 \). The shape of the active surface density is illustrated in Fig. 4. The initial contours of the Schwarzschild DF from Eq. (25) are shown in Fig. 5. One can also straightforwardly estimate the total active mass of such a disc, given by \( M_{\text{rat}} \approx 5.4 \). For such an almost scale invariant disc, the local Toomre parameter, \( Q \) (Toomre 1964)

\[
Q(J_\phi) = \frac{\sigma_r k(J_\phi)}{3.36 GS(J_\phi)}, \tag{86}
\]

which for \( Q > 1 \) ensures the stability of the disc with respect to local axisymmetric disturbances, becomes almost independent of the radius, especially in the intermediate regions of the disc. As illustrated in Fig. 6, \( Q \approx 1.5 \) between the tapers and increases strongly in the tapered regions.

The expression (10) of the secular diffusion flux requires summing on all the resonances \( \Phi \). S12 restricted perturbations forces to \( m_\phi = 2 \), so that we may impose this same restriction on the considered azimuthal number \( m_\phi \). Throughout our numerical calculations, we will restrict ourselves to only three different resonances which are: the inner Lindblad resonance (ILR) corresponding to \((m_\phi^{\text{ILR}}, m_\phi^{\text{OLR}}) = (-1, 2)\), the outer Lindblad resonance (OLR) given by \((m_\phi^{\text{OLR}}, m_\phi^{\text{OLR}}) = (1, 2)\) and the corotation (COR) for which \((m_\phi^{\text{COR}}, m_\phi^{\text{COR}}) = (0, 2)\). Moreover, all the calculations in the upcoming sections have also been performed while taking into account the contributions from the resonances with \( m_\phi = \pm 2 \), which were checked to be subdominant. Being able to perform such a restriction to the relevant resonances appearing in the secular flux \( \mathcal{F}_{\text{tot}} \) from Eq. (10) is an important step of the calculation.

Returning to the fast and slow coordinates from Eq. (14), one can note that the diffusion associated with the COR resonance amounts to diffusion along the \( J_\phi \)-axis. Such diffusion brings stars from one quasi-circular orbit to another of a different radius and is called radial migration. Conversely, the diffusion associated with the ILR and OLR resonances exhibits a non-zero diffusion component in the \( J_\phi \)-direction. It therefore increases the velocity dispersion within the disc so as to heat it, while either decreasing (ILR) or increasing (OLR) star’s angular momentum.

### 4.2. Disc amplification

One may now study the behaviour of the amplification eigenvalues \( \lambda_k \) given by Eq. (62), thanks to which one can perform the improved approximation of the small denominators. For a given resonance \( \Phi \) and angular momentum \( J_\phi \), the amplification function \( k_r \mapsto \lambda_k \) is presented in Fig. 7. As Eq. (62) only depend on \( s^2 \), the ILR and OLR resonances always have the...
which from Eq. (4) are not dominated only by the self-gravitating amplification.

The net fluxes involve simultaneously radial migration near \((J_\phi, J_r) = (1.8, 0)\), and heating near \((J_\phi, J_r) = (1, 0.1)\).

same response matrix eigenvalues. One can also note that the eigenvalues \(\lambda(k_r)\) are maximum for a frequency \(k_{\text{max}}(J_\phi)\), where \(\lambda(k_{\text{max}}) = \lambda_{\text{max}}\), in a region whose size is given by the width at half maximum \(\Delta k_\lambda\). Because of the scale-invariance property of the Mestel disc, it is straightforward to show that \(\Delta k_\lambda \propto 1/J_\phi\), \(k_{\text{max}} \propto 1/J_\phi\) and \(k_{\text{int/sup}} \propto 1/J_\phi\). One can then consider the behaviour of the amplification factor \(1/(1 - \lambda_{\text{max}})\), which encodes the strength of the self-gravitating amplification, as shown in Fig. 8. We note that the COR resonance is always more amplified than the ILR and OLR resonances, but the maximum amplification \((-3\) for the COR and \(-1.5\) for the ILR and OLR) remains sufficiently small, so that the susceptibility coefficients from Eq. (4) are not dominated only by the self-gravitating amplification.

4.3. Computing the diffusion flux

Given the knowledge of the eigenvalues, it is now straightforward to compute the susceptibility coefficients within the improved approximation of the small denominators thanks to Eq. (77), where the integration on \(k_r\) is performed for \(k_r \in [k_{\text{int}}; k_{\text{sup}}]\). One can then compute the associated drift and diffusion coefficients respectively given by Eqs. (79) and (80). The diffusion flux \(F_{\text{tot}}\) defined in Eq. (10) immediately follows, where the sum on \(m\) is restricted only to the three resonances ILR, COR and OLR. In Appendices E and F, we discuss two specific properties of such a truncated Mestel disc, namely the cancellation between the radial components of the diffusion and drift elements (the Schwarzschild conspiracy, Appendix E) and the natural and intrinsic presence of a temporal frequency bias (Appendix F), both of which enlighten the subtle arbitrations between the different resonances.

Finally, we may compute the divergence of this flux, \(\text{div}(F_{\text{tot}})\) given by Eq. (11) in order to compare quantitatively the WKB predictions with the results from S12’s simulations. Because the mass of the individual particles is given by \(\mu = M_\odot/N\), we will consider the quantity \(N\text{ div}(F_{\text{tot}})\), which is independent of \(N\). Figure 9 represents the contours of \(N\text{ div}(F_{\text{tot}})\). Comparisons of our WKB predictions with the results from S12’s simulation are illustrated in Figs. 10 and 11. In Fig. 9, red contours correspond to regions for which \(N\text{ div}(F_{\text{tot}}) < 0\), so that thanks to Eq. (11) they are associated with action-space regions where the WKB Balescu-Lenard equation predicts a decrement of the DF during secular evolution. In contrast, blue contours are associated with regions for which \(N\text{ div}(F_{\text{tot}}) > 0\), so that the DF will increase there. The overall picture involves two competing processes: i) the beginning of a ridge forming towards \((J_\phi, J_r) = (1, 0.1)\); and ii) the formation of an over density near \((J_\phi, J_r) = (1.8, 0)\). Point i) is in fact consistent with both the early time measurement of S12 as shown in Fig. 10 and the late time measurement of S12 as shown in Fig. 11. These qualitative agreements are in fact surprisingly good, given that the WKB theory is approximate and was only estimated for \(t = 0^\circ\). Interestingly, the early time measurement from Fig. 10 also displays a hint of an overdensity on the \(J_r = 0^\circ\) axis, in agreement with point ii), while the late time measurement suggests that the over density has split, with a hint of a second ridge forming. The time evolution of
so that Eq. (87) immediately becomes
\[ \frac{\partial F}{\partial \tau} = C_{\text{BL}}[F]. \] (90)

