ABSTRACT

Context. The ESA Rosetta spacecraft (S/C) is tracking comet 67P/Churyumov-Gerasimenko in close vicinity. This prolonged encounter enables studying the evolution of the volatile coma composition.

Aims. Our work aims at comparing the diversity of the coma of 67P/Churyumov-Gerasimenko at large heliocentric distance to study the evolution of the comet during its passage around the Sun and at trying to classify it relative to other comets.

Methods. We used the Double Focussing Mass Spectrometer (DFMS) of the ROSINA experiment on ESA's Rosetta mission to determine relative abundances of major and minor volatile species. This study is restricted to species that have previously been detected elsewhere.

Results. We detect almost all species currently known to be present in cometary coma with ROSINA DFMS. As DFMS measured the composition locally, we cannot derive a global abundance, but we compare measurements from the summer and the winter hemisphere with known abundances from other comets. Differences between relative abundances between summer and winter hemispheres are large, which points to a possible evolution of the cometary surface. This comet appears to be very rich in CO₂ and ethane. Heavy oxygenated compounds such as ethylene glycol are underabundant at 3 AU, probably due to their high sublimation temperatures, but nevertheless, their presence proves that Kuiper belt comets also contain complex organic molecules.

Key words. comets: individual: 67P/Churyumov-Gerasimenko

1. Introduction

Comets are visitors from the outer solar system. They are also important witnesses to the formation of our solar system. Because of their small size and the fact that they have spent 4.5 billion years far from the Sun where temperatures are low, comets are understood to be the least processed bodies in the solar system and thus represent time capsules with material from the early stages of our solar system. However, the chemical composition of comets could have changed through thermal and physical processes that they were subjected to until today. It is therefore important to measure the volatile inventory of chemical species in comets and compare it to other bodies in the solar system, interstellar matter, and protostellar objects. This comparison tells us about the primordial material and about

the formation processes, and it permits assessing the exogenous delivery of water, carbon, and prebiotic molecules to the early Earth.

Remote-sensing observations have improved our knowledge of a comet's volatile composition. A number of species are detected with ground-based and near-Earth space-based telescopes in the visual, infrared, microwave, and radio portions of the spectrum. A limitation is that symmetric species cannot be measured with radio or submillimeter observations, and that measurement from space is appropriate for species present in Earth's atmosphere (e.g., CO₂). Such observations have resulted in the identification of a number of volatile species for very many comets. The most extensive list of identified molecules up to now has been established from observations of C/1995 O1 (Hale-Bopp) and C/1996 B2 (Hyakutake) (Bockelée-Morvan et al. 2004; Mumma & Charnley 2011). Compilations of volatile compositions are often dominated by data from comets that are

SO ₂	NIST	C
CS ₂	NIST	C
S ₂	estimated	C

Notes. M refers to fragmentation pattern and sensitivity determined in the calibration facility. C refers to the sensitivities that were calculated from the function determined thanks to the calibration measurements.

understood to come from the Oort Cloud reservoir, the long-period comets (LPCs), and the intermediate-period Halley-type comets (HTCs) that are bright enough to be observed by IR and radio; Jupiter-family comets (JFCs), with fainter gas and dust production, have only rarely been investigated by radio and IR observations (Crovisier et al. 2009).

1P/Halley is the first HTC to date for which there exists a detailed volatile composition measurement, obtained in situ by mass spectrometry during the flyby of the European Space Agency's Giotto spacecraft in 1986 (Eberhardt 1999), recently complemented with remote-sensing observations (Rubin et al. 2011). We list in Tables 2 to 5 some molecules for a number of comets that we expanded with data collected from space missions to comets 1P/Halley, 9P/Tempel 1, and 103P/Hartley 2.

Taxonomic classification of comets is based (in part) on their volatile composition by identifying groups of comets that have a typical composition or that are depleted or enriched compared with the typical composition. For a detailed and comprehensive summary on chemical composition of comets based on radio and IR observations, see Mumma & Charnley (2011). More systematic taxonomic classifications of comets have been done in surveys of visible-range remote observations of comets that cover a number of radical species (C₂, C₃, CN, NH, NH₂, OH, O(¹D)), and the dust continuum measured as Af_p). Several surveys based on photometric or spectrophotometric observations of comets have been carried out over the past 30 yr (Cochran et al. 2012, 130 comets; A'Hearn et al. 1995, 85 comets; Fink 2009, 50 comets; Langland-Shula & Smith 2011, 26 comets).

There are a few difficulties in comparing ground-based visual radical taxonomies with abundances of molecules observed

in the IR and radio. First, the ground-based visual observations cover many more comets, and most of these comets are much fainter than the comets that are bright enough to be observed in the IR and radio. Therefore, the visual-range surveys are dominated by observations of short-period JFCs, while the IR and radio surveys are dominated by LPCs or new Oort Cloud comets.

