ABSTRACT

Recently, the vertical shear instability (VSI) has become an attractive purely hydrodynamic candidate for the anomalous angular momentum transport required for weakly ionized accretion disks. In direct three-dimensional numerical simulations of VSI turbulence in disks, a meridional circulation pattern was observed that is opposite to the usual viscous flow behavior. Here, we investigate whether this feature can possibly be explained by an anisotropy of the VSI turbulence. Using three-dimensional hydrodynamical simulations, we calculate the turbulent Reynolds stresses relevant for angular momentum transport for a representative section of a disk. We find that the vertical stress is significantly stronger than the radial stress. Using our results in viscous disk simulations with different viscosity coefficients for the radial and vertical direction, we find good agreement with the VSI turbulence for the stresses and meridional flow; this provides additional evidence for the anisotropy. The results are important with respect to the transport of small embedded particles in disks.

Key words. accretion, accretion disks – turbulence

1. Introduction

The exact origin of the driving mechanism of accretion disks is still not fully understood. To accrete matter onto the central object, the matter needs to lose its angular momentum, and because molecular viscosity is by many orders of magnitudes too small to facilitate the required angular transport, it has been suggested that disks are driven by turbulence. The discovery of a linear purely hydrodynamical vertical shear instability (VSI) has at-
extends from 0.4 \( r_0 \) to 2.5 \( r_0 \), where \( r_0 = 5.2 \) au. The initial density profile is given by vertical hydrostatic equilibrium

\[
\rho(r, z) = \rho_0 \left( \frac{r}{r_0} \right)^\phi \exp \left[ \frac{GM}{c_s^2} \left( \frac{1}{R} - \frac{1}{r} \right) \right],
\]

where \( \rho_0 \) is the gas mid-plane density at \( r = r_0 \), and \( \phi = -1.5 \). In our locally isothermal approximation the temperature of the disk is a function of the cylindrical radius only,

\[
T(r) = T_0 \left( \frac{r}{r_0} \right)^\phi,
\]

where we choose \( \phi = -1 \), which causes the disk aspect ratio to be constant and \( T_0 \) such that \( H/r = h = 0.05 \). The pressure is given by \( P = c_s^2 \rho \), where \( c_s \) is the isothermal sound speed with \( c_s \propto r^{-1/2} \). The gas moves initially with the angular velocity given by the Keplerian value, corrected by the pressure support (Nelson et al. 2013)

\[
\Omega(r, z) = \Omega_K \left[ (p + q) \left( \frac{H}{r} \right)^2 + (1 + q) - \frac{qr}{\sqrt{r^2 + z^2}} \right],
\]

with \( \Omega_K^2(r) = GM/r^3 \), and the meridional flow \((u_\phi, u_z)\) is set to zero. At the inner and outer boundary we use reflecting boundaries. To increase numerical stability for the turbulent runs, we damp the variables \( \rho, u_\phi, u_z \) to the initial values on a timescale of half a local orbit following the recipe by de Val-Borro et al. (2006), with a damping applied at the inner boundary from 0.4–0.5 \( r_0 \) and at the outer boundary from 2.3–2.5 \( r_0 \). At the vertical boundaries we use reflective boundaries when the flow is directed inward and zero gradient otherwise. The VSI model is inviscid, and for the \( \alpha \)-disk model the kinematic viscosity is given by \( v = 2/3 \Omega c_s H \), with a constant \( \alpha = 5 \times 10^{-4} \), which matches the outcome of VSI model.

### 3. Disk structure

We consider the structure of the VSI unstable disk to viscous disks described by an \( \alpha \)-parameter, and study the main differences. The VSI disk is evolved to a quasi-equilibrium state before the analysis is performed. We focus in particular on the flow field and stress tensor, and refer to Nelson et al. (2013) and Stoll & Kley (2014, 2016) for an analysis of the turbulent flow structure.

While the density distributions of the viscous and turbulent disks in equilibrium are very similar due to the necessary pressure equilibrium, there is an important difference in the meridional flow within the disk in particular for the radial velocity. We show the azimuthally averaged radial velocity \( u_r \) at \( r = r_0 \) as a function of the vertical distance for the turbulent and the standard viscous disk in Fig. 1. For the turbulent disk we averaged the velocity in time over 50 orbits and in space around \( r_0 \) in the region \( (0.8–1.25)r_0 \). For better visibility we rescaled the viscous case by a factor of 200. Obviously, the two radial velocity profiles have an opposite behavior. The standard viscous disk using a single (isotropic) value of \( \alpha \) shows the typical outflow in the midplane that has been predicted analytically by Urpin (1984) and was later shown in fully time-dependent numerical simulations (Kley & Lin 1992). This behavior of \( u_r(z) \) can be derived from the equilibrium angular moment equation that contains the vertical disk structure (Urpin 1984). In spite of the outwardly directed flow in the midplane, the total vertically integrated mass flow is nevertheless directed inward in case of accreting disks (Kley & Lin 1992).