Equation (90) corresponds to a rewriting of the Balescu-Lenard equation, where \( N \) is not present anymore. This will allow us to quantitatively compare the time during which the S12 simulation was run to the diffusion time predicted by our WKB Balescu-Lenard formalism. In order to ease this comparison, we place ourselves in the same units system as the one used by S12. Figure 7 of S12 for which the ridge was observed was obtained with the parameters \( N = 50 \times 10^6 \) and \( \Delta t_{S12} = 1400 \). Using the rescaled time introduced in Eq. (89), one obtains that S12 observed the resonant ridge after a time \( \Delta t_{S12} = \Delta t_{S12}/N \approx 3 \times 10^{-5} \). One can then compare this time with the typical time required to obtain a resonant ridge within our WKB formalism. Given the map of \( N \text{ div}(F_{\text{tot}}) \) described in Sect. 4.3, one can estimate the typical time for which this flux could lead to the features observed in S12. The contours presented in the Fig. 7 of S12 are separated by a value of \( 0.1 \times F_{\text{max}}^0 \), where \( F_{\text{max}}^0 \approx 0.12 \) corresponds to the maximum of the normalized DF from Eq. (25). As a consequence, to observe the resonant ridge, the DF should typically change by a value of the order of \( \Delta F_0 \approx 0.1 \times F_{\text{max}}^0 \). From Fig. 9, one can note that the maximum value of the divergence of the flux is given by \( |N \text{ div}(F_{\text{tot}})| \approx 0.4 \). Finally, thanks to Eq. (11), one may write the relation \( \Delta F_0 \approx \Delta t_{\text{WKB}} |N \text{ div}(F_{\text{tot}})| \), where \( \Delta t_{\text{WKB}} \) is the minimal time during which the WKB Balescu-Lenard equation has to be considered in order to develop a ridge. Thanks to the previous typical numerical values, one obtains that \( \Delta t_{\text{WKB}} \approx 3 \times 10^{-2} \). When comparing these two typical times, \( \Delta t_{S12} \) the duration during which S12 simulation was performed and \( \Delta t_{WKB} \) the duration required to observe secular diffusion in the WKB Balescu-Lenard formalism, one obtains the order of magnitude
\[ \frac{\Delta t_{S12}}{\Delta t_{WKB}} \approx 10^{-3}. \] (91)

Hence the direct application of the WKB-limited Balescu-Lenard equation does not allow us to predict the observed timescale for the diffusion features in simulations. Indeed, the timescale of collisional diffusion predicted by this WKB formalism seems much larger than the time during which the numerical simulation was performed. This discrepancy is also strengthened by the use of a softening length in numerical simulations, which induces an effective thickening of the disc, so as to slow down the collisional relaxation. A possible explanation for this timescale discrepancy is discussed in the next section.

## 4.5. Interpretation

In order to interpret S12’s simulation under the light of a collisional secular diffusion equation, such as the Balescu-Lenard equation and its WKB limit, one should first note the undisputed presence of collisional effects in S12’s simulation. Indeed, Fig. 2 of S12 shows that when the number of particles of the simulation is increased, the strength of the density fluctuations is delayed, which in turn is likely to be related to the amplitude of the secular features. The larger the number of particles, the later the effect of secular diffusion. Such dependence illustrates the fact that discreteness effects do play a role in the secular diffusion observed in S12.
Sellwood & Kahn (1991) have argued that a sequence of causally connected swing amplified transients could occur subject to a (possibly non-local) resonant condition between successive spiral waves. The Balescu-Lenard formalism captures precisely such sequences – in as much as it integrates over dressed correlated potential fluctuations subject to relative resonant conditions, but does not preserve causality nor resolve them on dynamical timescales. The exact initial phases are not relevant in the Balescu-Lenard formalism: see Appendix A for a sketch of a full derivation which makes this point clear.

The timescale discrepancy observed in Eq. (91) might be driven by the incompleteness of the WKB basis. Indeed, Eq. (26)’s basis – thanks to which the susceptibility coefficients were evaluated in Eq. (77) – does not form a complete set, as it can only represent correctly tightly wound spirals. It also enforces local resonances, and does not allow for remote orbits to resonate, or wave packets to propagate between such non-local resonances. The seminal works from Goldreich & Lynden-Bell (1965), Julian & Toomre (1966), Toomre (1981) showed that any leading spiral wave during its unwinding to a trailing wave undergoes a significant amplification, coined swing amplification. Because it involves open spirals this mechanism is not captured by the WKB formalism. This additional amplification is expected to increase the susceptibility of the disc and therefore accelerate secular diffusion (both drift and diffusion), so that the timescales discrepancy from Eq. (91) will become less restrictive. Following the notations from Toomre (1981), the truncated Mestel disc considered in the S12 simulation corresponds to $Q \approx 1.5$ and $X = 2$, so that Fig. 7 from Toomre (1981) shows that significant swing amplification (of order 10) may be expected. It has also been claimed (Toomre & Kalnajs 1991) that swing amplified shot noise in the shearing sheet approximation would behave like significantly heavier macro-particles. Such an amplification would keep a dependence of the secular response with the total number $N$ of particles, but would reduce significantly the effective number of particles.

The Balescu-Lenard WKB limit seems to capture qualitatively the main features of the initial diffusion process in action space (as discussed in Sect. 4.3), but falls short in predicting the relevant timescale. The remaining questions are therefore: what is the exact impact of swing amplification? Can it explain the timescale discrepancy?

5. Conclusion
We implemented the inhomogeneous Balescu-Lenard Eq. (2) for an infinitely thin galactic disc using two main approximations. We first assumed the disc to be tepid. We could then use the infinitely thin galactic disc using two main approximations. We implemented the inhomogeneous Balescu-Lenard Eq. (2) for $\xi$. The straightforward calculation in the WKB limit of the divergence of the full diffusion flux, $N \text{div}(\mathcal{F}_{\text{full}})$, illustrated in Figs. 9–11, recovered most of the secular features observed in S12. This qualitative agreement is impressive given the level of approximation involved in the WKB limit. The hints for the formation of a ridge – depletion and enrichment of orbits along a preferred direction – is qualitatively consistent with the findings of S12 and Fouvry & Pichon (2015), Fouvry et al. (2015a), without postulating additional assumptions about the source of fluctuations.

The comparison of the collisional time predicted in the WKB limit (Eq. (91)) to the diffusion time of S12 simulation, highlights nonetheless a significant quantitative overestimation. We provided a possible explanation which relies on the intrinsic limitations of the WKB formalism, as it cannot account for swing amplification, during which unwinding transient spirals are strongly amplified. This additional amplification, which involves explicitly non-local wave absorption and emission, may be the missing contribution required to reconcile quantitatively our predictions and the simulation. One venue will be to compute numerically exactly Eqs. (8) and (9) in action space – without assuming tightly wound spirals or epicyclic orbits – with a complete basis. This is the topic of an upcoming numerical investigation in Fouvry et al. (2015c).

Should this complementary investigation explain the timescale mismatch, one would be in a stronger position to validate the accuracy of $N$-body schemes to correctly capture secular evolution of discrete self-gravitating cold discs over very long timescales. This would clearly be a worthy assessment of such schemes relying on the Balescu-Lenard theory. Once the above described conundrum is resolved, we will also be able to evolve over secular times the Balescu-Lenard equation and predict the full cosmic time evolution of such discrete discs. This may also contribute to solving the timescale discrepancy.

In closing, beyond the application presented in Sect. 4, the above developed tightly wound Balescu-Lenard formalism may for instance describe the secular diffusion of giant molecular clouds in galactic discs (which in turn could play a role in migration driven metallicity gradients and disc thickening), the secular migration of planetesimals in partially self-gravitating protoplanetary discs, or even the long-term evolution of population of stars, gas blobs and debris near the Galactic centre. Such topics will be subject to further investigations.

fn5 In contrast, the formalism of secular forcing presented in Fouvry & Pichon (2015), Fouvry et al. (2015a) postulated a partially ad hoc shape of the perturbation power spectrum, see Eq. (F2).

fn6 An alternative middle ground would be to account for non-local interferences of the WKB wave packets, given by Eq. (26), which in turn would allow for non-local resonances to come into play.

where we have introduced the intrinsic frequencies of the system \( \Omega_i = \Omega_i(J_1) \), as in Eq. (1), and where \( \langle \ldots \rangle \) denotes an angular average. Because of our timescale-decoupling approach, we may neglect the time variation of \( F(J_1,t) \) in the calculation of the collision term (adiabatic approximation). It implies that \( F \) may be treated as a constant in Eq. (A.7) because \( F \) evolves on a (relaxation) timescale much larger than the (dynamical) time corresponding to the evolution of \( \delta F \). In order to be valid, this approximation requires that \( N \gg 1 \). Finally, we also assume that the distribution \( F \) remains Vlasov stable, so that its evolution is only governed by correlations and not by dynamical instabilities.