Second, despite decades of studies trying to clearly identify the parent molecules of the common cometary radicals as well as the chains of branching ratios and production or destruction rates needed to calculate overall production rates, there are only few hard and fast connections. Generally, it is understood that NH and NH₂ radicals come from NH₃ photodissociation (Fink et al. 1991). HCN is probably the main parent of CN, but various attempts to demonstrate the detailed quantitative connection that can easily be established (Combi & Delsemme 1980; Woodney et al. 2002; Fray et al. 2005) seem to work sometimes, but not always. A similar case has been made to connect C₂ to parents such as C₂H₂ and C₂H₆ (Helbert et al. 2005) with similar mixed success. More recently, Weiler (2012) studied the chemistry of C₂ and C₃ in cometary comae and concluded that C₂H₆ has little influence on C₂. Combi & Fink (1997) have made a case from analyzing its spatial distribution that C₂ is either mainly emitted as a granddaughter product of one or more molecules or perhaps emitted from organic grains.

In Tables 2 to 5 we show a list of parent molecule chemical compositions in a number of comets, not only including bright Oort Cloud Comets (1P/Halley, C/1995 O1 (Hale-Bopp), C/1996 B2 (Hyakutake), C/2001 A2 (LINEAR), C/2012 F6 (Lemmon), and C/2013 R1 (Lovejoy)), but also including more recent results from infrared observations of a few short-period JFCs (103P/Hartley 2, broken 73P/Schwassmann-Wachmann 3 (73P/SW3) fragments B and C, 2P/Encke, 9P/Tempel 1 before and after Deep Impact excavation, 6P/d'Arrest, 17P/Holmes, and 21P/Giacobini-Zinner). Tables 2 to 5 also list the classifications of each comet according to ground-based visual observations (A'Hearn et al. 1995; Fink 2009; Cochran et al. 2012; Langland-Shula & Smith 2011). These classifications generally agree with one another, although Fink (2009) has refined some extra classification that places comets 9P/Tempel 1 and 67P/Churyumov-Gerasimenko (hereafter 67P) in the "typical" subclass but for which C₂ is somewhat depleted.

The aim of this paper is to present high-resolution measurements from the Double Focusing Mass Spectrometer (DFMS), part of the Rosetta Orbiter Sensor for Ion and Neutral Analysis (ROSINA) of the inventory of cometary volatiles during two snapshot periods in the coma of 67P. Here we limit the analysis to molecules that have previously been detected in one or several other comets. We report their abundances relative to water. It is the first time that such an abundance list, including sulfur-, nitrogen-, and oxygen-bearing compounds, is provided for a JFC. Section 2 presents the conditions during the two observations. In Sect. 3 the principle of DFMS as well as the data treatment to retrieve the parent species and their abundances are described. Section 4 focuses on the abundances measured in the coma of 67P and contains its classification.

2. Observations

The measurements presented in this paper have been obtained before lander delivery. The data were acquired on 20 October 2014 between 07:54 and 08:37 (UTC) and on 19 October 2014 between 00:39 and 01:22 (UTC). The analyzed mass spectra with integration times of 20s were not averaged. Therefore the

Table 2. Comet type and classification with observed main species and hydrocarbons at comets.

Fig. 1. a) COPS data, spacecraft footprint, and comet position for the period between 18–21 October, 2014 (noon till midnight). The bottom panel shows the distance to the nucleus center, r_{67p} , and the heliocentric distance, r_{Sun} . The second panel from the bottom shows latitude and longitude, and above are phase angle and local time, LT. The top panel shows the measured COPS densities. The two reported intervals are indicated in blue (winter hemisphere at negative latitude, 19 October 2014 00:39:25–01:22:18) and red (summer hemisphere at positive latitude, 20 October 2014 07:53:51–08:37:45). Both observations occur at approximately the same longitude and at a phase angle of 90°. b) and c) show the illumination conditions as seen from the Rosetta spacecraft during the observations above the winter hemisphere on 19 October 2014 and above the summer hemisphere on 20 October 2014.

results presented are snapshots of the coma composition at the location of the spacecraft during the indicated times.

At these dates, Rosetta was on a terminator orbit with a period of 2 d 17 h, at 10 km from the nucleus. The different conditions are shown in Fig. 1. The upper panel shows the geometrical information for the S/C position at that time together with the measured total density from the Comet Pressure Sensor (COPS), part of the ROSINA experiment. COPS shows the diurnal and seasonal variations of the comet atmosphere as described by Bieler et al. (2015). The spectra are shown for the two observation intervals: one was measured over negative latitudes (blue), which corresponds to the winter hemisphere, the other one (red) over positive latitudes, which corresponds to summer. COPS data clearly show that outgassing is much higher over the summer hemisphere. This outgassing is mostly water. Other molecules, for example, CO₂, do not follow this trend. Their density can be higher over the winter hemisphere (Luspay-Kuti et al. 2015; Hässig et al. 2015). It is therefore clear that densities relative to water can vary over a wide range between the two hemispheres. It is currently not clear which values best represent the bulk composition of the nucleus. This will require detailed investigation of both hemispheres during

perihelion when outgassing is highest, and winter and summer are reversed compared to the measurement period analyzed here.