\[
\nu_i, z = \langle \nu_i, \nu_j \rangle_{\nu_i, \nu_j},
\]

where \( \nu_i \) with \( i \) in \( r, z \) denote the radial and vertical flow velocity \( u_r \) and \( u_z \), and \( \delta \nu_i \) is the deviation of the azimuthal velocity, \( u_\phi = \nu_\phi \), from unperturbed equilibrium, as given by Eq. (3). For the latter analysis it is beneficial that the stresses are calculated in cylindrical coordinates \( r, z \), see Sect. 4. Since we are interested in particular in the vertical dependence of the stresses, \( \nu_\phi \) is calculated by averaging over the full azimuth (2\( \pi \)) over a small radial range around a reference radius, and over time. Here, we time-average from orbit 80 to orbit 200 using a series of over 60 snap shots and space-average in radius from 0.75–1.35 \( r_0 \).
The results of this averaging procedure are shown in Fig. 2. The solid curves refer to the specific stresses \( R_{i\phi}(z)/\rho(r_0,z) \) (\( i = r, z \)) in units of \( c_s^2 \), where \( \rho(r_0,z) \) is the equilibrium density distribution, given by Eq. (1), and \( c_s \) is the sound speed, both at the reference radius \( r_0 \).

We compare it to the viscous shear stress prescription (see Eq. (6) with \( \nu = \nu_r = \nu_z \)) using \( \alpha = 5 \times 10^{-3} \) (dotted lines), which is close to the average of the \( r\phi \)-component of the specific VSI stress, \( 4 \times 10^{-4} \). We rescaled the \( z\phi \)-component of the viscous shear stress by a factor of 650 to match the value from the VSI stress. From this large rescaling factor it is immediately clear that \( R_{\phi z} \) is far larger than expected from an isotropic viscous shear stress. We note that the deviation of the vertical \( R_{\phi z} / \rho \)-profile from the constant \( S_{\phi z} / \rho \)-profile is not important for our argument, which is why for simplicity we chose a constant \( \alpha \). For the angular momentum transport only the vertical average of this stress component plays a role. In our case, the very large \( z\phi \)-component of the stress dominates the meridional flow and the influence of \( R_{\phi z} \) is small.

4. Anisotropic viscosity of the VSI turbulence

From our numerical studies of the VSI turbulence, in particular the vertical component of the Reynolds stress tensor, we can infer that the turbulence is non-isotropic. Even though we have integrated the hydrodynamical equations using spherical coordinates, we calculated and display \( R_{\phi z} / \rho \) in cylindrical coordinates because this is simpler to analyze, as we explain in the following. In our approach we investigate whether the turbulent Reynolds stresses, \( R \), can be modeled by a viscous ansatz where \( R \) is replaced by the standard viscous stress tensor, \( S \), with an effective turbulent eddy viscosity as introduced by Boussinesq. In cylindrical coordinates the change in angular momentum is given by the following evolution equation:

\[
\frac{\partial \rho r^2 \Omega}{\partial t} + \nabla \cdot (\rho r^2 \Omega \mathbf{u}) = -\frac{\partial P}{\partial \phi} + \nabla \cdot (r S_\phi).
\] (5)

For an axisymmetric flow, that is, when \( \partial / \partial \phi \) vanishes, the vector \( S_\phi \) (the \( \phi \)-row of the viscous stress tensor) is given by (Tassoul 1978)

\[
S_\phi = (S_{r\phi}, S_{z\phi}) = \left( \nu_r \frac{\partial \Omega}{\partial r}, \nu_z r \frac{\partial \Omega}{\partial z} \right).
\] (6)

Axisymmetry is expected for accretion disk flows, and we found this in our simulations. In Eq. (6) we allowed for the option of an anisotropic viscosity by splitting the kinematic viscosity into two components \( \nu_r \) and \( \nu_z \), where \( \nu_r \) refers to the radial part, which typically is the main contribution in accretion disks in driving the angular momentum transport and mass accretion. The \( \nu_z \) part connects to the vertical variation of the angular velocity \( \Omega \) and has commonly been assumed to be on the same order as \( \nu_r \). Indeed, using \( \nu_z = \nu_r \) and performing viscous axisymmetric, two-dimensional simulations, we find the typical meridional flow field in disks with outflow in the midplane and inflow in upper layers of the disk, as shown in Fig. 1 by the curve labeled "isotropic stress", as found in classic studies (Urpin 1984; Kley & Lin 1992). The outflow in the midplane can easily be derived by an analysis of the radial flow that can be obtained from the angular momentum equation (see also Fromang et al. 2011; Jacquet 2013). From Eq. (5) we find for the equilibrium state that

\[
u_r \propto \frac{1}{r^2}\frac{1}{\rho} \left( \frac{1}{r} \frac{\partial}{\partial r} \rho (r^2 S_{\phi z}) + \frac{\partial}{\partial z} \frac{\partial S_{\phi z}}{\partial z} \right).
\] (7)