The first step of the derivation of the Balescu-Lenard equation is then to study the short timescale evolution Eq. (A.7). One defines the Fourier-Laplace transform of the fluctuation \( \delta F \) as

\[
\tilde{\delta F}_m(J_1, \omega_1) = \int_0^{\infty} dt \, e^{-i\omega_1 t} \delta F(J_1,t), \quad \omega_1 = m_1 / (2\pi^2), \quad m = m_1, \Omega_1 = \omega_1, \quad \omega_1 \gg \Omega. \tag{A.9}
\]

valid for \( \text{Im}(\omega_1) \) sufficiently large. Similarly to Eq. (6), one also defines the spatial Fourier transform of the initial value as

\[
\tilde{\delta F}_m(J_1, 0) \equiv \int_0^{\infty} dt \, e^{-i\omega_1 t} \delta F(J_1, t, 0). \tag{A.10}
\]

Thanks to these transformations, Eq. (A.7) may be rewritten under the form

\[
\tilde{\delta F}_m(J_1, \omega_1) = \frac{m_1 \cdot \tilde{\delta F}_m(J_1, \omega_1)}{m_1 \cdot \Omega_1 - \omega_1} + \tilde{\delta F}_m(J_1, 0) \tag{A.11}
\]

where we have introduced the basis elements introduced in Eq. (3), so that we may decompose the potential fluctuations under the form

\[
\tilde{\delta \psi}(\theta_1, J_1, t) = \sum \tilde{a}_p(t) \psi_p(\theta_1, J_1). \tag{A.12}
\]

We introduce the Laplace transform of \( a_p(t) \) as

\[
\tilde{a}_p(\omega) = \int_0^{\infty} dt \, a_p(t) e^{i\omega t}. \tag{A.13}
\]

One can then take the inverse Fourier transform of Eq. (A.11), multiply by \( \tilde{\delta \psi}_m(J_1, J_2) \) and integrate over \( \theta_1 \) and \( J_1 \) (using the property that \( \int d\theta_1 dJ_1 = \delta(\theta_1, J_1) \)). One gets

\[
\tilde{a}_p(\omega) = -\left(2\pi^2\right)^d \delta(\omega - \Omega) \int \frac{dJ_2}{(m_2 \cdot \Omega_2 - \omega)} \psi_m^p(J_2), \tag{A.14}
\]

where the response matrix \( \tilde{M} \) is given by Eq. (5). Equation (A.14) can be rewritten under the form

\[
\tilde{\delta \psi}_m(J_1, \omega_1) = -\left(2\pi^2\right)^d \delta(\omega - \Omega) \int \frac{dJ_2}{(m_2 \cdot \Omega_2 - \omega)} \tilde{\delta F}_m(J_2, 0), \tag{A.15}
\]

where the susceptibility coefficients have been introduced in Eq. (4). One can now compute the collision term appearing in the r.h.s. of Eq. (A.8). It requires us to evaluate

\[
\left[ \frac{\partial \tilde{F}}{\partial \theta_1} \frac{\partial \tilde{\delta \psi}}{\partial \theta_1} \right] = \left[ \frac{\partial \tilde{F}}{\partial J_1} \frac{\partial \tilde{\delta \psi}}{\partial J_1} \right] \times \delta(\tilde{F}_m(J_1, \omega_1)) \tilde{\delta \psi}_m(J_1, \omega_2). \tag{A.16}
\]
Using Eq. (A.11), one immediately obtains that

\[
\langle \delta \tilde{F}_m(J, 1, \omega_1) \delta \tilde{f}_m(J, 1, \omega_2) \rangle =
\frac{m_1 \cdot \partial F / \partial J_1}{m_1 \cdot \Omega_1 - \omega_1} \left( \delta \tilde{f}_m(J, 1, \omega_1) \delta \tilde{f}_m(J, 1, \omega_2) \right) + \frac{\langle \delta \tilde{F}_m(J, 1, 0) \delta \tilde{f}_m(J, 1, \omega_2) \rangle}{i (m_1 \cdot \Omega_1 - \omega_1)}.
\]

(A.17)

In Eq. (A.17), the first term corresponds to the self-correlation of the potential whereas the second term corresponds to the correlations between the potential fluctuations and the distribution function at time \( t = 0 \). Each of these terms must then be considered one at a time. Assuming that there is no correlation in the initial phases, one can show (see Appendix C from Chavanis 2012a) that

\[
\langle \delta \tilde{F}_m(J, 1, 0) \delta \tilde{F}_m(J, 2, 0) \rangle = \frac{\mu}{(2\pi)^2} \delta \tilde{f} \delta \tilde{f} (J_1 - J_2) F(J_1).
\]

(A.18)

Hence, given Eq. (A.15), one can rewrite the first term of Eq. (A.17) under the form

\[
\langle \delta \tilde{F}_m(J, 1, 0) \delta \tilde{f}_m(J, 1, \omega) \rangle = \left( \frac{2\pi}{m} \right)^{1/2} \int_{D_{m,\omega}} \frac{1}{D_{m,\omega}(J_1, J_2, \omega)} \frac{1}{(m_1 \cdot \Omega - \omega)} F(J_1, J_2).
\]

(A.19)

If we consider only the contributions that do not decay in time, one can perform the substitution

\[
\frac{1}{(m_1 \cdot \Omega - \omega)(m_1 \cdot \Omega_1 + \omega)} \to
(2\pi)^2 \mu \delta \tilde{f} \delta \tilde{f} (J_1 - J_2) F(J_1).
\]

Starting from Eq. (A.19), thanks to the previous substitution and using the fact that \( D_{m,\omega}(J_1, J_2, \omega) = D_{m,\omega}(J_1, J_2, \omega) \), one can show that the first contribution from Eq. (A.16) takes the form

\[
\left\langle \frac{\partial F}{\partial \tilde{f}_1} \right\rangle = -2\pi \mu \sum_{m} \int_{D_{m,\omega}} \frac{m_1 \cdot \partial F / \partial J_1}{m_1 \cdot \Omega_1 - \omega} \delta \tilde{f}_m(J_1, J_2, \omega) \delta \tilde{f}_m(J_1, J_2, \omega)
\]

(A.20)

The last step of the calculation is to use the Landau prescription \( \omega \to \omega + i0^+ \) along with Plemelj formula

\[
\frac{1}{x \pm i0^+} = P \left( \frac{1}{x} \right) \mp i\pi \delta(x, x).
\]

(A.21)

where \( P \) is the principal value. One can then rewrite Eq. (A.20)

\[
\left\langle \frac{\partial F}{\partial \tilde{f}_1} \right\rangle = \pi (2\pi)^2 \mu \sum_{m} \int_{D_{m,\omega}} \frac{m_1 \cdot \partial F / \partial J_1}{m_1 \cdot \Omega_1 - \omega} \delta \tilde{f}_m(J_1, J_2, \omega) \delta \tilde{f}_m(J_1, J_2, \omega)
\]

