ABSTRACT

Context. Determining distances to individual field stars is a necessary step towards mapping Galactic structure and determining spatial variations in the chemo-dynamical properties of stellar populations in the Milky Way.

Aims. In order to provide stellar distance estimates for various spectroscopic surveys, we have developed a code that estimates distances to stars using measured spectroscopic and photometric quantities. We employ a Bayesian approach to build the probability distribution function over stellar evolutionary models given these data, delivering estimates of model parameters (including distances) for each star individually. Our method provides several alternative distance estimates for each star in the output, along with their associated uncertainties. This facilitates the use of our method even in the absence of some measurements.

Methods. The code was first tested on simulations, successfully recovering input distances to mock stars with $\lesssim 1\%$ bias. We found the uncertainties scale with the uncertainties in the adopted spectro-photometric parameters. The method-intrinsic random distance uncertainties for typical spectroscopic survey measurements amount to around 10% for dwarf stars and 20% for giants, and are most sensitive to the quality of $\log g$ measurements.

Results. The code was then validated by comparing our distance estimates to parallax measurements from the HIPPARCOS mission for nearby stars (< 300 pc), to asteroseismic distances of CoRoT red giant stars, and to known distances of well-studied open and globular clusters. The photometric data of these reference samples cover both optical and infrared wavelengths. The spectroscopic parameters are also based on spectra taken at various wavelengths, with varying spectral coverage and resolution: the Sloan Digital Sky Survey programs SEGUE and APOGEE, as well as various ESO instruments.

Conclusions. External comparisons confirm that our distances are subject to very small systematic biases with respect to the fundamental HIPPARCOS scale (+0.4% for dwarfs, and +1.6% for giants). The typical random distance scatter is 18% for dwarfs, and 26% for giants. For the CoRoT-APOGEE sample, which spans Galactocentric distances of 4–14 kpc, the typical random distance scatter is $\approx 15\%$ both for the nearby and farther data. Our distances are systematically larger than the CoRoT distances by about +9%, which can mostly be attributed to the different choice of priors. The comparison to known distances of star clusters from SEGUE and APOGEE has led to significant systematic differences for many cluster stars, but with opposite signs and substantial scatter. Finally, we tested our distances against those previously determined for a high-quality sample of giant stars from the RAVE survey, again finding a small systematic trend of +5% and an rms scatter of 30%. Efforts are underway to provide our code to the community by running it on a public server.

Key words. stars: distances – Galaxy: structure – stars: statistics – methods: statistical – surveys

1. Introduction

A crucial step towards studying stellar populations and their variation across the Galaxy is to measure reliable stellar

distances. Currently, parallax method is only viable for very local stars, although the recently launched *Gaia* satellite (Perryman et al. 2001) is expected to dramatically increase the number of parallax and proper motion measurements within a

Table 1. Spectroscopic stellar surveys for which distances were computed with our method.

Survey	Year	N_{stars}	Spatial coverage	Typical S/N	λ range	R
SEGUE (DR9 G dwarfs)	2004–2008	$\approx 120\,000$ (35 000)	≈ 1300 deg ²	25 (35)	0.38–0.92 μm	2000
APOGEE (DR10 HQ giants)	2011–2014	$\approx 100\,000$ (22 000)	≈ 2800 deg ²	100 (120)	1.5–1.7 μm	22 500
RAVE (DR4 HQ giants)	2006–2013	$\approx 500\,000$ (9000)	$\approx 20\,000$ deg ²	30 (70)	0.84–0.88 μm	7500

Notes. For each case we provide basic information, such as duration, number of stars for different signal-to-noise ratios (S/N), spatial and spectral coverage, and spectral resolving power.

significant portion of the Milky Way. Precise distances may also be obtained from asteroseismology, but only for a fraction of stars subject to systematic variability studies (Miglio 2012; Rodrigues et al. 2014). Indirect methods of distance determination, based on photometric and spectroscopic quantities and their relation to stellar absolute magnitudes, can be used for much more distant stars. Photometric distances have been applied to multiband optical and near infra-red data from different surveys to model the spatial distribution of Galactic stars and to study its substructures (e.g., Jurić et al. 2008; Correnti et al. 2010; Minniti et al. 2011). Recent Sloan Digital Sky Survey III (SDSS-III, Eisenstein et al. 2011) spectroscopic surveys, such as the Sloan Extension for Galactic Understanding and Exploration (SEGUE, Yanny et al. 2009) and the Apache Point Observatory Galactic Evolution Experiment (APOGEE, Allende Prieto et al. 2008a) have produced many more observational constraints, including stellar atmospheric parameters, kinematical and chemical data, which can be used to estimate reliable distances to tens of thousands of stars sampled from the SDSS and 2MASS (Skrutskie et al. 2006) photometric data. These surveys have already had a clear impact on our understanding of the Galaxy (Carollo et al. 2007, 2010, 2012; Lee et al. 2011a; Schlesinger et al. 2012; Cheng et al. 2012; Bovy et al. 2012b,a; Anders et al. 2014; Hayden et al. 2015). The recently completed RAdial Velocity Experiment (RAVE) survey (Steinmetz et al. 2006) has also provided atmospheric parameters, radial velocities and chemical abundances for six individual elements for more than 400 000 stars (Kordopatis et al. 2013). Ongoing spectroscopic surveys, such as the *Gaia*-ESO Survey (GES; Gilmore 2012), Galactic Archaeology with HERMES survey (GALAH; Zucker et al. 2012), or LAMOST Experiment for Galactic Understanding and Exploration (LEGUE; Deng et al. 2012), are continuously increasing the number of stars with available spectroscopic information. In fact, these large spectrophotometric data sets will, when analysed together, enable a description of the structure and substructures of the Galaxy with unprecedented detail, excellent statistics, and full use of the 6D phase-space information. Phase-space reconstruction of stellar distributions, coupled with spectroscopic abundances for large samples, will continue to provide challenging quantitative tests to models of Galaxy formation and evolution.

In order to take full advantage of the large set of available spectroscopic and photometric parameters from recent surveys, probabilistic inference has been used by several authors to infer ages, absolute magnitudes, extinction, and distances, among other parameters (e.g., Pont & Eyer 2004; Jørgensen & Lindegren 2005; Bailer-Jones 2011; Serenelli et al. 2013; Schönrich & Bergemann 2014). In the context of stellar distances, a series of papers with increasing levels of sophistication has been presented by the RAVE collaboration (Breddels et al. 2010; Zwitter et al. 2010; Burnett & Binney 2010). Burnett & Binney (2010) make use of a comprehensive set of measured parameters and their estimated uncertainties to infer, for

each star, the probability distribution that a set of chosen stellar models generate the data. The method was further refined by Burnett et al. (2011) and Binney et al. (2014a), and later used to study Galactic chemo-dynamics in, e.g. Boeche et al. (2013a,b), Binney et al. (2014b) or Kordopatis et al. (2015).

In this paper, we follow a similar theoretical background as those authors, and implement a code that computes spectrophotometric distances with the goal of mapping large stellar samples in three dimensions or in phase-space. We are motivated by the analyses of SDSS-III SEGUE and APOGEE data led by the Brazilian Participation Group (BPG) and the Leibniz-Institut für Astrophysik Potsdam (AIP), which are presented in Anders et al. (2014) and Brauer (2015). These papers use APOGEE giants and SEGUE G-dwarfs, respectively, to improve chemo-dynamical constraints to the Galactic components, especially the discs (see discussions in Minchev et al. 2014b; Chiappini et al. 2015). Since SEGUE and APOGEE targets were selected based on different photometric data and have different spectral coverage and resolution, our basic challenge is to ensure that accurate distances are computed in a homogeneous way for data sets of vastly different provenance. Our emphasis is therefore on confronting our distance estimates with as many reference samples as possible. A direct comparison with the RAVE distances obtained by Binney et al. (2014a) for the high-quality giant sample studied in Boeche et al. (2013a) is also provided. In Table 1 we list the main characteristic of the surveys to which we have applied our method.

The outline of the paper is as follows. In Sect. 2 we review the method, introduce our notation, and show the results of initial validation tests. An analysis of the performance of our code in terms of internal accuracy and precision is provided. We further discuss how biased stellar parameters and prior assumptions influence the estimated distances. In Sect. 3 we compare our distances to several previous distance determinations, which can be used as a reference, given their higher precision and more controlled systematics. We also compare our results for a high-quality sample of RAVE giant stars to those obtained by the RAVE collaboration. Our summary, conclusions, and future plans are provided in Sect. 4.

2. The method

The general method adopted for this study uses a set of measured photometric and spectroscopic parameters, such as metallicity, $[\text{Fe}/\text{H}]$, alpha element enhancement, $[\alpha/\text{Fe}]$, effective temperature, T_{eff} , surface gravity, $\log g$, intrinsic apparent magnitude, m , and colours, to estimate the distance to individual stars. These quantities are compared to predictions from stellar evolutionary models. The comparison between model and measured parameters follows a statistical approach that is similar to previous works (Burnett & Binney 2010; Burnett et al. 2011; Binney et al. 2014a).