3. DFMS data treatment

The results presented in this paper come mainly from the DFMS instrument (see [Balsiger et al. 2007](#) for a detailed description). More precisely, they are based on the high-resolution mode observations.

3.1. DFMS operating principle

During the time of observation, the instrument was pointed in the nadir direction at a cometocentric distance of about 10 km from the center of mass, so that the neutral gas escaping from the comet nucleus was able to freely enter the instrument. Figure 2 shows a sketch of the ion optical elements of DFMS. A repelling electrostatic potential prevents the entry of positively charged ions. The principle of neutral detection and the data treatment process for the high-resolution mode are described here in detail.

The neutrals are bombarded by electrons that are emitted from a filament and accelerated through a 45 V potential in the ion source. The resulting ions (atomic or molecular ions or charged molecular fragments of the original neutrals) are then accelerated by the mass-dependent acceleration voltage V_{accel} . The analyzer section of DFMS has a Nier-Johnson geometry in which a deflection of 90° in a radial electrostatic energy analyzer (ESA) is combined with a magnetic deflection of 60° . V_{accel} determines which ions will be transmitted through the DFMS ion optics. The ESA focuses ions with different entry angles but with the same energy, while ions with different energies are spatially separated. The kinetic energy of the ions in the ESA is related to V_{accel} and the ESA radius according to

$$E_{\text{ESA}} = \frac{2V_{\text{accel}}}{r_{\text{ESA}}}. \quad (1)$$

An energy slit after the ESA filters the ion energy to the desired value ($E_{\text{ESA}} \pm 1\%$). Depending on V_{accel} and the properties of the magnetic sector (magnetic field and magnetic sector radius, Eq. (2)), only ions centered around a certain m/q value, the commanded mass-over-charge (CM), will hit the detector as dictated by

$$m/q = \frac{r_B^2 B^2}{2V_{\text{accel}}}. \quad (2)$$

For heavy ions ($m/q > 70$), for which V_{accel} is low, a post-acceleration voltage is applied on the front side of the detector to increase the sensitivity. The Micro Channel Plate/Linear Electron Detector Array (MCP/LEDA) detector consists of two microchannel plates with angled channels rotated 90° relative to each other that produce a chevron shape, placed in front of a position-sensitive imaging detector with two rows of 512 pixels (LEDA channels A and B). A detailed discussion of the detector setup and the MCP can be found in ([Berthelier et al. 2002](#); [Nevejans et al. 2002](#); [Balsiger et al. 2007](#)). Upon impact of an ion on the MCP, a cascade of electrons is produced, depending on the ion species, the energy of the ion, and the MCP performance. The overall MCP gain at the location of impact (possibly including some nonlinearity) is determined by selecting a gain step from a predefined list of steps, each of which corresponds to a setting of the potential difference between the MCP front and back planes. The LEDA analog measurements are converted

into a digital signal and are obtained as ADC counts as a function of LEDA pixel number for both LEDA rows. Typically, 3000 individual 6.6 ms exposures at the same CM, equivalent to a 19.8 s total measurement time, are accumulated to produce a spectrum.

3.2. Intensity correction

The ADC counts for each spectrum and each LEDA channel need to be corrected for the offset that is due to the initial charge applied for proper operation. The offset function is fitted by removing regions where peak signals are detected and fitting the remaining ADC counts as a function of pixel number. The number of offset-corrected ADC counts (representing the number of electrons collected by each pixel) is divided by the overall MCP gain factor g_{MCP} that corresponds to the selected gain step to obtain the number of ions that impinged on the MCP during the exposure.

The gain at each pixel of the LEDA detector arrays is a measure of the combined response of the MCP and the LEDA. This MCP/LEDA pixel gain, g_p , evolves with time, mainly because impinging ions degrade the coating inside the MCP microchannels that is responsible for the electron cascade effect. Because of the choice of CM values, typically significant ion peaks are recorded near the middle of the pixel arrays; these center pixels therefore degrade faster than the other pixels. Consequently, detector aging needs to be checked on a regular basis. This aging effect can be compensated for by applying pixel gain correction factors. These represent the efficiency of the electron cascade process for each MCP/LEDA pixel for a certain detector gain step. They are obtained by collecting raw data for a certain ion (e.g., H_2O^+) in low-resolution mode for a sequence of CM values to scan the peak across the pixel arrays of the MCP/LEDA. Such pixel gain measurements are performed regularly every few months depending on the total accumulated charge on the detector. The dimensionless pixel gain correction factors are then calculated by taking the sum of the offset-corrected peak intensities for each pixel and scaling these such that $g_p = 1$ away from the center of the arrays; in doing so, the assumption is made that the pixels away from the center are aging less rapidly.