(A.22)

Similarly, one can rewrite the second term of Eq. (A.17) under the form

\[
\left\langle \frac{\partial F}{\partial \tilde{f}_1} \right\rangle = \left( \frac{2\pi}{m} \right)^{1/2} \int_{D_{m,\omega}} \frac{1}{D_{m,\omega}(J_1, J_2, \omega)} \frac{1}{(m_1 \cdot \Omega_1 - \omega)} F(J_1).
\]

(A.23)

Using symmetries of the matrix \([I - \tilde{M}]^{-1}\), starting from Eq. (A.23), one can show that the second contribution from Eq. (A.16) finally takes the form

\[
\left\langle \frac{\partial F}{\partial \tilde{f}_1} \right\rangle = -2\pi \mu \sum_{m} \int_{D_{m,\omega}} \frac{m_1 \cdot \partial F / \partial J_1}{m_1 \cdot \Omega_1 - \omega} \delta \tilde{f}_m(J_1, J_2, \omega) \delta \tilde{f}_m(J_1, J_2, \omega)
\]

(A.24)

Combining the two contributions obtained in Eqs. (A.22) and (A.24), one can rewrite Eq. (A.16) under the form

\[
\left\langle \frac{\partial F}{\partial \tilde{f}_1} \right\rangle = \pi (2\pi)^2 \mu \sum_{m} \int_{D_{m,\omega}} \frac{m_1 \cdot \partial F / \partial J_1}{m_1 \cdot \Omega_1 - \omega} \delta \tilde{f}_m(J_1, J_2, \omega) \delta \tilde{f}_m(J_1, J_2, \omega)
\]

(A.25)

Hence, using the slow evolution Eq. (A.8), we recover the Balescu-Lenard equation introduced in Eq. (2). As a final remark, one may notice that on the short dynamical timescale, the evolution is governed by Eq. (A.7), which involves the fluctuating components \( \delta F \) and \( \delta \psi \) of the distribution function and the potential. In contrast, on the long secular timescale, the evolution is governed by Eq. (A.8), which after an angle-average only involves the mean distribution function \( F \). Indeed, thanks to the ensemble average, all the cross-correlations between the fluctuations \( \delta F \) and \( \delta \psi \), as in Eqs. (A.18), (A.19) and (A.23) can be expressed in terms of the underlying smooth distribution function \( F \) only, so that the fluctuating components are absent from the secular Balescu-Lenard collision operator from Eq. (A.25).

Appendix B: Turning off collective effects

The reference Chavanis (2013b; see also Appendix A of Chavanis 2012a) considers the inhomogeneous Balescu-Lenard equation without collective effects. This collisional kinetic equation is the equivalent of the Landau equation for inhomogeneous systems. It can be straightforwardly obtained as an approximation of the Balescu-Lenard Eq. (2). Indeed, one has to make the substitution from the dressed susceptibility coefficients \( 1/D_{m,\omega}(J_1, J_2, \omega) \) to the bare ones given by \( A_{m,\omega}(J_1, J_2) \), so that the inhomogeneous Balescu-Lenard equation without collective effects (i.e. the inhomogeneous Landau equation) is given by

\[
\frac{\partial F}{\partial t} = \pi (2\pi)^2 \mu \sum_{m} \int_{D_{m,\omega}} \frac{m_1 \cdot \partial F / \partial J_1}{m_1 \cdot \Omega_1 - \omega} \delta \tilde{f}_m(J_1, J_2, \omega) \delta \tilde{f}_m(J_1, J_2, \omega)
\]

\[
\times [A_{m,\omega}(J_1, J_2)]^2 \left\langle \frac{m_1 \cdot \partial F / \partial J_1}{m_1 \cdot \Omega_1 - \omega} \delta \tilde{f}_m(J_1, J_2, \omega) \delta \tilde{f}_m(J_1, J_2, \omega) \right\rangle
\]

(B.1)

where the coefficients \( A_{m,\omega} \) are associated with the Fourier transform in angles of the interaction potential (Pichon 1994; Chavanis 2013b) and read

\[
A_{m,\omega}(J_1, J_2) = \frac{1}{(2\pi)^2} \int_{D_{m,\omega}} \partial \phi \partial \phi \left( \nabla \cdot [u(x) \cdot 1 - \nabla \cdot (u(x) \cdot 1)] \right) e^{-i(m_1 \cdot \theta_1 - m_2 \cdot \theta_2)},
\]

(B.2)

where \( u(x) \) is the binary potential of interaction given by \( u(x) = -G / |x| \) in the gravitational case. A key remark at this stage is that the expression (B.2) does not require the introduction of biorthogonal basis elements as in Eq. (3), whereas
in order to estimate the dressed susceptibility coefficients from Eq. (4), one must necessarily rely on Kalnajs’ matrix method (Kalnajs 1976). It is however possible to express $A_{m,m'}$ using the potential basis. Indeed, for a fixed value of $x_2$, we consider the function $x_1 \mapsto u(x_1 - x_2)$. One can then decompose this function on the basis elements $\psi_j^{\chi}(x_1)$, so that we may write

$$u(x_1 - x_2) = \sum_p a_p(x_2) \psi_j^{\chi}(x_1),$$  \hspace{1cm} (B.3)

where it is important to note that the basis coefficients $a_p(x_1)$ are functions of $x_1$. Thanks to the biorthogonality property of the basis detailed in Eq. (3), one can obtain the expression of the coefficients $a_p(x_2)$ which reads

$$a_p(x_2) = -k \int dx_1 u(x_1 - x_2) \psi_j^{\chi}(x_1)$$

$$= - \left[ k \int dx_1 u(x_1 - x_2) \psi_j^{\chi}(x_1) \right]^{*}$$

$$= - \psi^{\chi}(x_2),$$  \hspace{1cm} (B.4)

where we used the fact that $u$ is a real function. Hence we finally obtain

$$u(x_1 - x_2) = \sum_p \psi_j^{\alpha}(x_1) \psi_j^{\chi}(x_2).$$  \hspace{1cm} (B.5)

Taking appropriately a Fourier transform with respect to the angles as in Eq. (B.2), we obtain

$$A_{m,m'}(J_1, J_2) = \sum_p \psi_{m'}^{\beta}(J_1) \psi_m^{\alpha}(J_2).$$  \hspace{1cm} (B.6)

This fairly simple relation allows us to express the bare susceptibility coefficients $A_{m,m'}$ using the potential basis. One does not need anymore to perform a Fourier transform in angles of the interaction potential because the resolution of Poisson’s equation has been implicitly hidden in the effective construction of the basis elements. Neglecting the collective effects in the expression (4) of the dressed susceptibility coefficients amounts to taking $M(\omega) = 0$, so that we obtain

$$\left. \frac{1}{D_{m,m'}(J_1, J_2; \omega)} \right|_{\omega \text{col}} = -A_{m,m'}(J_1, J_2).$$  \hspace{1cm} (B.7)

The negative sign in Eq. (B.7) plays no significant role in the kinetic equations since one has to make the substitution of the square modulus $1/|D|^2 \mapsto |A|^2$ in the Balescu-Lenard Eq. (2) to obtain the inhomogeneous Landau Eq. (B.1). Using our WKB basis, one can proceed similarly as in the dressed case, by limiting oneself only to local resonances. Equation (76) therefore becomes in the bare case

$$A_{m,m'}(R_1, J_1, R_2, J_2) = - \frac{G}{2 R_1} \int_0^\infty \frac{dk_1}{k_1} \sum_{m'} J_{m'} \left[ \frac{2 \pi k_1}{\lambda_{12}} \right] J_{m'} \left[ \frac{2 \pi k_1}{\lambda_{12}} \right].$$  \hspace{1cm} (B.8)