In brief, assuming that the errors in the measured parameters follow a normal distribution, the probability that a measured value of some quantity, $x \pm \sigma_x$, is consistent with some theoretical value, x_0 , is given by

$$P(x, \sigma_x | x_0) = \mathcal{N}_{x_0, \sigma}(x) = \frac{1}{\sqrt{2\pi} \sigma_x} \exp \left[-\frac{(x - x_0)^2}{2\sigma_x^2} \right]. \quad (1)$$

We can easily extend this reasoning to a set of (independent) measured parameters, $\mathbf{x} = \{x_1, \dots, x_n\}$, with associated Gaussian uncertainties, $\sigma_{\mathbf{x}}$, whose theoretical values according to a given model are \mathbf{x}_0 , by writing:

$$P(\mathbf{x}, \sigma_{\mathbf{x}} | \mathbf{x}_0) = \prod_i \mathcal{N}_{x_{0,i}, \sigma_i}(x_i) \quad (2)$$

where the product is taken over all the measured parameters of a single star confronted with the model values. The expression above gives the likelihood of measuring the set $\{\mathbf{x}, \sigma_{\mathbf{x}}\}$ given a model \mathbf{x}_0 . According to Bayes's theorem, we may compute the posterior probability distribution (the probability of the model, given the data) as:

$$P(\mathbf{x}_0 | \mathbf{x}, \sigma_{\mathbf{x}}) = \frac{P(\mathbf{x}, \sigma_{\mathbf{x}} | \mathbf{x}_0) P(\mathbf{x}_0)}{P(\mathbf{x}, \sigma_{\mathbf{x}})}, \quad (3)$$

where the numerator contains the likelihood and model prior probability, and the denominator only depends on the measured parameters and their uncertainties¹.

To evaluate the probability of a specific model quantity, $\theta := x_{0,i}$, we consider the marginal posterior probability distribution for this quantity, which is obtained by integrating over all variables of Eq. (3), except θ :

$$p(\theta) := P(\theta | \mathbf{x}, \sigma_{\mathbf{x}}) = \int dx_{0,0} \dots dx_{0,i-1} dx_{0,i+1} \dots dx_n P(\mathbf{x}_0 | \mathbf{x}, \sigma_{\mathbf{x}}). \quad (4)$$

As mentioned earlier, a typical set of measured parameters includes $\mathbf{x} = \{[M/H], T_{\text{eff}}, \log g, \text{colours}, m\}$. As for the stellar models, besides the theoretical values of the same parameters, they also involve other quantities such as mass m_* , age τ , and absolute magnitude M_{abs} . In addition, we take $\theta = d$, where d is the star's model distance computed as $d [\text{pc}] = 10^{0.2(m - M_{\text{abs}} + 5)}$.

2.1. Distance uncertainties

Our code can deliver various statistics for the desirable quantity. In this work, and following [Rodrigues et al. \(2014\)](#), we compute a star's distance d as the median of the marginalised posterior probability distribution, $p(d)$ (Eq. (4)). To estimate the uncertainties, we report the 68% and 95% upper and lower credible intervals of the median, d_{68L} , d_{68U} , d_{95L} , and d_{95U} . When quoting a single uncertainty value, we use the definition

$$\sigma(d) := 0.5 \cdot (d_{68U} - d_{68L}).$$

Whenever there is some ambiguity, we use the subscript BPG to denote our Bayesian distance estimates².

¹ Because we are only interested in inferring the best model parameter (in our case the distance) for a specific set of models, this term is dropped in further computations, as it merely represents a constant that can be normalised out (e.g. [Ivezić et al. 2013](#), Chap. 5).

² BPG is short for the SDSS-III Brazilian Participation Group.

Fig. 1. Stellar parameter distributions of the simulated PARSEC sample in the $T_{\text{eff}} - \log g$ diagram (without observational errors added). *Upper left:* solar-scaled metallicity; *upper right:* mass (in M_{\odot}); *lower left:* luminosity (in L_{\odot}); *lower right:* age (in years).

2.2. A test suite of simulated stars

We use a set of simulated stars drawn from a grid of PARSEC 1.2S stellar models ([Bressan et al. 2012](#); [Tang et al. 2014](#); [Chen et al. 2015](#)), with a narrow metallicity step of $\Delta[M/H] = 0.1$, spanning the range $-2.2 \leq [M/H] \leq 0.6$, and age steps of $\log \tau [\text{yr}] = 0.05$ in the range $7.5 \leq \log \tau [\text{yr}] \leq 10.15$, to verify the method and our implementation. Specifically, we randomly select 5000 models that fall into the parameter regime targeted by large-scale spectroscopic surveys, by restricting model space to $3000 < T_{\text{eff}} < 7000$ K and $1 < \log g < 5$ (see Fig. 1). These simulated stars are assigned random distances between 0.1 and 6 kpc, drawn from a uniform distribution. The simulated photometry is in the 2MASS JHK_s system ([Cutri et al. 2003](#)), with no extinction applied.

By adding typical (conservative) Gaussian random errors to the model observables, we then create two sets of simulated spectrophotometric observations from this file: a set of spectroscopically measured quantities resembling high-resolution observations ($e_{T_{\text{eff}}} = 100$ K, $e_{\log g} = 0.1$ dex, $e_{[Z/H]} = 0.1$ dex)³, and a set resembling low-resolution observations ($e_{T_{\text{eff}}} = 200$ K, $e_{\log g} = 0.2$ dex, $e_{[Z/H]} = 0.15$ dex), hereafter referred to as high- and low-resolution-like. We assume that the errors are uncorrelated and the observational uncertainties are correctly estimated. Photometric errors are also assumed to be Gaussian and of the order of 0.01 mag.

Some of the effects of possible deviations from these assumptions are discussed in the next sections (stellar parameter biases, incomplete parameter sets, extinction, Galactic density priors). Other effects (e.g. $[\alpha/\text{Fe}]$ -enhanced isochrones, correlated and non-Gaussian stellar parameter errors) are beyond the scope of this paper, and deferred to a future investigation.

³ These values can be considered typical for stellar parameters obtained from high signal-to-noise-ratio (S/N) spectra from a multi-object high-resolution spectrograph like FLAMES/GIRAFFE or APOGEE. For very high-resolution spectra from, e.g., HARPS or UVES, these values may even be lower by about a factor of 2.

Fig. 2. Results from the test with the simulated PARSEC sample with high-resolution-like observational errors (see Sect. 2.2; $e_{r_{\text{eff}}} = 100$ K, $e_{[Z/H]} = 0.1$ dex, $e_{\log g} = 0.1$ dex, and $e_{m_{\text{obs}}} = 0.01$ mag), using the full input parameter set (set 1: $\mathbf{x} = \{[M/H], T_{\text{eff}}, \log g, m, \text{colours}\}$). *Left six panels:* relative distance errors (observed – true) of the simulated stars shown as a function of the (true) main stellar model parameters T_{eff} , $[M/H]$, $\log g$, mass m_* , age τ , and distance d_{true} . The solid line marks the identity line, dashed lines indicate distance deviations of 20%. *Upper right panel:* relative distance error distribution in the $T_{\text{eff}} - \log g$ diagram. *Lower right panel:* relative distance uncertainty distribution in the $T_{\text{eff}} - \log g$ diagram. Clearly, distances to giant stars are much more prone to systematics and have larger uncertainties.

2.3. Internal accuracy and precision

Figure 2 summarises our results from the test with the simulated PARSEC sample with high-resolution-like observational errors, when using the following set of measured quantities as an input: $\mathbf{x} = \{[M/H], T_{\text{eff}}, \log g, m, \text{colours}\}$. In each panel except for the last, we show the relative deviations of our estimated values from the true distances, $(d_{\text{BPG}} - d_{\text{true}})/d_{\text{true}}$, as a function of the model parameters.

The first row of this figure demonstrates that our distance errors are typically below 20% and do not show any strong systematics with the measured quantities T_{eff} , $[Z/H]$ and $\log g$ themselves. However, the upper right panel (distribution of distance errors in the $T_{\text{eff}} - \log g$ diagram) in particular reveals that our distances for main-sequence and subgiant stars are much better recovered than for giants (mean deviation -0.5% , rms scatter 10.6% vs. 1.8% and 23.3% , respectively). This is a known problem because of the larger overlap of models with very different luminosities in the giant region of the Hertzsprung-Russell diagram (see Fig. 1).

The second row of Fig. 2 examines the dependency of our distance errors with the model parameters which are not directly measured through spectroscopic observations: mass, age, and distance. While there is no correlation between the distance errors and the true distances themselves, we do see some systematic trends with mass and age. In particular, our code tends to slightly overpredict the distances to very old, very low-mass giant stars, while the code underpredicts the distances for very young ($\tau < 100$ Myr) giants with super-solar masses. However,

when taking the Galactic star formation history and initial mass function (IMF) into account, these groups typically represent a negligible minority of the stars targeted by large spectroscopic stellar surveys; their fraction is clearly overrepresented in our test sample. We can therefore be confident that our code delivers unbiased distance estimates for the vast majority of stars.