The ADC counts for each pixel are converted into ion counts per second using

$$I(p) = \frac{\text{ADC}}{g_p g_{\text{MCP}}} \frac{c_{\text{adc}} c_{\text{leda}}}{t}, \quad (3)$$

where $I(p)$ is the ion current per pixel, $c_{\text{adc}} = 2.5\text{V}/(2^{12} - 1)$ is the ADC conversion factor, $c_{\text{leda}} = 4.2 \times 10^{-12}\text{ F}$ is the LEDA capacitance, and t the total integration time. The number of ions per second and per pixel can then be calculated by dividing $I(p)$ by the elementary charge e .

3.3. Mass calibration

Mass calibration consists of associating pixel numbers with mass-per-charge (m/q) ratios. The relation is given by

$$M(p) = M_0 e^{(p-p_0) \frac{x}{Dz}}, \quad (4)$$

where $M(p)$ gives the mass-per-charge ratio corresponding to pixel p , M_0 is the CM value, p_0 is the center MCP pixel where M_0 is located, $x = 25\text{ }\mu\text{m}$ is the center-to-center distance between adjacent pixels, $D = 127\,000\text{ }\mu\text{m}$ is the dispersion factor, and $z = 6.4$ (somewhat smaller for lower masses) denotes the zoom factor associated with the high-resolution modes.

(2007); [13] this work; comments: a) CS cannot be resolved from CO₂ by ROSINA.

In reality, however, the mass calibration relation is more complicated, especially when post-acceleration is applied. As a result of the non-symmetric electrical fields in the detection region, the ion beam is asymmetrically deflected. These dependencies on M_0 can be fitted using mass calibration measurements, in which an association can be made between the observed peaks (giving p) and the corresponding ion mass-per-charge (giving M), and this for various commanded M_0 values. This has been done with the utmost caution, because in principle there is no unambiguous way to identify which ion is associated with a particular peak. However, as we show in this paper, many ions can indeed be identified as products of the ionization and/or fragmentation of cometary neutrals in the ion source. Nevertheless, the mass calibration fit remains an approximation because p_0 and z do not only depend on M_0 , but also on instrument parameters, in particular the magnet temperature. In practice, this means that the calibration relation has to be re-established for each measurement sequence.

3.4. Determination of parent species and their abundances

The measured signal is correlated with the density in the coma in several steps. First, for each peak of the selected mass spectra, the number of particles per time registered by the detector as a function of mass must be determined. From this, the parent species can be identified. Together with the instrument specific sensitivity factors and the fragmentation pattern for each species, the density of the species in the coma can be inferred. This last step then needs calibration data from the instrument. As each mass spectrometer has its own characteristics depending on geometry, ionization, and detector yield, the sensitivity, and the fragmentation pattern should be derived from measurements. Ideally, this should be done with the flight model before launch.

Despite the high-mass resolving power of DFMS, peaks in calibrated high-resolution spectra are often not completely separated, and peak-fitting is necessary to obtain individual ion currents. DFMS peak shapes can be modeled by two co-located Gaussians with a 9:1 intensity proportion and a 1:3 width ratio. Peak-fitting results in a determination of a peak area corresponding to each ion, which results in the total ion current

and the total number of ions per second. As each mass is associated with an ion, we obtained a list of detected ions versus their total number per second.

The goal is then to infer which neutrals entered the instrument, and in what quantities. A complicated inversion has to be performed, typically based on the list of mass centroids versus number of particles, taking into account the fragmentation patterns of all likely neutrals, and possibly taking into account isotopic abundance ratios. Electron ionization (EI) of neutrals in the ion source can result in the formation of a singly charged atomic or molecular ion, but it can also produce multiply charged ions. In addition, a neutral molecule may break up into several fragment ions. The fragmentation pattern of a given neutral describes the identities and relative abundances of such product ions. The pattern depends on the design of the ion source and the electron energy used. In principle, this pattern has to be measured for DFMS for each species. For most relevant neutrals, this has been done using the instrument copy in the calibration facility. The list of the calibrated species can be found in Table 1. For compounds that are poisonous, detrimental to the instrument, or otherwise impossible to measure, we rely on the literature. Generally, we used the National Institute of Standards and Technology (NIST) database for such compounds, even though the mass spectra in NIST have been acquired with an electron energy of 70 eV compared to the 45 eV electron beam in DFMS.