This expression of the bare susceptibility coefficients can be straightforwardly obtained from the dressed ones by imposing $J = 0$. One should note that because of the absence of the amplification term $1/(1 - k_0^2)$, the approximation of the small denominators cannot be used. Hence a physically motivated evaluation of the expression (B.8) becomes more subtle to perform, especially because of the possibly important role that the Coulomb logarithm $1/k_0$ might play. Finally, one obtains that even for exactly local resonances, i.e. $m_1 = m_2$ and $R_1 = R_2$, the use of our WKB formalism allowed us to obtain non-diverging bare susceptibility coefficients. On the other hand, one could try to estimate the bare susceptibility coefficients starting from Eq. (B.2), i.e. without using any potential basis. Using the polar coordinates $(R, \phi)$, one has to compute

$$A_{m,m'}(J_1, J_2) = - \frac{G}{(2\pi)^2} \int d\theta_1 d\theta_2 d\phi_1 d\phi_2$$

$$\times \frac{e^{-im_1\theta_1} e^{im_2\phi_1}}{\sqrt{R_1^2 + R_2^2 - 2R_1 R_2 \cos(\phi_1 - \phi_2)}}.$$  \hspace{1cm} (B.9)

By azimuthal symmetry, it is straightforward to show (Pichon & Cannon 1997) that

$$A_{m,m'} \propto \delta^2_{m_1, m_2}.$$  \hspace{1cm} (B.10)

Hence the different $m_\phi$-modes of the $A_{m,m'}$ coefficients are independent. This result is identical to what was obtained in Eq. (65) for the dressed case. In order to illustrate the regularizing role of the WKB basis from Eq. (26), we will place ourselves in the context of an extremely tepid disc, and therefore assume $J_1 = J_2 = 0$. Thanks to the epicyclic mapping from Eq. (24), one can drop all the dependences on $\theta_\phi$ appearing in $R$ and $\phi$. Equation (B.9) then immediately implies that

$$m_1^2 = m_2^2 = 0,$$  \hspace{1cm} (B.11)

and the bare susceptibility coefficients are given by

$$A_{m,m'}(R_1, 0, R_2, 0) = - \frac{G}{(2\pi)^2} \delta^2_{m_1, m_2} \int d\theta_1 d\theta_2$$

$$\times \frac{e^{-im_1\theta_1} e^{im_2\theta_1}}{\sqrt{R_1^2 + R_2^2 - 2R_1 R_2 \cos(\theta_1 - \theta_2)}}.$$  \hspace{1cm} (B.12)

In this illustrative limit, we have by construction no contributions from the ILR and OLR resonances for which $m_\phi \neq 0$. After an immediate change of variables, using $\Delta = \theta_1 - \theta_2$, it becomes

$$A_{0,0,0,0}(R_1, 0, R_2, 0) = - \frac{G}{2\pi \sqrt{2} R_1} \int d\Delta$$

$$\times \frac{e^{-i\Delta}}{\sqrt{(R_1 - R_2)^2 + 2R_1 R_2 (1 - \cos(\Delta))}}.$$  \hspace{1cm} (B.13)

The resonance condition from Eq. (68) takes the form $m_\phi \Omega_g(R_1) = m_\phi \Omega_g(R_2)$ because we restricted ourselves in Eq. (B.11) to the case $m_1 = 0$. Hence assuming that the function $R_0 \mapsto \Omega_g(R_0)$ is a monotonic function, one has to satisfy the constraint $R_1 = R_2$, so that we are restricting ourselves only to local resonances as in Eq. (72). For such resonances, Eq. (B.13) becomes

$$A_{0,0,0,0}(R_1, 0, R_1, 0) = - \frac{G}{2\pi \sqrt{2} R_1} \int d\Delta$$

$$\times \frac{e^{-i\Delta}}{\sqrt{1 - \cos(\Delta)}}.$$  \hspace{1cm} (B.14)

At this stage, one must note that this integral is divergent. Indeed, for $\Delta \to 0$, one has $1/\sqrt{1 - \cos(\Delta)} \sim \sqrt{2}/\Delta$. Hence the expression of the bare susceptibility coefficients derived from the Fourier transform of the interaction potential as in Eq. (B.2),

This also explains why the factorization assumption

$$A_{m,m'}(J_1, J_2) = A_{m}(J_1) A_{m'}(J_2)$$

used in Chavanis (2007) does not hold.
when restricted to exactly local resonances becomes logarithmically divergent. This divergence, which is observed in the case of focal resonances, is induced by the interaction of singular orbits. It is important to remark that this divergence was not present in Eq. (B.8) when computing the bare susceptibility coefficients using the WKBI basis from Eq. (26). This implies that the WKBI basis is not complete. For a complete biorthogonal basis, the expression (B.6) of the $A_{m, m'}$ coefficients is an exact expression. However, our calculation shows that the scale-decoupled WKBI basis we used, possesses a subtle regularizing incompleteness which gets rid of the diverging contributions to the coefficients $A_{m, m'}$ in the limit of exactly local resonances.

Appendix C: The Schwarzschild DF case

When considering a Schwarzschild distribution function as in Eq. (25), while relying on the approximation of the small denominators from Eq. (78), one can explicitly perform the remaining integration on the radial action $J^r_1$ in the expressions (79) and (80) of the drift and diffusion coefficients. We now detail this explicit calculation. For such a Schwarzschild distribution function, it is straightforward to check that the gradients of the distribution function with respect to the actions are given by

$$\frac{\partial F}{\partial J_r} = -\frac{\kappa}{\sigma^2} F, \quad \frac{\partial F}{\partial J_\phi} = F \frac{\partial}{\partial J_\phi} \left[ \frac{\Omega \Sigma}{\pi \kappa \sigma^2} \right] - \frac{\kappa J_r}{\sigma^2}.$$  \hfill (C.1)

Using the expression of the susceptibility coefficients from Eq. (78), after some simple algebra, one can rewrite the drift coefficients from Eq. (79) under the form

$$A_{m_1}(J_1) = -g_{m_1}(J_0', J_1') \int dJ_2^r \exp \left[ -\frac{\kappa}{\sigma^2} J_r^2 \right] J_{m_1}^r \left[ \sqrt{\frac{2 \pi}{\kappa}} k_{\text{max}} \right]$$

$$\times \left[ m^2 \frac{\partial}{\partial J_\phi} \left[ \ln \left( \frac{\Omega \Sigma}{\pi \kappa \sigma^2} \right) - J_\phi \frac{\partial}{\partial J_\phi} \left( \frac{\kappa}{\sigma^2} \right) \right] - m^2 \frac{\kappa}{\sigma^2} \right].$$

Similarly, the diffusion coefficients from Eq. (80) take the form

$$D_{m_1}(J_1) = g_{m_1}(J_0', J_1') \int dJ_2^r \exp \left[ -\frac{\kappa}{\sigma^2} J_r^2 \right] J_{m_1}^r \left[ \sqrt{\frac{2 \pi}{\kappa}} k_{\text{max}} \right].$$ \hfill (C.3)