Finally, in the lower right panel of Fig. 2, we show the distance uncertainties for the simulated stars, again as a function of T_{eff} and $\log g$. Evidently, the internal precision of our method is much better for main-sequence stars than for giants (excluding the red-clump/horizontal-branch stars at $\log g \sim 2.5$, for which we also find accurate and precise distances). A comparison between the upper and lower right panels of this figure also shows that our code determines reliable and unbiased statistical uncertainties.

2.4. Sensitivity to input observables

Initial tests showed that, among the input measured quantities, $\log g$ is most critical to estimate unbiased distances, since it is the quantity that best discriminates between low-luminosity dwarfs and more luminous giants, which otherwise share similar values of temperature, metallicities, and colours. Dropping $\log g$ from the fitting procedure leads to overestimated distances for dwarf stars, and underestimated distances to giants, respectively. Similar tests also showed that cutting models with $|\mathbf{x}_0 - \mathbf{x}| > 3\sigma_{\mathbf{x}}$ decreases the processing time without appreciably changing the final distance estimates.

Based on these initial assessments, we implemented a code that estimates distances using the method described above and based on four distinct sets \mathbf{x} :

1. $\mathbf{x} = \{[M/H], T_{\text{eff}}, \log g, m, \text{colours}\}$
2. $\mathbf{x} = \{[M/H], T_{\text{eff}}, \log g, m\}$
3. $\mathbf{x} = \{[M/H], \log g, m, \text{colours}\}$
4. $\mathbf{x} = \{[M/H], m, \text{colours}\}$, but with a cut in models whose $\log g$ differ by more than 0.5 dex from the measured value.

The code can accommodate other sets if so desired. The advantage of implementing different sets of parameters for distance determination is to provide flexibility: distances can be estimated even in the absence of one or two parameters from the set with the largest number of parameters (set 1). Furthermore, the alternative distance estimates may be compared to provide a means to evaluate the sensitivity of the method to the particular combination of spectroscopic and photometric parameters adopted.

Often, the data set in a given sample only includes $[Fe/H]$ values, which are used in place of $[M/H]$. When $[\alpha/Fe]$ values are available, we adopt the empirical relation $[M/H] = [Fe/H] + [\alpha/Fe]$ for the comparison with PARSEC isochrones (e.g., [Anders et al. 2014](#)). Another important issue is extinction: the photometric data, m , and colours, must be corrected for extinction and redenning before comparing with the models. The exact procedure depends on the bandpasses used, on the available extinction estimates and on the assumed extinction coefficients.

The top panels of Fig. 3 show the results of applying the method to our simulated observations (see Sect. 2.2). The distribution of the relative distance errors, $(d_{\text{BPG}} - d_{\text{true}})/d_{\text{true}}$, are shown for the four parameter sets listed above, for both the high-resolution-like (left panel) and the low-resolution-like simulations, and for giants and dwarfs separately.

The four distance estimates proposed lead to reasonable results as attested by these error distributions. Surprisingly, there is only a very small systematic degradation in the precision of our distances as we move down from sets 1 to 4. As noted above, set 1 in the high-resolution case yields mean distance errors of -0.5% with an rms scatter of 10.6% for main-sequence stars ($\log g > 4.0$), while for giants the numbers are expectedly a bit worse ($+1.8\%$ bias and 23.3% precision).

For the other three sets, these numbers are $-0.2\% \pm 11.3\%$, $-0.7\% \pm 13.1\%$, $-2.9\% \pm 21.5\%$ for dwarfs, and $+1.7\% \pm 24.3\%$, $+1.8 \pm 23.4\%$, $+2.8\% \pm 25.1\%$ for giants, respectively. This trend is expected, at least in the context of simulations, since the usage of more measured parameters tends to better constrain the stellar models that best describe each star.

As is shown in Fig. 3 (top right panel), these numbers are slightly worse for the low-resolution case. The relevant numbers for this and all other comparison samples are listed in Table 3. In the following, we use only the full input parameter set (set 1: $\mathbf{x} = \{[M/H], T_{\text{eff}}, \log g, m, \text{colours}\}$).

The bottom panels of Fig. 3 show the distributions of our distance uncertainties, $\sigma(d_{\text{BPG}})/d_{\text{BPG}}$, for each of the four input sets, and for dwarfs and giants separately. Again, we also show the numbers for the low-resolution case. As expected, the uncertainty distributions for dwarfs peak at $<10\%$, while the distributions for giants are broader and peak at larger values.

2.5. Effect of systematic stellar parameter errors

We studied the effect of constant shifts in each of the spectroscopic input parameters on our distance estimates to gain some

Fig. 3. Distance accuracy and precision for the four input observable sets introduced in Sect. 2.4. *Upper panels:* distribution of relative distance errors, $(d_{\text{BPG}} - d_{\text{true}})/d_{\text{true}}$, for the sample of simulated stars drawn from PARSEC models (see Fig. 1) with high-resolution-like observational errors (*left*; see Sect. 2.2) and low-resolution-like errors (*right*). In each panel, we use the distances based on the four sets of measured parameters listed in Sect. 2.4. The results for dwarfs are shown in black, the results for the giants in grey. Solid lines: set 1 ($\mathbf{x} = \{[M/H], T_{\text{eff}}, \log g, m, \text{colours}\}$); dashed lines: set 2 ($\mathbf{x} = \{[M/H], T_{\text{eff}}, \log g, m\}$); dash-dotted lines: set 3 ($\mathbf{x} = \{[M/H], \log g, m, \text{colours}\}$); dotted lines: set 4 ($\mathbf{x} = \{[M/H], m, \text{colours}\}$, with a cut in models whose $|\Delta \log g| < 0.5$ dex). *Bottom panels:* distributions of our relative (internal) distance uncertainties, $\sigma(d_{\text{BPG}})/d_{\text{BPG}}$.

insight into the robustness of our method to systematics in the stellar parameters used. Figure 4 shows the results of this experiment: in each panel, all except for one input parameter are kept constant for the whole simulated high-resolution sample, while the remaining parameter is shifted by a certain amount. The figure shows the effect on the relative distance error (observed – true) as a function of this shift. As before, we treat dwarfs and giants separately because these two groups display distinct systematic trends.

The most striking observation from Fig. 4 is that even a substantial systematic shift in the temperature ($|\Delta T_{\text{eff}}| \lesssim 200$ K) or metallicity scale ($|\Delta [Z/H]| \lesssim 0.2$ dex) does not terribly affect neither accuracy nor precision of our distances. This is in stark contrast to systematic shifts in the surface gravity parameter (which are in fact quite commonly found even in high-resolution spectroscopic surveys; e.g. [Holtzman et al. 2015](#)).

2.6. The model priors

In order to determine distances to stars in the Milky Way, we use our current knowledge about the Galaxy and its components to build the model prior probability distribution, $P(\mathbf{x}_0)$. This includes basic information concerning the distributions of stars as a function of position, mass, age, and metallicity.

Fig. 4. Effects of systematic shifts in the spectroscopically observed stellar parameters T_{eff} (left), $[Z/H]$ (middle) and $\log g$ (right panels) on our determined distances. For this exercise, we again use the simulated PARSEC sample with high-resolution-like observational errors and the full input parameter set (set 1: $\mathbf{x} = \{[M/H], T_{\text{eff}}, \log g, m, \text{colours}\}$). In each panel, the errorbars show the mean and standard deviation of the relative distance errors, as a function of the value of a fixed shift in the particular stellar parameter. Dwarfs ($\log g > 4$) and giants are shown separately in the top and bottom rows, respectively.

In particular, we assume that all stars follow a Chabrier initial mass function (Chabrier 2003) and incorporate the probability that a randomly selected star falls within a given mass range, $p(m_\star)$. This involves an integral over the mass function which is provided by the model isochrones.

We take the effect of observing a given star in a small but finite solid angle into account, by applying a geometric prior $\propto s^2 ds$ called the volume element, where s is the model distance. We further assume different age and spatial distributions for the basic Galactic components, namely the thin disc, thick disc, and spheroid. We here adopt the same Galactic structural parameters as Binney et al. (2014a), and refer to this work for a detailed justification.

The age distributions, $p(\tau)$, are taken to be uniform with an upper limit of 10 Gyr for the thin disc, and lower limits of 8 and 10 Gyr for the thick disc and halo, respectively.

The spatial priors for the thin and thick discs are given, respectively, by

$$p_{\text{thin}}(R, Z) \propto s^2 ds \cdot \exp(-R/h_{R,\text{thin}}) \cdot \exp(-|Z|/h_{Z,\text{thin}}),$$

$$p_{\text{thick}}(R, Z) \propto s^2 ds \cdot \exp(-R/h_{R,\text{thick}}) \cdot \exp(-|Z|/h_{Z,\text{thick}}),$$

where (R, Z) are cylindrical coordinates with origin at the Galactic centre, whose values are computed given the model distance s and a direction (l, b) , and h_R and h_Z are the respective scale lengths and heights. In computing the cylindrical coordinates, we use $R_0 = 8.33$ kpc as the distance from the Sun to the Galactic centre.