For this study, the parent species identification consisted of successively removing the fingerprint of the potential parents starting from the species with the highest mass. If all the parent species are identified, the remaining number of particles for each ion should be zero. The success of this identification strongly depends on the list of parent species selected and the correctness of their fragmentation patterns (measured with the copy of DFMS or coming from NIST). In our case, the parent list includes all the species that have previously been detected in cometary atmospheres and some new compounds that were tentatively identified in the data during the mass calibration. This step also enables calculating the correct number of particles for each parent species. When analyzing the spectrum of a mixture, some peaks (e.g., CO at $m/q = 28$), are a combination of fragments (e.g., the ionization of CO₂ leads to the CO fragment at $m/q = 28$) and parent (e.g., parent CO in the coma). The

Fig. 2. DFMS ion optics: neutrals enter the source where they are ionized (bottom center) before they pass the electrostatic analyzer (left bottom), the magnet (top left), and then arrive at the detector (top right). Taken from Balsiger et al. (2007). The inset shows a picture of the DFMS sensor in the same orientation.

differentiation of isomers (molecules with the same molecular formula but where the atoms have a different arrangement in space) depends on the presence of considerably different fragmentation patterns between these isomers. More often than not, they cannot be distinguished from each other, and therefore the obtained result is not necessarily a unique solution.

The sensitivity of a mass spectrometer for a particular neutral gives the ratio of the detected total ion current to the neutral density in the instrument. This is the product of ionization cross section, instrument throughput, and detector yield. All these parameters are species dependent.

More specifically for DFMS, the relation between the ion current on the detector, I_i (in μA), sensitivity for gas j , S_j (in cm^3), the electron emission current, I_{em} (in μA), the fragmentation pattern for ion species i from gas j (e.g., O^+ from CO_2), Q_{ij} , and the neutral density, n_j (in cm^{-3}) can be written as

$$I_i = I_{\text{em}} S_j Q_{ij} n_j, \quad (5)$$

or, if the parent species can readily be identified (e.g., H_2O),

$$I_{\text{parent}} = I_{\text{em}} S_{\text{parent}} n_{\text{parent}}. \quad (6)$$

The sensitivity factors are key parameters to determine the abundances of the parent molecules identified in the coma. Calibration measurements with the ground model of DFMS were performed in the calibration chamber CASYMIR

(Westermann et al. 2001; Graf et al. 2004) to determine fragmentation pattern and sensitivity of the potential parent species in the coma of 67P. Nevertheless, it was clear from the beginning that not all the species could be analyzed for the reasons mentioned above.

To be able to determine the abundance of the species that cannot be (or have not been) studied in our calibration facility, we therefore determined from calibration measurements a function that links the mass-to-charge ratio to the sensitivity of the compounds. Table 1 lists the sensitivities and fragmentation patterns that were measured with the copy of DFMS and those calculated from this function. The uncertainties of the results depend on whether the compounds could be calibrated or not.

An example for a molecule that was calibrated in the calibration facility is given in Fig. 3. H_2^{32}S is ionized and fragmented by the electron impact ion source: products can be found at mass 34 u/e, where we see the parent H_2^{32}S (and the heavy isotope ^{34}S , which is a fragment of H_2^{34}S , but also of other sulfur-bearing species possibly present in the background of the vacuum chamber), at mass 33 u/e for H^{32}S (and the ^{33}S isotope), and at mass 32 for the fragment ^{32}S . Comparison of the data from space then allowed us to determine the density of H_2^{32}S at the entrance of DFMS. A mass spectrum of mass 34 u/e from space is shown in Fig. 4. Of course, in space as well as in the

(a) Mass per charge 32 u/e spectrum

(b) Mass per charge 33 u/e spectrum

(c) Mass per charge 34 u/e spectrum

Fig. 3. Laboratory calibration measurement of H_2S with the corresponding sulfur isotopes and further contribution from vacuum-chamber background.

calibration facility, other molecules, atoms, or fragments may be on the same interger mass as shown in Fig. 4.

The curves in Fig. 4 were measured at different times. The black curve is background from the S/C, measured very far (2.71×10^6 km) from the comet in April 2014, when the comet was at 4 AU from the Sun. The S/C is still outgassing, even after ten years in space (Schläppi et al. 2010). Some small signature

Fig. 4. In-flight mass per charge 34 u/e spectra showing spacecraft background (black) obtained in April 2014 before entering the coma of the comet and at a distance of 10 km from the center of the nucleus above the winter (blue) and the summer (red) hemisphere.

of H_2^{32}S can be seen, which is probably due to conformal coating or electronics inside the S/C. The blue curve was measured at a distance of 10 km from the comet in a terminator orbit. The red curve was measured in the same orbit, but one day later.