In Eqs. (C.2) and (C.3), in order to shorten the notations, we introduced the function $g_{m_1}(J_0', J_1')$ defined as

$$g_{m_1}(J_0', J_1') = \frac{\mu}{(m_1 \cdot \Omega')} \frac{G^2 \Omega \Sigma (\Delta k_1)^2}{R_1^2 \kappa \sigma^2} \left[ \frac{1}{1 - \lambda_{\text{max}}} \right]^2$$

$$\times J_{m_1}^r \left[ \sqrt{\frac{2 \pi}{\kappa}} k_{\text{max}} \right].$$

where we used the shortened notation

$$\frac{1}{(m_1 \cdot \Omega')} = \left[ \frac{1}{\Omega} \right]_{J_0'}.$$ \hfill (C.4)

for the term appearing as a prefactor in the expressions (79) and (80) of the drift and diffusion coefficients. In addition to the integration formula (57), we may also rely on the additional identity

$$\int dJ_1^r J_1^r e^{-\beta J_1^r} J_{m_1}^r \sqrt{\beta} = \frac{e^{-\beta^2/2\alpha}}{\alpha^2} \left\{ \frac{\beta^2}{2\alpha^2} + 1 + |m_1| \right\} I_{m_1} \left[ \frac{\beta^2}{2\alpha^2} + \frac{\beta^2}{2\alpha} \frac{I_{\text{max}}[\beta^2]}{2\alpha} \right].$$ \hfill (C.5)

where $\alpha > 0, \beta > 0$, and $m_1 \in \mathbb{Z}$. In analogy with the definition from Eq. (58), we also introduce $\chi_{\text{max}}$ as

$$\chi_{\text{max}} = \frac{\sigma^2 k_{\text{max}}^2}{\kappa^2}.$$ \hfill (C.6)

One can then immediately perform the integration on $J^r_1$ from Eq. (C.3), so that the diffusion coefficients are given by

$$D_{m_1}(J_1) = h_{m_1}(J_0') \sqrt{\frac{2 \pi}{\kappa}} k_{\text{max}} \chi_{\text{max}},$$ \hfill (C.7)

where the function $h_{m_1}(J_0')$ is defined as

$$h_{m_1}(J_0') = \frac{\mu}{(m_1 \cdot \Omega')} \frac{G^2 \Omega \Sigma (\Delta k_1)^2}{R_1^2 \kappa^2} \left[ \frac{1}{1 - \lambda_{\text{max}}} \right]^2 e^{-\chi_{\text{max}} I_{m_1}[\chi_{\text{max}}]}.$$ \hfill (C.7)

After some algebra, the drift coefficients from Eq. (C.2) are given by

$$A_{m_1}(J_1) = -h_{m_1}(J_0') \left\{ -m_1^2 \frac{\kappa}{\sigma^2} + m_1^2 \frac{\partial}{\partial J_\phi} \left[ \ln \left( \frac{\Omega \Sigma}{\pi \kappa \sigma^2} \right) \right] \right\} + m_1^2 \frac{\kappa}{\sigma^2} \frac{\partial}{\partial J_\phi} \left[ \frac{\sigma^2}{\kappa} \right] \left( 1 + |m_1| \right) - \chi_{\text{max}} \left[ I_{m_1}[\chi_{\text{max}}] \right].$$ \hfill (C.9)

These explicit expressions of the diffusion and drift coefficients obtained in Eqs. (C.7) and (C.8) allow us to estimate in a simple way the secular flux in the entire action space $J = (J_\phi, J_r)$, once we assume that the distribution function is a Schwarzschild DF given by Eq. (25) and that the susceptibility coefficients can be approximated by Eq. (78).

Appendix D: Relation to other kinetic equations

The kinetic equation governing the collisional evolution of a system of $N$ stars at the order $1/N$ is the inhomogeneous Balescu-Lenard Eq. (2). This equation conserves the total number of stars and the energy, and monotonically increases the Boltzmann entropy (H-Theorem). We note that the collisional evolution of the system is due to a condition of resonance encapsulated in the term $\delta_{m_1 m_1'} (\Omega - m_1' \cdot \Omega)$. In general, this condition can allow for local and non-local resonances. In the case of tepid discs considered in the present paper, assuming that only tightly wound spirals are sustained by the disc, we justified in Eq. (72) the fact that the resonances are purely local, so that $m_1 = m_1'$ and $J_\phi = J_\phi'$. Furthermore, because of the epicyclic approximation, the intrinsic frequencies of the system, given by Eq. (22), depend only on $J_\phi$, so that $\Omega = \Omega(J_\phi)$. Under these conditions, the Balescu-Lenard equation giving the collisional evolution of $F = F(J_\phi, J_r, t)$ may be rewritten as

$$\frac{\partial F}{\partial t} = 4\pi G \mu \frac{\partial}{\partial J} \left[ \sum \frac{1}{|m_1| \sqrt{(m_1 \cdot \Omega_m) |m_1'|}} \int dJ_1' dJ_\phi' \delta_{m_1 m_1'} (J_\phi - J_\phi') \right]$$

$$\times \frac{\delta_0(J_\phi - J_\phi')}{|D_{m_1}(J_\phi, J_\phi', J_r, J_r')|}$$

$$\times F(J_\phi', J_r', t) \frac{\partial F}{\partial J} (J_\phi, J_r, t) - F(J_\phi, J_r, t) \frac{\partial F}{\partial J} (J_\phi', J_r', t).$$ \hfill (D.1)
The integration on $J'_g$ is straightforward because of the $\delta_0$-function (local resonance), and we are left with
\[
\frac{\partial F}{\partial t} = 4\pi^3 \mu \frac{\partial}{\partial J} \left[ \sum_m m \frac{1}{|\omega_r| [m \cdot \Omega]} \int dJ' \right] \times \frac{1}{|D_{m,m}(J_g, J_r, J'_g, J'_r, m \cdot \Omega)|^2} \times m \left[ F(J_g, J'_g, t) \frac{\partial F}{\partial J}(J_g, J_r, t) - F(J_g, J'_g, t) \frac{\partial F}{\partial J}(J_g, J'_r, t) \right],
\] (D.2)
where the susceptibility coefficients are generally given by Eq. (77).

The kinetic Eq. (D.2) is an integro-differential equation that governs the evolution of the system as a whole. It describes the effects of encounters between any test particle characterized by the angle-action coordinates $(J_g, J_r)$ and the field particles characterized by the (running) angle-action coordinates $(J'_g, J'_r)$. Actually, there is no distinction between test and field particles, so that they are characterized by the same distribution function $F(\cdot, t)$ that evolves in a self-consistent manner, hence the integro-differential character of the kinetic equation. This is a characteristic of the Balescu-Lenard equation describing the evolution of the system as a whole.