For the halo, we assume a power-law density profile with spherical symmetry:

$$p_{\text{halo}}(r, l, b) \propto s^2 ds \cdot r^{-\gamma},$$

where $r(s, l, b)$ is a radial spherical coordinate. Again, as in Binney et al. (2014a), we adopt $\gamma = 3.39$.

The three density profiles are normalised at the solar location, which, for simplicity, we take to be $(R, z) = (R_0, 0)$ and $r = R_0$, in cylindrical and spherical coordinates, respectively. The normalization values are again from Binney et al. (2014a).

We assume that the three basic Galactic components follow Gaussian metallicity distribution functions (MDFs), $p_i([Z/H])$, exactly as described by Binney et al. (2014a). Our final model prior is then given as

$$P(\mathbf{x}_0) = p(m_\star) \sum_i p_i(\tau) p_i(r) p_i([Z/H]).$$

3. External validation

In this section, we present results of the application of our method described in the previous section to a number of reference samples for distance determination. These include distances computed from astrometric parallaxes obtained by ESA's HIPPARCOS mission (Perryman 1989; Perryman et al. 1997; van Leeuwen 2007), precise asteroseismic distances produced by the CoRoT-APOGEE collaboration for a set of solar-like oscillating red giant stars (Anders et al. 2015), and distances to well-studied open and globular clusters. As in the previous sections, we use d_{BPG} to refer to our distances in all figures. Those taken as reference are referred to as d_{ref} . In Table 2, we provide information about the sources, derivation methods and precision of the parameters in the reference samples. The results of the comparison with the reference samples are summarised in Fig. 5 and Table 3. We also compare our distance estimates with those obtained by Binney et al. (2014a) for a sample of giant stars from the RAVE survey. This last comparison represents a cross-check of the implementation of the algorithm rather than a benchmark test, as the authors follow a similar theoretical background.

Figure 5 presents the comparison of our spectro-photometric distances (BPG) to those from the reference samples. The first three panels of each row show our relative distance residuals with respect to the reference set, as a function of the main spectroscopic parameters T_{eff} , $[Z/H]$ and $\log g$. The last panel of each row shows the residuals as a function of the reference distance. Each row corresponds to a particular reference sample discussed in this section.

3.1. Comparison with the HIPPARCOS scale – The FGK star sample of Bensby et al. (2014)

As a first validation test of our spectro-photometric distance algorithm, we use the high-resolution FGK dwarf sample of 714 solar-neighbourhood stars with well-determined atmospheric parameters by Bensby et al. (2014). Hereafter, we refer to this sample as the HIPPARCOS–Bensby sample because precision parallaxes from HIPPARCOS (van Leeuwen 2007) are available for these stars. We use the optical photometry from the Tycho-2 catalogue (Høg et al. 2000), and set $\text{mag} = V_T$, $M_{\text{abs}} = M_{V_T}$ and $\text{colours} = \{B_T - V_T\}$ in the set of parameters to be compared to the models. As throughout this paper, the models used for this comparison are from the PADova TRIeste Stellar Evolution Code (PARSEC 1.2S, Bressan et al. 2012; Tang et al. 2014; Chen et al. 2015), with a narrow metallicity step of $[M/H] = 0.1$ and age steps of $\log \tau(\text{yrs}) = 0.05$.

Fig. 5. Relative distance residuals (estimated – reference) as a function of the main spectroscopic parameters T_{eff} , $[Z/H]$ and $\log g$ as well as the reference distances d_{ref} . *Top rows:* comparison to the astrometric distance scale provided by the HIPPARCOS satellite, using the [Bensby et al. \(2014\)](#) FGK dwarf sample (1st row) and the APOGEE-HIPPARCOS giant sample (2nd row). *3rd row:* APOGEE clusters. *4th row:* CoRoT-APOGEE sample. *5th row:* SEGUE clusters. The central dashed line is the identity line, whereas the upper and lower lines indicate deviations at the 20% level.

The top row of Fig. 5 shows the results of our distance code for the HIPPARCOS–Bensby sample. There is little or no systematics in the residuals with the parameters themselves. The mean and rms residuals over all stars are 0.4% and 18.2%. In fact, the observed rms residual is comparable to the expected errors in the parallaxes and in our distances based on the high-resolution simulation (presented in Sect. 2.2) combined together. Because the HIPPARCOS–Bensby sample combines high-resolution spectroscopic data for nearby dwarf stars with accurate parallaxes, it is arguably the best reference sample to test our code against.

We have validated that, as in our simulation tests described in Sect. 2, the four sets of parameters yield acceptable distances. In our subsequent validation analyses, we concentrate on the full parameter set $\{T_{\text{eff}}, [Z/H], \log g, \text{colours}\}$, since it makes full use

of the set of spectroscopic and photometric parameters which is common to the surveys to which we are applying our method.

3.2. APOGEE

The SDSS-III project APOGEE has acquired high-resolution, near infrared (NIR) spectra ($R \approx 22\,500$) of $>100\,000$ stars selected from the 2MASS Point Source Catalogue ([Cutri et al. 2003](#)), most of which are red giant stars located at low Galactic latitudes. APOGEE is providing a unique spectroscopic sample of disc-dominated stars with unprecedented volume coverage, for which precision kinematical and abundance measurements are available. For more details about APOGEE data, we refer to [Ahn et al. \(2014\)](#), [Alam et al. \(2015\)](#), and [Holtzman et al. \(2015\)](#).

Table 2. Summary of the reference data: parameter ranges, uncertainties, and provenance.

Sample	Dist. range [kpc]	$\sigma(T_{\text{eff}})$ [K]	T_{eff} range [K]	$\sigma \log g$	$\log g$ range	σ [Fe/H]	[Fe/H] range	photom.	Magnitude range
Simulated sample	0.1–6	100	3000–7000	0.1	1.0–5.0	0.1	–2.2–0.5	JHK_s ³	distance-limited
HIPPARCOS-Bensby	<0.3 ¹	30–100 ²	4800–7000	0.1	3.0–4.8	0.1	–2.5–0.5	$B_T V_T$ ³	$V < 9^2$
HIPPARCOS-APOGEE	<0.3 ¹	90	3800–5500	0.2	1.0–4.0	0.1	–1.0–0.5	JHK_s ⁵	$(J - K)_0 > 0.5; H < 7$
CoRoT-APOGEE	1–6 ⁴	100 ⁴	4000–5300	0.05	1.6–3.0	0.1	–0.8–0.5	JHK_s ⁵	$(J - K)_0 > 0.5; H < 13.8^4$
APOGEE Clusters	1–12 ^{6,7}	100 ⁸	3700–5000	0.2	1.0–3.4	0.1	–1.0–0.5	JHK_s ⁵	$(J - K)_0 > 0.5; H < 13.8^9$
SEGUE Clusters	1–12 ^{6,7}	130 ¹⁰	4700–7000	0.21	1.6–5.0	0.11	–3.0–0.0	$ugriz$ ¹¹	$0.48 < (g - r)_0 < 0.55; r_0 < 20.2^{12}$

Notes. $\log g$ values in the CoRoT-APOGEE sample are based on asteroseismic measurements. All other non-photometric parameters were derived spectroscopically; the relevant references are given in the footnotes indicated in the third column.

References. (1) van Leeuwen (2007); (2) Bensby et al. (2014); (3) Høg et al. (2000); (4) Anders et al. (2015) and references therein; (5) Cutri et al. (2003); (6) WEBDA Database; (7) Harris (1996); (8) Ahn et al. (2014); (9) Zasowski et al. (2013); (10) Ahn et al. (2012); (11) Fukugita et al. (1996); (12) Lee et al. (2008a).

Validation of APOGEE stellar parameters partly relies on calibrating star clusters with many probable member stars with well-determined parameters (Mészáros et al. 2013; Holtzman et al. 2015). In this section, we use two APOGEE subsamples to test our distances. In Sect. 3.2.2, we use a set of 678 CoRoT stars in the exoplanet fields LRA01 and LRC01 (e.g., Miglio et al. 2013), which have been co-observed within an APOGEE ancillary campaign, and whose asteroseismic analysis has provided high-precision surface gravities (Anders et al. 2015). In Sect. 3.2.3, we make use of the APOGEE calibration cluster data set.

In the case of APOGEE, we set $m = K_s$, $M_{\text{abs}} = M_{K_s}$, and colours = $\{(J - H), (H - K_s)\}$, all of which are corrected for extinction before computing the distances. For the cluster stars, extinction values are based on the Rayleigh-Jeans Colour Excess method (RJCE, Majewski et al. 2011; Nidever et al. 2012; Zasowski et al. 2013). This method is based on stellar colour excesses measured using fluxes in near- and mid-infrared bands, where almost all stellar spectra are in the Rayleigh-Jeans regime and therefore have very similar intrinsic colours. For the stars in common with CoRoT, we use the precise extinctions calculated by Anders et al. (2015), using the method described in Rodrigues et al. (2014).