Different sources contribute to the uncertainties of the derived densities: there is a statistical error given by the number of ions, which is mostly negligible unless the signal is very weak. Some uncertainty is due to the changing pixel gain and the overall detector gain. There is an error from curve fitting, especially if there are overlapping peaks. There is a contribution to the uncertainty from calibration, or in the case of compounds that could not be calibrated, from the estimate of instrument sensitivity and the fragmentation pattern.

For calibrated compounds, the uncertainties are generally around 20%, mainly due to the pixel gain correction. For uncalibrated compounds, the uncertainties can be up to a factor of 2, principally explained by the error on the inferred sensitivity. To normalize the abundances, they are usually expressed relative to water. As DFMS measures one mass after the other, water is not measured simultaneously with the other species. The time difference can be up to 20 min. This results in an uncertainty on the water abundance that can be partly compensated for by taking into account the COPS densities, which are transmitted every minute. However, the range given in Tables 2 to 5 is dominated not by instrument uncertainty, but by different outgassing according to Rosetta's position with respect to the comet and the Sun.

4. Results and discussion

We here limit ourselves to parent molecules that have previously been detected in comets. This limitation has a practical reason. To calibrate the instrument, the sensitivity and fragmentation pattern for each species have to be determined. The calibration prior to arrival at the comet was obviously focused on molecules previously known to be present in cometary comae (with some exceptions due to toxicity, corrosiveness, etc.). From our measurements at the comet, it is clear that other parent molecules are present. These molecules require laboratory calibration as well and will be presented in a later paper.

Rosetta arrived at the comet in early August 2014. Once it was within 100 km from the nucleus, the background from

the S/C became significantly lower than the signal from the coma (Bieler et al. 2015). The coma was already clearly water dominated, with strong contributions of CO and CO₂, except over the winter hemisphere, where CO or even CO₂ sometimes were the dominant species. It is clear not only from the relative abundances, but also from the different spatial distribution that CO must be predominantly a parent species and only a fraction ranging between a few percent up to <40% originates from CO₂ (Hässig et al. 2015).

Unexpectedly, a rich diversity of minor species such as sulfur-bearing compounds and hydrocarbons was found in the coma on arrival at the comet at 3.5 AU. The measurements in this paper were obtained at 3.15 AU, shortly before lander delivery, when the S/C was on an orbit in the terminator plane at 10 km from the nucleus center. This corresponds to the time when ROSINA/COPS measured the highest gas densities in 2014. During these orbits, the S/C flew over the winter as well as the summer hemisphere. The field of view (FOV) of DFMS is wide, so that particles outgassing from all areas facing the S/C over the whole comet always contributed to the signal (Bieler et al. 2015). Over the winter hemisphere the S/C faced large poorly illuminated areas, whereas over the summer hemisphere most of the area facing the S/C was sunlit, see Figs. 1b and c. We selected mass scans over the winter and summer hemisphere. The two scans were taken at approximately the same longitude, but at different latitudes (Fig. 1a). In both scans the S/C sees contributions from the summer and the winter hemispheres, but with different proportions.

Table 2 shows the relative abundance of the main species and hydrocarbons. CO varies between 2.7% and 20% relative to water. This is comparable to what has been measured in LP comets (cf. 13% at comet 1P/Halley; Rubin et al. 2011), but higher than for JFCs. However, it has to be stated that these measurements were made at 3 AU, whereas most of the other measurements were obtained much closer to the Sun with higher water production. At the two locations CO₂ varies between 2.5% and 80%, which seems to be higher than at other comets such as Hale-Bopp and 103P/Hartley 2, again taking into account the heliocentric distance differences. Here the difference between summer and winter hemisphere is extremely large (cf. Hässig et al. 2015). Comparing these results with other instruments onboard the Rosetta S/C, we also observed much stronger CO₂/H₂O ratio variations than the Visible Infrared Thermal Imaging Spectrometer (VIRTIS). The CO₂/H₂O production rate ratio measured by VIRTIS-H is in the same order of magnitude, but ranges from 2 to 30% (Bockelée-Morvan et al. 2015) compared to 2.5 to 80% in our study. In the regions with strong solar illumination, VIRTIS-H measured a mean value of between 3 and 6%. This low value is compatible with our measurement (2.5%) in the summer hemisphere. VIRTIS-H also derived an upper limit for the CO/H₂O column density ratio from specific CO₂ measurements (CO/H₂O < 1.8%). This value is somewhat lower than the value we obtained in the summer hemisphere (2.7%). We conclude that our measurements roughly agree with CO₂/H₂O and CO/H₂O ratios determined by VIRTIS-H. Nevertheless, we note that the VIRTIS-H values have been obtained after averaging observations over a long and different time period (from 24 November 2014 to 24 January 2015). Moreover, as their data have been averaged, weaker variations in the column density ratios are expected. In addition, comparing local in situ measurements to line-of-sight integrated remote-sensing measurements can also lead to some differences.