D.1. Fokker-Planck limit

We can also use this formalism to directly obtain the Fokker-Planck equation governing the relaxation of a test star in a bath of field stars, assumed to be in a steady state with a distribution function $F_0(J_g, J'_g)$. Proceeding as in Chavanis (2012a), we just have to replace in Eq. (D.2) the distribution function of the field particles $F(J_g, J'_g, t)$ by the static distribution $F_0(J_g, J'_g)$, while the time-evolving distribution function of the test particle is rewritten as $P(J_g, J, t)$ for clarity. This heuristic procedure is justified in Chavanis (2012a) by an explicit calculation of the diffusion and drift coefficients of the Fokker-Planck equation. It transforms the integro-differential Eq. (D.2) into a differential equation
\[
\frac{\partial P}{\partial t} = 4\pi^3 \mu \frac{\partial}{\partial J} \left[ \sum_m m \frac{1}{|\omega_r| [m \cdot \Omega]} \int dJ' \right] \times \frac{1}{|D_{m,m}(J_g, J_r, J'_g, J'_r, m \cdot \Omega)|^2} \times m \left[ F_0(J_g, J'_g, t) \frac{\partial P}{\partial J}(J_g, J_r, t) - P(J_g, J, t) \frac{\partial F_0}{\partial J}(J_g, J'_r, t) \right],
\] (D.3)
which can be interpreted as a Fokker-Planck equation. If we assume that the field particles are at statistical equilibrium (thermal bath), described by the Boltzmann distribution
\[
F_0(J) = C e^{-\beta H(J)},
\] (D.4)
then, using the relation $\frac{\partial F_0}{\partial J} = -\beta F_0 \Omega$ (see the definition of $\Omega$ in Eq. (1)), we can reduce the Fokker-Planck Eq. (D.3) to the form
\[
\frac{\partial P}{\partial t} = \frac{1}{\beta} \left[ \sum_m m D_{m}(J) m \cdot [\frac{\partial P}{\partial J} + \beta \Omega(J) P] \right],
\]
with the diffusion coefficient
\[
D_{m}(J) = \frac{4\pi^3 \mu}{|\omega_r| [m \cdot \Omega]} \int dJ' \frac{F_0(J_g, J'_g, t)}{|D_{m,m}(J_g, J_r, J'_g, J'_r, m \cdot \Omega)|^2}.
\] (D.6)

We note that the friction term in the Fokker-Planck Eq. (D.5) is proportional and opposite to the intrinsic frequency $\Omega$, and that the friction coefficient $\xi$ satisfies a (generalized) Einstein relation $\xi = D \beta$ (for each resonance) (Chavanis 2012a).

This Fokker-Planck formalism may have other applications. For example, if we consider a system with two species of particles (e.g. characterized by different masses $m_A$ and $m_B$), and if species B has reached an equilibrium state with a distribution $F_0(J_g, J'_g)$, we can use Eq. (D.3) to describe the relaxation of species A due to the encounters with particles of species B (but neglecting the encounters between particles of species A). This approach is further discussed in Appendix F of Chavanis (2013b). On the other hand, for a single species system, we may describe the early dynamics of the system as a whole with a good approximation by replacing $F(J_g, J'_g, t)$ in the Balescu-Lenard Eq. (D.2) by the initial distribution function $F_0(J_g, J'_g)$, leading again to an equation of the form (D.3).

D.2. Other kinetic equations

We now compare the previous results to other related kinetic equations. For spatially homogeneous systems with long-range interactions, the Balescu-Lenard equation reads (see Chavanis 2012c):
\[
\frac{\partial F}{\partial t} = \pi(2\pi)^d \mu \frac{\partial}{\partial \phi} \left[ \frac{\int dk dk' k \cdot k' \delta(k) \delta(k') \delta(1) \delta(k \cdot (v - v'))}{|\epsilon(k, \omega)|^2} \right] 
\times k \left[ F(v', t) \frac{\partial F}{\partial v}(v', t) - F(v', t) \frac{\partial F}{\partial v}(v', t) \right],
\] (D.7)
where
\[
\epsilon(k, \omega) = 1 - (2\pi)^d \hat{u}(k) \int dk' \frac{k \cdot \partial F/\partial v}{k' \cdot u - \omega}
\] (D.8)
is the dielectric function. For one-dimensional systems, it reduces to the trivial form
\[
\frac{\partial F}{\partial t} = 2\pi^2 \mu \frac{\partial}{\partial v} \left[ \int dk dk' \frac{\hat{u}(k)^2}{|\epsilon(k, \omega)|^2} \delta(1) \delta(v - v') \right] 
\times \left[ F(v', t) \frac{\partial F}{\partial v}(v', t) - F(v', t) \frac{\partial F}{\partial v}(v', t) \right] = 0.
\] (D.9)

In $d > 1$, there are always resonances between particles with different velocities, implying that the Balescu-Lenard equation relaxes towards the Boltzmann distribution on a timescale of the order $N_{D}$, where $t_D$ is the dynamical time. By contrast, in $d = 1$, the resonances become local (in velocity space) and since the term in brackets is anti-symmetric with respect to the interchange of $v$ and $v'$, the Balescu-Lenard diffusion current vanishes exactly. This implies that the relaxation time is larger than $N_{D}$, presumably of the order $N^2 t_D$, corresponding to the next order term in the expansion of the dynamics in powers of $1/N$. The Fokker-Planck equation describing the evolution of a test particle in a bath of field particles is discussed in Chavanis (2012c, 2013a).

The kinetic equation governing the collisional evolution of a system of $N$ point vortices in two-dimensional hydrodynamics at the order $1/N$ can be written, in the axisymmetric case, as (see Chavanis 2012b):
\[
\frac{\partial \omega}{\partial t} = 2\pi^2 \frac{1}{r} \frac{\partial}{\partial r} \int r'^2 \chi(r', \Omega, t) \delta([\Omega(r, t) - \Omega(r', t)] 
\times \left[ \omega(r', t) \frac{\partial \omega}{\partial r}(r, t) - \omega(r, t) \frac{\partial \omega}{\partial r}(r', t) \right],
\] (D.10)
where $\omega(r, t)$ is the profile of vorticity, $\Omega(r, t)$ the profile of angular velocity, and $\chi(r', \Omega, r, t)$ is related to the dressed potential of interaction between the point vortices (see Chavanis 2012b for more details). This equation conserves the total number of point vortices and the energy, and monotonically increases the Boltzmann entropy (H-theorem). If the profile of angular velocity is monotonic, the kinetic equation reduces to the form

$$
\frac{\partial \omega}{\partial t} = 2\pi^2 \frac{1}{r} \frac{\partial}{\partial r} \int_{r_0}^{r_\infty} \frac{d \Omega}{\Omega} \chi(r', \Omega, r, t) \frac{1}{\Omega(r, t)} \delta_D(r - r') \times \left[ \omega(r', t) \frac{1}{r} \frac{\partial \omega}{\partial r}(r, t) - \omega(r, t) \frac{1}{r'} \frac{\partial \omega}{\partial r}(r', t) \right] = 0.
$$

For non-monotonic profile of angular velocity, one can have non-local resonances (i.e. distant collisions between point vortices), as studied in Chavanis & Lemou (2007). This produces a diffusion current. If the profile of angular velocity is, or becomes, monotonic, the resonances are purely local and, since the term in brackets is anti-symmetric with respect to the interchange of $r$ and $r'$, the diffusion current also vanishes. This implies that the relaxation time is larger than $Nt_D$ as discussed above. The Fokker-Planck equation describing the evolution of a test vortex in a sea of field vortices is discussed in Chavanis (2012b).