We use the calibrated stellar parameters determined by the APOGEE Stellar Parameters and Chemical Abundances Pipeline (ASPCAP; Holtzman et al. 2015; García-Pérez et al. 2015). Some minor improvements on the DR12 calibrations of metallicity and surface gravity have been applied; they are described in Appendix A. Since $[\alpha/\text{Fe}]$ is again available, we assume that $[\text{M}/\text{H}] = [\text{Fe}/\text{H}] + [\alpha/\text{Fe}]$ for APOGEE stars⁴.

For the comparison with the CoRoT sample (Sect. 3.2.2), APOGEE surface gravities were replaced by those from asteroseismic scaling relations (e.g., Miglio et al. 2013). Table 2 summarises the data provenance.

3.2.1. The HIPPARCOS–APOGEE sample

Through a fiber feed from the New Mexico State University 1m telescope at Apache Point Observatory to the APOGEE spectrograph, it is also possible to use APOGEE to observe smaller numbers of bright stars, one at a time (Holtzman et al. 2015, Sect. 2.3). Apart from calibration, this set-up is also being used within an ancillary campaign to observe several hundred red giant stars with measured HIPPARCOS parallaxes

(Feuillet et al., in prep.). The data processing and stellar parameter determination works in exactly the same way as for the data taken with the SDSS 2.5 m telescope.

We have used the DR12 HIPPARCOS–APOGEE sample of 712 stars with precise parallaxes ($\sigma(\pi)/\pi < 10\%$) to fundamentally validate our stellar distance estimates for giant stars also. The second row of Fig. 5 shows our results. The mean and rms residuals amount to +1.6% and 26.4%, respectively.

Recalling the tests performed in Sect. 2, we find that these numbers are very much comparable with the trends found for the giant sample of simulated “high-resolution” stars (see Table 3). Taking further into account that the HIPPARCOS parallaxes for these relatively distant objects are also affected by uncertainties of the order of 10%, the results indeed supersede expectations. Furthermore, we find no systematic trends with either of the stellar parameters.

3.2.2. APOGEE – comparison with asteroseismology: the CoRoT-APOGEE sample

Another important test for our distance method is the comparison with asteroseismically derived distances. It has been shown by recent studies (e.g., Miglio 2012; Silva Aguirre et al. 2012, 2013) that stellar distances (or equivalently, radii) determined from CoRoT and *Kepler* lightcurves, either via asteroseismic scaling relations or by comparing asteroseismic parameters to predicted values from a grid of models, agree within a few percent with HIPPARCOS parallaxes and eclipsing binary data. For example, Silva Aguirre et al. (2012) show that distances can be derived with 5% precision for solar-like stars by coupling the infrared flux method to determine T_{eff} and bolometric fluxes to the grid-modelling of the measured values of the frequency of maximum oscillation power, ν_{max} , and of the frequency difference between dominant oscillation modes, $\Delta\nu$. We therefore compared our spectro-photometric distances based on APOGEE stellar parameters with the distances obtained from CoRoT data for 678 stars in the fields LRA01 and LRC01, which have been successfully observed by both instruments. The reference distance scale is that of Anders et al. (2015) who used the well-tested stellar parameter estimation code PARAM (da Silva et al. 2006; Rodrigues et al. 2014), which is based on a similar theoretical background as this paper, but differs in a number of details. PARAM utilises the parameter set $\{T_{\text{eff}}, [Z/\text{H}], \Delta\nu, \nu_{\text{max}}\}$ to estimate the posterior probability over the stellar models first (i.e. it delivers mass, radius, age, and absolute magnitude pdfs). In a second separate step, it compares the derived absolute magnitude pdfs with a number of broad-band photometric measurements to derive individual stellar distances and extinctions. The code has

⁴ We here refer to ASPCAP’s cluster-calibrated $[\text{M}/\text{H}]$ values (Alam et al. 2015; Holtzman et al. 2015) as $[\text{Fe}/\text{H}]$, as ASPCAP metallicities were calibrated on literature $[\text{Fe}/\text{H}]$ values.

Table 3. Summary of the results for the reference distance samples we used.

Sample	N_{stars}	Dist. range [kpc]	Mean rel. residuals [%]	rms rel. residuals [%]
Simulated “high-res.” stars	5000	0.1–6	+1.2	20.9
Dwarfs ($\log g > 4$)	1248	0.1–6	−0.5	10.6
Giants ($\log g < 4$)	3752	0.1–6	+1.8	23.3
Simulated “low-res.” stars	5000	0.1–6	+3.3	33.4
Dwarfs ($\log g > 4$)	1248	0.1–6	−0.6	15.5
Giants ($\log g < 4$)	3752	0.1–6	+4.6	37.4
HIPPARCOS-Bensby dwarfs	714	≤ 0.2	+0.4	18.2
HIPPARCOS-APOGEE giants	712	< 0.3	+1.6	26.4
CoRoT-APOGEE giants	644	1–12	+8.7	14.9
APOGEE clusters – cluster age prior	392	1–15	−16.5	29.9
SEGUE clusters – field priors	419	1–12	+14	43
$\Delta \log g = +0.25$ dex; field priors	425	1–12	−2	35
$\Delta \log g = +0.25$ dex; clus. age priors	385	1–12	+13	39

been extensively tested in [Rodrigues et al. \(2014\)](#) and [Anders et al. \(2015\)](#); it delivers very precise distances for asteroseismic targets ($\sigma(d) \lesssim 2\%$). The distance scale of [Anders et al. \(2015\)](#) does not provide a completely independent benchmark because we use the same data and similar methods to derive stellar distances. However, the code serves as an important cross-check for the implementation of our code.

The comparison is shown in the fourth row of [Fig. 5](#). We again show the relative distances residuals between our distances (BPG) and those from CoRoT-APOGEE. The general picture is reassuring, despite the limited number statistics. Our code converged for 644 stars, the mean and rms relative distance residuals are +8.7% and 14.9%, respectively. No strong trends are seen with metallicity, effective temperature, or surface gravity.

The systematic differences between the two methods may arise from the different handling of priors, while the rms scatter is more likely to be attributed to our use of only three photometric passbands instead of the multi-wavelength photometry used by PARAM, and to minor differences in building the distance pdf. For simplicity, and because of the high quality of acquired data, [Anders et al. \(2015\)](#) opted to use an IMF prior plus flat priors on Galactic structure to derive distances. However, their sample extends over a large range of Galactocentric distances, so that small systematic shifts like that measured here are not excluded.

In summary, we find a very good agreement between the two methods, modulo a small systematic trend which we attribute to our choice of more comprehensive priors, and a scatter of $\sim 15\%$ which could be reduced by the inclusion of more photometric observations in our data set.

3.2.3. APOGEE – cluster comparison

In the third row of [Fig. 5](#), we compare our spectro-photometric distances with those obtained from isochrone fitting of star cluster colour-magnitude diagrams (CMDs). We again restrict the comparison to the spectro-photometric distances based on the parameter set 1 in [Sect. 2](#). We use a subsample of the ~ 400 open and globular cluster stars that are used for calibration of ASPCAP, as described in [Mészáros et al. \(2013\)](#), [Holtzman et al. \(2015\)](#). We again refer to [Table 2](#) for a summary of the data used. Most of the stars with reliable parameters belong to the globular clusters M 5, M 13, M 15, M 92, M 107, and to the open cluster M 67. The cluster distances and ages are adopted from the WEBDA cluster database in the case of open clusters and [Harris \(1996\)](#) for the globular clusters. [Table 4](#) summarises the cluster properties.

Table 4. Summary of the properties of star clusters used as reference for APOGEE and SEGUE distance estimates: dereddened cluster distance moduli, ages, metallicities, reddenings, and numbers of stars observed by APOGEE and SEGUE.

Cluster	$(m - M)_0$	$\log(\tau)$	[Fe/H]	$E(B - V)$	N_{APO}	N_{SEGUE}
NGC 188	11.55	9.63	−0.02	0.082	5	
NGC 2158	13.52	9.02	−0.23	0.36	15	10
NGC 2420	12.45	9.05	−0.26	0.029	16	125
NGC 5466	16.02	10.13	−1.98	0.0	5	
NGC 6791	13.06	9.64	+0.15	0.117	22	37
NGC 6819	11.86	9.17	+0.07	0.238	23	
NGC 7789	11.84	9.23	−0.08	0.217	4	
M 2	15.50	10.11	−1.65	0.06	3	64
M 3	15.07	9.69	−1.5	0.12	18	35
M 5	14.46	10.02	−1.29	0.03	84	
M 13	14.33	10.06	−1.53	0.02	46	149
M 15	15.39	10.07	−2.37	0.10	31	78
M 35	10.37	7.97	−0.16	0.262		6
M 53	16.32	10.10	−2.1	0.02	13	
M 67	9.79	9.41	0.00	0.059	48	50
M 71	13.01	10.00	−0.78	0.25	2	
M 92	14.65	10.14	−2.31	0.02	34	39
M 107	15.05	10.14	−1.02	0.33	39	
Be 29	15.86	9.025	−0.44	0.157	9	

Notes. Almost all of the listed clusters were used for APOGEE calibration, while SEGUE targeted a larger number of cluster members in some selected calibration clusters.