For the hydrocarbons, while CH₄ fits well with what has been obtained from other JFCs, C₂H₂ is rather abundant. This is

even more pronounced for C₂H₆, which is up to 3.3% of the total number density on the winter hemisphere. This value is much higher than for any other comet. Moreover, the C₂H₆/CH₄ ratio is higher than 1 (≈ 2.5 and ≈ 6 in the summer and winter hemisphere, respectively). For comets C/2001 A2 (LINEAR) and C/1996 B2 (Hyakutake), for which the ethane relative abundance was also high, this ratio was roughly 1 (Magee-Sauer et al. 2008; Mumma et al. 1996). This high abundance of C₂H₆ relative to CH₄ is interesting as it can provide insights into the chemistry occurring in the solar nebula. Mumma et al. (1996) have discussed the different scenarios: this ratio may indicate that acetylene, produced in the gas phase and condensed onto icy grains, has been hydrogenated in the interstellar dense cloud. It may also reflect the processes (irradiation) that the ices have undergone. The ion-molecule reactions to produce ethane are also mentioned. Nevertheless, these reactions are not favorable at low temperature, and currently we cannot exclude any of these possibilities.

On the other hand, it is not really clear which molecules contribute to the C₂ chains used to apply the remote-sensing-based taxonomy of “carbon chain normal” or “depleted”. Therefore, a classification in the same sense cannot be made from our data. Assuming that the contribution to C₂ is mainly from C₂H₂ (see discussion in Weiler 2012), and that the contribution to CN is mainly from HCN, we set [HCN] = [CN] as well as [C₂H₂] = [C₂] and [H₂O] = [OH] assuming that all parents are eventually photodissociated and contribute to the remotely observed column densities. From our data, the ratio of CN/OH for 67P for the summer hemisphere is $\log([CN]/[OH]) \sim -3$ and for $\log([C_2]/[OH]) \sim -3.3$ (see Tables 2 and 4). The summer hemisphere has the highest outgassing and is most appropriate for comparison with remote sensing. These results would mean that 67P is carbon-chain depleted if we consider only the summer hemisphere. For the winter hemisphere, this completely changes, and 67P would be carbon-chain normal. This has to be taken with caution: the measurements are made at 3 AU compared to less than 2 AU for most other comets. It is reasonable to expect that the water production rate increases relative to more volatile species as the comet’s heliocentric distances decreases (Biver et al. 2002). Once the comet will be bright enough for spectroscopic analysis from the ground and C₂, C₃, and CN can be measured, it should be possible to obtain a better picture of which parent molecules are responsible for the observed column densities of [C₂], [C₃], and [CN].

Table 3 shows the relative abundance of the oxygenated species. Methanol falls well within the range of other JFCs. Luspay-Kuti et al. (2015) showed that methanol is more closely related to water than other more volatile species. The relative abundance of methanol therefore changes less than other more volatile species between summer and winter hemisphere. The same is true for formaldehyde. It was postulated that formaldehyde can also be produced from thermal degradation of grains and therefore has a distributed source (Meier et al. 1993). At 10 km from the coma, mostly direct sublimation from the nucleus surface is observed and, in addition, the temperatures are probably too low to allow breaking up of H₂CO polymers at these distances from the Sun. It will be important to follow the evolution of H₂CO with heliocentric and cometocentric distances to determine whether the grain production hypothesis holds true. All other oxygenated species are lower than observed at comets Hale-Bopp, Lemmon, or Lovejoy, the only three comets so far where they have been measured. No direct comparison can be made due to the different class of comets, and of course again due to heliocentric distance. Ethylene glycol

has been detected at a level of 8×10^{-6} compared to water. This is very low compared to concentrations in the three Oort cloud comets. Ethylene glycol has a high sublimation temperature, which may be the main reason for the very low abundance that is only observed over the summer hemisphere. But its presence nevertheless proves that Kuiper belt comets also contain complex organics. No clear peak of NH_2CHO is present in our mass spectra, but it might be hidden by another peak present at this mass. Therefore, we derived an upper limit for this compound.

Table 4 shows the relative abundance of the nitrogen-bearing species. HCN, and HNC are probably typical for comets in general, as the values do not differ very much between the different classes. Little NH_3 and CH_3CN have been observed. No well-resolved cyanoacetylene peak at $m/q = 51$ is found. We here also calculated an upper limit. Taken together with the N_2 value measured by Rubin et al. (2015), our measurements of 67P confirm that cometary volatiles are depleted in nitrogen.