If we focus on purely local resonances, we note that the inhomogeneous Balescu-Lenard Eq. (D.1) is different from Eqs. (D.9) and (D.11) because it is two-dimensional in $J_r$ and $J_\phi$, and the resonances act only on $J_r$. Therefore, purely local resonances do not yield a zero flux, contrary to Eqs. (D.9) and (D.11). This really is an effect of the two-dimensionality of the system. Indeed, for local resonances, the 1D inhomogeneous equation also yields a zero flux:

$$
\frac{\partial F}{\partial t} = 2\pi^2 \frac{1}{r} \frac{\partial}{\partial r} \int \frac{m}{\Omega(J)} \left| \frac{\partial \Omega(J - J')}{2 \Omega_m(J, J, m \Omega)^2} \right| \times \left[ F(J', t) \frac{\partial F}{\partial J}(J, t) - F(J, t) \frac{\partial F}{\partial J}(J', t) \right] = 0.
$$

**Appendix E: The Schwarzschild conspiracy**

The Schwarzschild distribution function introduced in Eq. (25) and considered in S12 simulation has the specificity to be exponential in the $J_r$-direction, so that $F$ is Boltzmannian with respect to the $J_r$ variable. It is known (e.g. Chavanis 2012a) that the (complete) Boltzmann distribution is the steady state of the Balescu-Lenard Eq. (2). Therefore, we can expect that the (partial) exponential behaviour of the Schwarzschild distribution will induce simplifications that we now detail. In analogy with Eq. (10), the flux associated with a given resonance $m$ is defined as

$$
\mathcal{F}_m = m \left[ A_m(J) F(J) + D_m(J) m \cdot \frac{\partial F}{\partial J} \right] \equiv m \mathcal{F}_m,
$$

where we used the same shortened notation for the resonant factor $1/(m \cdot \Omega)^2$ as in Eq. (C.4). The flux can then be decomposed as $\mathcal{F}_m = \mathcal{F}_m^t + \mathcal{F}_m^\phi$ with

$$
\mathcal{F}_m^t = \frac{m_r}{(m \cdot \Omega)^2} \int \frac{d J_r^2}{|D_m|^2} F(J_r^2) \left[ \frac{\partial F}{\partial J_r} \left( J_r \right) - F(J_r) \frac{\partial F}{\partial J_r} \left( J_r^2 \right) \right],
$$

and

$$
\mathcal{F}_m^\phi = \frac{m_\phi}{(m \cdot \Omega)^2} \int \frac{d J_\phi^2}{|D_m|^2} F(J_\phi^2) \left[ \frac{\partial F}{\partial J_\phi} \left( J_\phi \right) - F(J_\phi) \frac{\partial F}{\partial J_\phi} \left( J_\phi^2 \right) \right].
$$

Appendix F: Temporal frequency selection

An important feature of the diffusion Eq. (7) is that the diffusion takes place along specific resonance directions associated with the vectors $m$ as discussed in Eq. (16). Hence being able to determine the dominant resonance is crucial in order to estimate the direction of the secular diffusion in action space. The
temporal frequency associated with a given resonance \( m \) in a location \( j \) of action-space is given by \( \omega = m \cdot \Omega \). Thanks to the expression (83), one immediately obtains that for a Mestel disc, one has

\[
0 < \omega_{\text{ILR}} < \omega_{\text{COR}} < \omega_{\text{OLR}}. \tag{F.1}
\]

In Fouvy & Pichon (2015), Fouvy et al. (2015a), we studied the same S12 simulation using the WKB limit of the secular diffusion equation, which intends to describe the secular forcing of a collisionless self-gravitating system perturbed by an external source. An essential assumption of this approach was to consider the external perturbation as originating from numerical Poisson shot noise, and therefore assume it to be proportional to the local active surface density. The autocorrelation of the external perturbation \( \psi^{\text{eff}} \) was taken to be equal to

\[
\left\langle |\psi^{\text{eff}}|^{2} \right\rangle (\omega, k_{r}, J_{\phi}) \propto \Sigma(J_{\phi}). \tag{F.2}
\]

One can remark that this crude assumption on the noise properties has no \( \omega \) dependence, so that all resonances are equally favoured by the Poisson shot noise and are perturbed similarly whatever their associated intrinsic frequencies \( \omega \approx m \cdot \Omega \). This ad hoc and simple noise approximation is one of the limitations of the formalism presented in Fouvy & Pichon (2015), Fouvy et al. (2015a). In contrast, in the WKB Balescu-Lenard equation described in this paper, this preferential selection of the resonances based on their intrinsic frequency is naturally present. Indeed, one can note in the expression (E.4) of the flux associated with a resonance \( m \), the presence of the prefactor \( 1/(m \cdot \Omega)^{\prime} \) which arose in Eq. (67) when handling the resonance condition. For the Mestel disc, whose intrinsic frequencies are given by Eq. (83), this term can be straightforwardly computed and reads

\[
\frac{1}{(m \cdot \Omega)^{\prime}} = \frac{1}{|\partial_{\phi} + \sqrt{2} m_{\perp}|} \frac{1}{|\partial_{\phi} / \partial J_{\phi}|} \tag{F.3}
\]

Comparing the ILR resonance to the OLR and COR, one immediately obtains that

\[
\frac{(m_{\text{OLR}} \cdot \Omega)^{\prime}}{(m_{\text{ILR}} \cdot \Omega)^{\prime}} = \frac{2 + \sqrt{2}}{2 - \sqrt{2}} \approx 5.8, \quad \frac{(m_{\text{COR}} \cdot \Omega)^{\prime}}{(m_{\text{ILR}} \cdot \Omega)^{\prime}} = \frac{2}{2 - \sqrt{2}} \approx 3.4. \tag{F.4}
\]

Hence because the ILR resonance is associated with lower intrinsic temporal frequency \( \omega = m \cdot \Omega \), the resonant factor \( 1/(m \cdot \Omega)^{\prime} \) naturally tends to favour the ILR resonance with respect to the OLR and COR, and therefore performs natively a temporal frequency biasing which was absent from the ad hoc assumption of Eq. (F.2) describing the external forcing considered in Fouvy & Pichon (2015), Fouvy et al. (2015a).

One can even be more specific when comparing the ILR and OLR resonances. The only difference between these two resonances is the sign of \( m \). The expression (62) of the amplification eigenvalues shows that its value only depends on \( s^{2} \), so that \( \lambda_{\text{ILR}} = -\lambda_{\text{OLR}} \). The expression of the susceptibility coefficients from Eq. (77) is also independent of the sign of \( m \), so that \( 1/|\partial_{\Omega_{\text{ILR}}}^{2} | = 1/|\partial_{\Omega_{\text{OLR}}}^{2} | \). Hence, when considering the flux \( F_{\text{m}} \) given by Eq. (4.2), one notes that between the ILR and OLR resonances, \( F_{\text{m}} \) only changes through the factor \( 1/(m \cdot \Omega)^{\prime} \). Thanks to Eq. (F.4), one immediately obtains

\[
\frac{F_{\text{ILR}}}{F_{\text{OLR}}} \approx 5.8. \tag{F.5}
\]

The secular diffusion flux associated with the OLR resonance is therefore always much smaller than the one associated with the ILR resonance because of this effect of temporal frequency biasing.

As a conclusion, the temporal frequency selection effect described in Eq. (F.4) will tend to favour the ILR resonance because it is associated with a smaller intrinsic frequency. However, one can observe in Fig. 8 that the COR resonance is always more amplified than the ILR resonance. Finally, the crucial remark is to note that the susceptibility coefficients from Eq. (77) involve Bessel functions \( J_{m} \), which are such that \( \lim_{x \to 0} J_{m}(x) = 1 \) if \( m_{\perp} = 0 \), or \( 0 \) otherwise. As a consequence, close to the \( J_{\phi} = 0 \) axis, the COR resonance will always tend to become the dominant resonance. There is therefore a non-trivial arbitration between these opposite effects when considering the respective contributions of the various resonances to the full secular diffusion flux.

Fig. E.1. Contours in action-space \((J_{\phi}, J_{r})\) of the difference between the sampled anisotropic DF of S12 simulation \( F_{\text{an}} \propto J_{r}^{3} \exp[-E/\sigma_{r}^{2}] \) and its Schwarzschild epicyclic approximation \( F_{\text{Sch}} \) from Eq. (25). The plotted quantity is \(|F_{\text{an}} - F_{\text{Sch}}|/F_{\text{Sch}}\), and contours labels are expressed in percentages.