The right panel in this comparison shows a hint that our distances are being underestimated for more distant clusters. The global mean residual is -16.5% , with an rms scatter of 30%. All clusters, except for NGC 2420 ($d_{\text{ref}} \approx 3$ kpc), have most of their stars with residuals smaller than 30%. Instead of the field star priors discussed in [Sect. 2.6](#), we have used a simple age prior for each cluster. This adopted cluster prior simply assumes a log-normal distribution of cluster stellar ages, whose mean is the literature age estimate for the cluster and the dispersion is taken as $d \log \tau = 0.1$. We find that for most APOGEE clusters this prior is irrelevant, but the age prior improves the agreement with the reference distances for NGC 2420 and NGC 2158, while it negatively affects M 71, which is the oldest and most metal poor cluster on the list.

The comparison suggests that our spectro-photometric method, despite the scatter, yields distances that are in general agreement with the cluster scale, but subject to significant systematics, especially as a function metallicity (see [Fig. 5](#), third

Fig. 6. Comparison of our distances and host cluster distances d_{cluster} for a subsample of clusters with SEGUE observations. For each cluster the median distance and 68% quantiles (as error bars) are shown assuming the following different scenarios: open diamonds – uncalibrated SSPP DR9 parameters with field priors; black pentagons: a $\log g$ shift of 0.25 dex and field priors; and red circles: a shifted $\log g$ and a simple cluster age prior. For visibility the different symbols are slightly offset with respect to d_{cluster} . The lower panel shows the distance residuals, similar to the right column of panels in Fig. 5.

row, second panel). The fact that we do not see these systematic trends in our comparison with the HIPPARCOS scale suggests that the cluster distances might be subject to improvements in the underlying stellar physics (e.g. the inclusion of rotation; Brandt & Huang 2015b), and less of a gold standard than commonly assumed. Another important caveat is the possible contamination of the cluster sample with non-members.

Regarding the uncertainty of isochrone-based cluster distances, it has been shown by Pinsonneault et al. (2000) that open cluster distances, which are usually determined via measuring the main-sequence shift relative to the Hyades cluster, may be subject to zero-point shifts. Such shifts may result from changes in the adopted distance to the Hyades and interstellar reddening, as well as to the metal and helium abundance, and the age of the Hyades (e.g. Brandt & Huang 2015a). However, assuming a conservative error of 0.1 mag for the cluster distance moduli, the uncertainties in the spectroscopic distances are still by far the most important.

3.3. SEGUE clusters

The Sloan Extension for Galactic Understanding and Exploration (SEGUE) is a large optical spectroscopic survey at low resolution ($R \approx 2000$, Smeed et al. 2013). The goal of SEGUE is to deepen our knowledge about the Galactic structural components and their stellar content, sampling them mostly at high latitudes (Yanny et al. 2009; Eisenstein et al. 2011). In this sense, SEGUE is largely complementary to APOGEE in terms of coverage of the Galactic components. For more information on the spectra and instruments we refer to Gunn et al. (2006) and Smeed et al. (2013). SEGUE data have been processed through the SEGUE Stellar Parameter Pipeline (SSPP), which is described, along with its improvements, in a

series of papers (Lee et al. 2008a,b, 2011b; Allende Prieto et al. 2008b; Smolinski et al. 2011). Particularly important to SSPP is the validation of the derived stellar parameters. Field stars with high-resolution spectra and known members of well-studied star clusters have been used for that purpose (Allende Prieto et al. 2008b; Lee et al. 2008b; Smolinski et al. 2011).

As in the case of APOGEE (see Sect. 3.2.3), we use the sample of cluster stars, whose distances are well known from isochrone fitting, to further test our distance estimates. In the case of SEGUE data, we set $\text{mag} = g$, $M_{\text{abs}} = M_g$, and colours $=\{(u-g), (g-r), (r-i), (i-z)\}$ (see Gunn et al. 1998 for a description of the SDSS camera and Fukugita et al. 1996 for information on the photometric system). The spectroscopic and photometric data are from the SDSS ninth data release (DR9; Ahn et al. 2012) database. Since $[\alpha/\text{Fe}]$ is available for all SEGUE stars in our reference clusters, we assume that $[\text{M}/\text{H}] = [\text{Fe}/\text{H}] + [\alpha/\text{Fe}]$ in order to compare the data to the model $[\text{M}/\text{H}]$ values. As previously mentioned, all measured quantities have associated uncertainties. The measured photometric quantities also must be corrected for extinction and reddening to allow for a direct comparison to the models. Again, the data for the clusters used here are listed in Table 4.

The original sample contained eleven clusters, among open and globular, totalling a bit over 1000 stars. For 593 stars, a complete set of spectroscopic and photometric parameters and associated uncertainties allowed us the use of parameter set 1 to estimate distances. As the sample is spectroscopic, in all other cases the missing parameter(s) was (were) photometric. Distances were successfully computed, i.e. at least one model was found within 3σ of all the measured quantities, for 425 out of the 593 stars, pertaining to the eight clusters listed in the table. We include only those clusters with at least five confirmed members and successfully derived distances using our approach. Their distances, ages and metallicities were again taken from the WEBDA database in the case of open clusters, and from Harris (1996) in the case of the globular clusters.

In the last row of Fig. 5, we show the distance residuals of individual stars against $[\text{Fe}/\text{H}]$, T_{eff} , $\log g$, and reference cluster difference, similar to what we did with the other samples in this section. The scatter is larger than in previous samples, attesting to the lower resolution of the data. Still, most of the stars have residuals close to or within the 20% lines and do not exhibit any strong systematics with the spectroscopic parameters. The more deviant points correspond to a fraction of the low-metallicity ($[\text{Fe}/\text{H}] < -1.0$) giant and subgiant ($\log g \leq 4.0$) stars, located beyond ≈ 6 kpc. The mean and rms residuals over all stars are 0.14 ± 0.43 after applying a 3σ clipping. Our individual distances are biased towards large values for a significant fraction of the stars in the more distant globular clusters. This trend is opposite to what was observed in the case of APOGEE clusters (see Sect. 3.2.3). If we consider only the 3 clusters with $d_{\text{ref}} < 5$ kpc, the mean and rms scatter are reduced to 0.03 ± 0.27 .

We further investigated the cause of this systematic overestimate of the distances to part of the SEGUE stars in the more distant clusters. In analysing the distribution of different SEGUE spectroscopic parameters, it became clear that the $\log g$ parameter for our sample, as published in DR9, appears to be underestimated for most stars in those clusters. Recalling that $\log g$ is the most important quantity to efficiently separate dwarf and giant stellar models, we decided to correct for this shift heuristically.

The contours (black) in Fig. 7 show the distribution of a large sample of SEGUE G-dwarf stars (sample compiled from DR9 and described and analysed in Brauer 2015) in the $\log g$ vs. T_{eff} (left panel) and $\log g$ vs. $[\text{Fe}/\text{H}]$ (right panel) plane.

Fig. 7. *Left panel:* contours show the density of SEGUE dwarfs in the $\log g$ vs. $[\text{Fe}/\text{H}]$ plane. The colour density map corresponds to the same type of stars simulated by the TRILEGAL code. *Right panel:* same as in the previous panel, but stars are shown in the $\log g$ vs. T_{eff} plane.

For comparison, we also present the density distributions for a mock sample of G-dwarf stars obtained from TRILEGAL simulations (Girardi et al. 2005, 2012) covering the same SEGUE plates as present in the SEGUE G-dwarf data sample. These simulations were carried out using ADDSTAR, a web-based tool that uses parallel processing to efficiently run TRILEGAL with many independent pointings (Balbinot et al. 2012). The TRILEGAL G-dwarf mock sample shown here has been compiled by applying the same overall cuts to the simulation that were used for the SEGUE G-dwarf data sample including the colour–magnitude limits for SEGUE G-dwarfs. For a detailed description of the TRILEGAL mock sample see Brauer (2015).

A clear shift is seen in both panels in the sense that the data have systematically lower values of $\log g$ for a fixed T_{eff} or metallicity by ≈ 0.25 dex. The comparison with the population synthesis model reveals that the SSPP $\log g$ values published in DR9 are underestimated and that shifting the $\log g$ values for the SEGUE stars is clearly needed, at least for the purpose of deriving reliable distances. Further details about the TRILEGAL mock G-dwarf sample, the discrepancies seen in stellar parameters between data and simulation, and the underestimated surface gravity values published with DR9 are given in Brauer (2015).