Table 5 shows the relative abundance of the sulfur-bearing species. The abundance of H_2S in 67P is comparable to the values measured in LPCs, but 67P is depleted in all other sulfur-bearing species. Here we have to be cautious: except for H_2S , no other sulfur-bearing species has been calibrated due to their poisonous or corrosive nature. Error bars may therefore be high. Except for H_2S and CS in comet 73P/SW3, no sulfur-bearing species have ever been measured in JFCs, which precludes a direct comparison. The higher relative abundance value of SO in the summer hemisphere compared to the winter hemisphere is really surprising. An explanation might be that SO might be a fragment of molecules with even higher masses (other than SO_2). No such molecules were detected in our data, but it might just be that their abundances are not high enough. To explain this ratio, however, this also means that these potentially unidentified parents are stronger in the summer than in the winter hemisphere.

The ratio of water production for the two measurement periods is approximately $\text{H}_2\text{O}_{\text{summer}}/\text{H}_2\text{O}_{\text{winter}} = 16$. For CO_2 , this ratio is much lower. The absolute number of neutral detected with DFMS is even higher in the winter than in the summer hemisphere. This means that its absolute production rate is higher over the winter than over the summer hemisphere. We calculated the summer-to-winter hemisphere abundance ratio for CO_2 and found that it is around 0.5. This cannot be explained by temperature differences between summer and winter hemisphere. For CO, CH_4 , C_2H_2 , C_2H_6 , HCN, CS_2 , and OCS, the summer-to-winter hemisphere abundance ratio is also lower than that of water. It is between 1 and 4. (see Luspay-Kuti et al. 2015 and Hässig et al. 2015). These large differences may reflect the evolution of the cometary surface: the northern hemisphere was processed over the last orbit, during which it was the summer hemisphere for 5.5 yr and lost most of its highly volatiles, but relatively little (<1 m) of its surface layer. This surface layer may therefore be depleted in volatiles and/or closed off for sublimation from deeper layers. A chemically differentiated nucleus such as this has been modeled by Flammer et al. (1998) for Hale-Bopp, where they assumed an evolution of a dust layer on top followed by a devolatilized ice-dust layer underneath that partly inhibited the sublimation of volatiles from deeper layers. For 67P this is further complicated by the rotation axis and the irregular shape that leads to pronounced seasonal effects, where the thickness of these layers may vary considerably between hemispheres and locations on the nucleus. The southern hemisphere, which is the winter hemisphere during the time of the reported observations, has become sunlit in May 2015 and then experienced a short, but intense summer, during which time it

eroded by a few meters (Keller et al. 2015) and probably again exposed layers containing many highly volatile species. This can be studied in the next few months around perihelion and might then shed light on how volatiles are trapped in the cometary ice. This is needed to be able to connect our measurements to the bulk composition and also to ground-based observations.

5. Conclusions

The ROSINA instrument has detected many volatile species in the cometary coma at 3 AU. The relative abundances differ significantly between summer and winter hemispheres, most probably due to the surface evolution of the comet. In general, the mean values obtained are comparable with measurements from other comets with a few notable exceptions: CO and CO_2 are very abundant compared to those measured in JFCs. Heavy oxygen-bearing molecules are depleted, but most probably due to their high sublimation temperatures. Ethane is very abundant on the southern (winter) hemisphere. N-bearing molecules are typical, but together with the low measured N_2 (Rubin et al. 2015), nitrogen is clearly depleted.

From the ROSINA measurements we cannot conclude that this comet is carbon-chain normal or depleted because it is not clear which parent molecules contribute to the measured column densities from remote sensing. Because relative abundances are very different for the two hemispheres, it is hard to say at this time which values represent the bulk abundance. It will be important to monitor the changes during the equinox in May 2015 as well as during perihelion. It will also be important to have combined measurement campaigns with remote-sensing instruments to find the parents of $[\text{C}_2]$, $[\text{C}_3]$, and $[\text{CN}]$ and to be able to compare data from the different regions above the nucleus with what is seen from Earth.

Acknowledgements. The authors thank the following institutions and agencies, which supported this work: work at the University of Bern was funded by the State of Bern, the Swiss National Science Foundation, and the European Space Agency PRODEX Program. Work at the Southwest Research Institute was supported by subcontract no. 1496541 from the Jet Propulsion Laboratory (JPL). Work at BIRA-IASB was supported by the Belgian Science Policy Office via PRODEX/ROSINA PEA 90020. This work was supported by CNES grants at LATMOS and LPC2E. Work at the University of Michigan was funded by NASA under contract JPL-1266313. The results from ROSINA would not be possible without the work of the many engineers, technicians, and scientists involved in the mission, in the Rosetta spacecraft, and in the ROSINA instrument team over the past 20 yr, whose contributions are gratefully acknowledged. We here acknowledge the work of the whole European Space Agency (ESA) Rosetta team. Rosetta is an ESA mission with contributions from its member states and NASA. All ROSINA data are available on request until they are released to the Planetary Science Archive of ESA and the Planetary Data System archive of NASA.