We thus decided to test the effect of applying a shift of 0.25 dex to the $\log g$ values when computing the distances. The results are shown in Fig. 6, in which we compare the median spectro-photometric distances of each cluster with the reference cluster distances for different $\log g$ calibrations and/or priors used. The open diamonds correspond to median cluster distances using the SEGUE data as they come from DR9. The black pentagons show the effect of shifting $\log g$ as explained above. The global mean offset relative to the reference distances has been reduced to -2.4% , although the rms relative residual remains high (35%). For the three more nearby clusters, the distances become systematically underestimated by -18% although the scatter around the mean residual has decreased considerably to 12%. The result of adopting a simple age prior for the clusters, as done for APOGEE data, is shown with the red circles of Fig. 6. This choice has a sizable effect on the distances in that they are increased for the more distant clusters, yielding a mean and rms relative residual of $+0.13 \pm 0.39$.

We conclude that, despite the large scatter in distances of individual cluster stars, there is a general agreement between our median distances for SEGUE cluster stars and those from CMD fitting. The distances of fraction of the stars at lower metallicities and $\log g$, located in the more distant globular

clusters, are overestimated via our method. This seems to be because the SEGUE $\log g$ scale is systematically too low, as attested by simulated samples of SEGUE stars.

Finally, we emphasize that the SEGUE data are very distinct from APOGEE in terms of spectral range and resolution. These data also probe much larger distances than the HIPPARCOS-based data used in Sect. 3.1.

3.4. RAVE

RAVE collected medium-resolution ($R \sim 7500$) CaII triplet spectra of $\geq 400\,000$ stars with $9 < I < 13$. For $> 200\,000$ of these stars, Burnett et al. (2011) have been able to derive spectro-photometric distances with spectroscopic parameters from the RAVE pipeline (Kordopatis et al. 2011) as well as near-infrared photometry from 2MASS (Skrutskie et al. 2006; Cutri et al. 2003). Their method has provided the background for this, which is largely based on the Bayesian approach proposed by Burnett et al. (2011). More recently, Binney et al. (2014a) presented an improved version of the method. In this section, we use their distances for a high S/N sample containing ≥ 9000 giant stars (Boeche et al. 2013a) to cross-check the implementation of our method (details in Appendix C). The spectroscopic parameters are taken from the RAVE data release 4 (DR4; Kordopatis et al. 2013), the photometry is from 2MASS.

In order to derive distances for RAVE stars, we set $m = K_s$, $M_{\text{abs}} = M_{K_s}$, and colours = $\{(J - H), (H - K)\}$. We adopt the A_V extinction values that have been computed for individual RAVE objects by Binney et al. (2014a) to deredden the NIR magnitudes of the stars. The conversion between the extinction in the optical and near-IR wavelength range is performed following Rieke & Lebofsky (1985). We adopted the $[\text{Fe}/\text{H}]$ and $[\alpha/\text{Fe}]$ estimates from the chemical RAVE pipeline (Boeche et al. 2011; Kordopatis et al. 2013) to make our metallicity scale more compatible with the stellar models, as in the previous sections.

Despite the use of a very similar theoretical framework, there are some differences between the way distances are estimated by Binney et al. (2014a) and in this paper. The Padova isochrone grid Binney et al. (2014a) used (Bertelli et al. 2008) is not the same isochrone grid that we used. And the Binney et al. (2014a) grid was restricted to $[\text{Fe}/\text{H}] \geq -1$. Also, they use a slightly different IMF (Aumer & Binney 2009), and apparently they did not use the volume element $s^2 ds$ in the density priors presented in Sect. 2.6. They also apply a kinematic correction for their distances (Schönrich et al. 2012). From the data side, we have

Fig. 8. Comparison of our distance estimates against the RAVE DR4 distances from Binney et al. (2014a) for the high-S/N sample of Boeche et al. (2013a). In each panel the vertical axis shows the absolute distance residuals normalised to the combined uncertainty from both methods, $\sigma_{d_{\text{combined}}} = \sqrt{\sigma_{d_{\text{BPG}}}^2 + \sigma_{d_{\text{RAVE}}}^2}$, as a function of the main spectroscopic parameters T_{eff} , $[Z/H]$ and $\log g$ as well as the RAVE distance, d_{RAVE} .

used a slightly different metallicity scale, namely that of the RAVE chemical pipeline instead of the RAVE stellar parameter pipeline, and we handled the α -enhancement differently.

Figure 8 shows the comparison of our distance estimates with the distances from Binney et al. (2014a) for the giant sample analysed in Boeche et al. (2013a). To make this comparison compatible with our approach described in Sect. 2, we use the $\langle s \rangle$ distance estimate from the calibrated DR4 catalogue from Binney et al. (2014a). This distance estimate is the expectation value computed from their model pdf over distances instead of their corresponding parallaxes. Since neither of the distances being compared are supposed to be at the same level of precision as those in our reference samples, we have changed the way we compare them. Instead of computing the relative residual with respect to any one of the estimates, we normalise the residual by the combined uncertainty from both, which are added in quadrature. Our distance scale seems to be slightly compressed relative to RAVE DR4: we find systematically larger (smaller) distances than RAVE for stars with $d_{\text{RAVEDR4}} < 1$ ($d_{\text{RAVEDR4}} > 1$) kpc. The effect, however, is small. The vast majority of the stars have distance residuals well accommodated by the expected uncertainties in the two estimates being compared. The mean and rms normalised residuals are 0.00 ± 0.33 , after a 3σ clipping to eliminate the very few strongly deviant points between the two methods. Looking separately at the two distances regimes, we have mean relative residuals of 6% and -16% for $d_{\text{RAVEDR4}} < 1$ and $d_{\text{RAVEDR4}} > 1$ kpc, respectively.

3.5. Effect of different priors

In Fig. 9, we assess the effect of the adopted model priors on our distance estimates. For this purpose, we use the high-quality RAVE sample (≈ 9000 stars) presented in Sect. 3.4.

The aim of this exercise is merely to be able to quantify the effect of the adopted priors on a particular stellar population; the aim is not the justification of these priors, which is discussed in Sect. 2.6. For the internal consistency checks discussed in Sects. 2.3–2.5, we did not use any priors, which is the appropriate decision for our simulation, but not for real Milky Way stellar populations.

The top row of panels in Fig. 9 compares distances based on no assumed priors, as used in the simulations, to those using only the IMF prior, as presented in Sect. 2.6; it includes a correction for a uniform age distribution. The distances in the middle panels include the spatial priors, but still exclude the specific age distributions and MDFs of individual Galactic components presented

in Sect. 2.6. The comparison with the distances that also take the specific age distributions and MDFs of individual Galactic components into account is illustrated in the bottom panels in the figure.

It is clear from the figure that inclusion of age and metallicity priors both tend to systematically reduce the distances of a significant fraction of the stars. Restricting the thick disc and halo samples to old ages, in particular, prevents models of young luminous stars to be included in their distance estimates. Similarly, associating disc stars with relatively metal-rich models also tends to reduce their distances. A large number of stars are unaffected by the specific choice of model priors. Using all stars with estimated distances $s < 6$ kpc (when all priors are included, comprising the vast majority of the RAVE high-quality sample) we obtain a mean residual of 5% and a scatter of 6% between the distances of all priors and spatial only priors. This is, in fact, smaller than the systematic residuals and scatter found with respect to more precisely determined distances, as discussed in Sect. 3.

4. Summary and conclusions

We implemented a code to estimate distances to field stars based on their measured spectroscopic and photometric parameters. The theoretical background is very similar to that of Burnett & Binney (2010) and subsequent papers from the same authors. Briefly, given a set of measured quantities, these are compared to model values and the posterior probability distribution function is derived for each star using a Bayesian approach. The distance is then determined as the median value of the posterior pdf marginalised over the other parameters.

We used simulated stars from PARSEC models as a first validation test of our distances. We showed that distances based on four different sets of parameters are well recovered, without significant systematic biases, and statistical uncertainties that scale with the uncertainties of the input parameters. Distances to dwarf stars are more accurately recovered, with $< 1\%$ mean residual and 10% rms errors for a high-resolution simulated sample; typical errors for giant stars are about twice those values. The method is most sensitive to $\log g$, and starts breaking down if this parameter is removed from the data set, also yielding strong systematic distance errors as a function of bias in this parameter.

Our simulations also show that the estimated distance uncertainties are in general agreement with the errors, with the uncertainty distribution peaking at $\approx 10\%$ ($\approx 20\%$) for dwarf (giant) stars in a mock high-resolution sample, reaching significantly larger values when spectroscopic parameters are less precise.

RAVE Stars: Effect of adopted priors

Fig. 9. Effect of the adopted priors (Sect. 2.6) on our spectro-photometric distances (BPG), illustrated for the case of the RAVE sample. In each panel, we show the relative distance residuals (priors – no priors) with respect to the case where no priors were used, as a function of the main stellar parameters T_{eff} , $[Z/H]$, $\log g$, and as a function of position in the Galaxy (*right panels*). *Top row*: results for distances computed using the IMF prior and a flat prior in age instead of the logarithmic one implicit in the spacing of isochrones in $\log \tau$. *Middle row* also includes the spatial density priors. Finally, the *bottom row* includes the MDF and age priors for the different Galactic components.

We demonstrated that distances of nearby stars with parallaxes from HIPPARCOS and precise atmospheric parameters are successfully recovered, with only very small systematic trends, and random errors consistent with the expected combination of errors in the parallaxes and in our distances. The relative random errors are of the order of 20% or less, with $<1\%$ systematic errors, for nearby FGK dwarf stars. For giants with HIPPARCOS parallaxes, the random and systematic residuals in our distance estimates are also as expected based on our mock samples.

For more distant stars, we have validated the code using giant stars with asteroseismic observations, as well as certain members of well-studied star clusters. In the latter case, we compared our distances to the cluster distances taken from the literature.

Our distances for giant stars in common between APOGEE and CoRoT typically agree within 15%. A systematic overestimate in our distances in comparison to those inferred from asteroseismology at the level of $\approx 9\%$ may result from the use of a more set of comprehensive Galactic priors and a less comprehensive set of photometric measurements than our reference.

We used star clusters included in the SDSS-III SEGUE and APOGEE samples for a final set of validation tests, this time covering a larger range in distances out to ≈ 12 kpc. The distance scatter among individual cluster stars is larger than the distance residuals for the more nearby stars with parallax measurements. For APOGEE clusters, there is a small trend with distance itself, in the sense of underestimating the distances to the more distant cluster stars ($d \gtrsim 6$ kpc).

In the case of SEGUE, scatter tends to be higher than APOGEE, which is consistent with the lower resolution of the spectra. In particular, for a fraction of the low-metallicity giant and subgiant stars that predominate in the more distant globular clusters used, our distances tend to be overestimated, which

is in contrast to the trend seen in APOGEE. We have identified the probable origin for this discrepancy as a systematic bias in the SEGUE $\log g$ values. Applying a shift of 0.25 dex to the SEGUE $\log g$ reduces the mean distance residual over individual stars from 14% to -2% when all clusters are considered. The scatter is also significantly reduced for the more nearby cluster SEGUE stars. Despite the large scatter observed for a subset of the SEGUE stars, the inferred average distances to the SEGUE clusters are in good agreement with those quoted in the literature.

We also compared our distances to those for a sample of high-quality RAVE stars, which are determined with similar approaches to the method presented here (Binney et al. 2014a). Despite the large scatter and a slight systematic trend, our distances for the same sample of red giant stars studied in Boeche et al. (2013a) agree, within the expected uncertainties, with those derived by Binney et al. (2014a).

The validation results are all summarised in Table 3, where we show the data set used, the number of stars and range of reference distances in each, and the mean and rms relative residuals. The table allows us to evaluate the distances globally, specially when confronted to those from astrometry, asteroseismology, and well-calibrated star clusters. The systematic residuals are usually less than 9% while the scatter scales with the quality of the input spectro-photometric parameters, where the most distant SEGUE clusters are our worst case.

The Brazilian Participation Group on SDSS-III is using the code we presented and validated here to derive distances for tens of thousands of stars belonging to the SEGUE and APOGEE surveys. These surveys are complementary in many ways, including the directions and Galactic components they probe more efficiently. When analysed together, provided that reliable distances

are available, they allow us to perform a 3D mapping of Galactic structure using different stellar tracers, determination of chemokinematic relations in the Galaxy, and ultimately, confrontation of these constraints with models of Galactic formation and evolution (Minchev et al. 2013, 2014a). Initial science analyses based on these distances are provided by Junqueira et al. (2015) and Anders et al. (2014).

Appendix A: APOGEE distances and calibration of stellar parameters

For the computation of distances to APOGEE stars, we make use of the ASPCAP stellar parameters bundled in the twelfth data release of the Sloan Digital Sky Survey (SDSS DR12; [Alam et al. 2015](#)). The APOGEE data products contained in this release are described in detail in [Holtzman et al. \(2015\)](#). While we generally use the stellar parameter calibrations provided by these authors, we have adopted slightly different calibrations for metallicity and surface gravity, which are explained below.

Our APOGEE distances will be released within an SDSS DR12 value-added APOGEE distance catalogue.

Surface gravity for red-clump stars: [Holtzman et al. \(2015\)](#) use the very accurate and precise surface gravities from the APOGEE-*Kepler* sample ([Pinsonneault et al. 2014](#)) to calibrate out systematic shifts in the surface gravities delivered by ASPCAP. They demonstrate (their Fig. 4) that these systematics are different for red-giant branch (RGB) and core-He burning red-clump stars (RC). The offset between both groups is about 0.2 dex. However, the authors only provide a surface gravity calibration for RGB (their formula 3), and for RC stars defer to the APOGEE RC catalogue described by [Bovy et al. \(2014\)](#), who provide very precise distances to these stars. Because we wanted to test our distance code on *all* APOGEE giant stars, we have separately fit the calibration relation for the stars contained in the RC catalogue, i.e.

$$\log g_{\text{RC}} = \log g_{\text{calib}} - \left(7.21 \times 10^{-5} \cdot (T_{\text{eff}}[\text{K}] - 4400) + 0.129\right)$$

Metallicities in the super-solar regime: ASPCAP metallicities have been calibrated using open and globular cluster metallicities from the literature. Figure 6 of [Holtzman et al. \(2015\)](#) shows the result of the external metallicity calibration: in the metal-poor regime, the raw ASPCAP metallicities are up to 0.3 dex too high compared to the literature, while the values are similar at solar metallicities. The authors have therefore opted to fit a second-order polynomial to the data (their formula 6). Since there are very few calibration clusters above solar metallicity, however, the quadratic calibration relation may be overfitting the data at the metal-rich end, and, therefore, overestimate metallicities in this regime. We have thus opted to use the calibrated values *only when* $[Z/H] < 0.0$, and to otherwise use the uncalibrated values.

Appendix B: SEGUE distances

For the computation of SEGUE distances, we use the results of the SEGUE Stellar Parameter Pipeline (SSPP; [Lee et al. 2008a,b, 2011a; Smolinski et al. 2011](#)) for a clean sample of G dwarfs (details will be provided in [Brauer 2015](#)). From SDSS DR8 to DR9, it underwent a couple of modifications providing improved stellar parameters for all SEGUE objects within the scope of DR9. In particular, there are some obvious systematic shifts in the individual parameters when comparing DR8 and DR9 SSPP values for the same objects.

The most significant deviation is observed for the surface gravity showing a clear overall decrease of the parameter by 0.2 dex to 0.3 dex to lower values. This finding is in agreement with the fact that the DR9 surface gravity is in general lower by about ~ 0.2 dex ([Rockosi et al., in prep.](#)). Possible explanations for the decrease are the following: (1) the surface gravity estimates, from the reanalysis of the high-resolution spectra that are used to calibrate the DR9 SSPP results are in general lower by 0.13 dex than those from the older high-resolution analysis; (2) for some of the $\log g$ estimation methods utilised by the SSPP, new synthetic spectral grids were used; and (3) the line index methods MgH and CaI2 were not considered any longer – which may have had a substantial effect since those estimators produced higher $\log g$ values compared to others. The overall lower gravity is certainly caused by a combination of the above facts.

Besides the shift in surface gravity, the temperatures in DR9 tend to be systematically larger than in DR8 by ~ 50 K. This temperature shift occurs because of the IRFM temperature scale being utilised to calibrate the SSPP DR9 temperature estimators.

While the metallicity scale did not change significantly, the $[\alpha/\text{Fe}]$ abundances shifted to higher values by about 0.1 dex.

Log g calibration: as shown in Sect. 4, accurate absolute surface gravity values are crucial for computing spectro-photometric distances. Any systematic under- or overestimation of the surface gravity leads to significant under- or overestimation of our distances. Hence, as justified in Sect. 3.3, we decided to calibrate the SEGUE DR9 surface gravity values by applying a shift of 0.25 dex and thus increasing the $\log g$ of each object in the G-dwarf sample by the same amount. Apart from this modification, we use the SEGUE DR9 values delivered by the SSPP.

Appendix C: RAVE distances

We used the RAVE giant sample assembled by [Boeche et al. \(2013a\)](#). This sample comprises stars with the highest quality spectra and abundances. The following quality criteria have been applied: (1) only spectra with a signal-to-noise ratio of at least 60 were selected on which the RAVE pipeline converged to a single point of the parameter space (Flag `Algo_Conv` = 0); (2) the chemical pipeline converged ($\chi^2 < 1000$); (3) the number of defective pixels along the spectrum is small (`frac` > 0.99); and (4) every object that is not classified as a normal star, according to the morphological classification described in [Matijević et al. \(2012\)](#), was excluded. Like [Binney et al. \(2014a\)](#), we use the stellar parameters from DR4 ([Kordopatis et al. 2013](#)). The applied cuts to select RAVE giants are $0.5 \text{ dex} < \log g < 3.5 \text{ dex}$ and $4000 \text{ K} < T_{\text{eff}} < 5500 \text{ K}$. This ensures that only cool giants are selected and problems with the grid limits of the automated pipeline are avoided by setting the lower limit in $\log g$. The resulting RAVE giant sample comprises 9098 stars.

We will also provide distances for the full RAVE DR4 sample in the near future.