Expanding Eq. (3) around the midplane (small \( z \)), we find

\[
\Omega(r,z) = \Omega_K(r) \left( 1 + \frac{q z^2}{4 r^2} + \frac{q + p}{2} \frac{z^4}{r^4} \right).
\] (8)

where \( q \) and \( p \) are the exponents in the radial power laws of the density and temperature, respectively, and \( h = H/r \) denotes the relative scale height of the disk. Using this relation for \( \Omega(r,z) \), we find

\[
\frac{\partial \Omega}{\partial z} = \Omega_K \frac{q}{2} z \frac{z}{r^2}
\] (9)

and then, neglecting terms of order \( z^2/r^2 \)

\[
S_{\phi z} = q \rho \nu z \frac{\Omega_K}{2} \frac{z}{r} \quad \text{and} \quad S_{r\phi} = -\rho \nu r \frac{3}{2} \Omega_K.
\] (10)

Combining this with the \( S_{\phi z} \) relation, we find

\[
S_{\phi z} = -q \frac{3}{4} S_{r\phi} \frac{\nu z}{\nu r} \frac{z}{r}.
\] (11)

This is plotted in the lower panel in Fig. 2 using \( \nu_z = 650 \nu_r \), which demonstrates that the linear dependence of the specific \( S_{\phi z} \)-stress is a direct consequence of Eq. (11). From Eq. (7) we find for the relation determining the sign of \( u_r \) in the midplane the following relation:

\[
u_r(z = 0) \propto \left( 2 S_{r\phi} + r \frac{\partial S_{r\phi}}{\partial r} + r \frac{\partial S_{z\phi}}{\partial z} \right)

\propto \rho \left( \nu_r \left( -3 + \frac{3}{2} q + \frac{3}{2} + \frac{9}{4} + \frac{q}{2} \nu_z \right) \right).
\] (12)

where for the last step we assumed that the viscosity has an \( \alpha \)-type behavior with \( \nu \sim \alpha c_s^2 / \Omega_K \) and \( \rho \sim r^p \) and \( c_s^2 \sim r^q \). We note that the direction of flow in the disk midplane can be influenced by the slopes \( (p,q) \) in the disk stratification (Fromang et al. 2011; Philippov & Rafikov 2017). From the above relation we find directly that for our disk with slopes \( q = -1 \) and \( p = -3/2 \) that

\[
u_r(z = 0) \propto \left( \frac{3}{2} \nu_r - a_z \right).
\] (13)
For isotropic turbulence with $\alpha_r = \alpha_\theta$ we therefore have outflow in the disk midplane. For the turning point we find that $\alpha_r$ must be larger than 1.5$\alpha$. Upon increasing $\alpha_r$ over $\alpha$, the midplane radial velocity becomes more and more negative, and the entire vertical flow profile eventually reverses. In our numerical simulations of viscous disks using different values for $\nu$ we could indeed find the observed flow reversal for moderate values of $v_z/v_r$. By increasing $\nu$ further, we found that the VSI turbulence can be modeled by an anisotropic eddy viscosity with $\nu$ over two magnitudes larger than $v_r$ (650 for our chosen parameter, as shown in Fig. 2).

In performing the comparison simulations, we initially tried to use the same spherical coordinate system that we used for the turbulent VSI simulations by just increasing $v_\phi$ over $v_r$ in the corresponding components of the stress tensor in spherical coordinates. However, this did not lead to the expected results, in particular, the inversion of the parabola of $u_r(z)$. The results displayed in Fig. 1 were therefore obtained using a cylindrical coordinate system. Because the usage of a spherical coordinate system is beneficial in disk simulations, the equations need to be transformed from $r, \tau$ to $R, \theta$.

This means we need to transform the viscous part, $\nabla \cdot (\nu S_{\phi \phi})$, to spherical coordinates. The transformation equations are

$$\begin{align*}
  r &= R \sin \theta, \quad \text{and} \quad z = R \cos \theta, \quad (14) \\
  \text{and the components of the stress tensor transform according to} \\
  S_{\phi \phi} &= S_{\phi \phi} \sin \theta + S_{\phi z} \cos \theta, \quad (15) \\
  S_{\theta \phi} &= S_{\phi \phi} \cos \theta - S_{\phi z} \sin \theta. \quad (16)
  \end{align*}$$

The derivatives of $\Omega$ transform then as

$$\begin{align*}
  \frac{\partial \Omega}{\partial r} &= \sin \theta \frac{\partial \Omega}{\partial R} + \cos \theta \frac{\partial \Omega}{\partial \theta}, \quad (17) \\
  \frac{\partial \Omega}{\partial z} &= \cos \theta \frac{\partial \Omega}{\partial R} - \sin \theta \frac{\partial \Omega}{\partial \theta}. \quad (18)
  \end{align*}$$

Using Eq. (6) in Eqs. (15) and (16) and substituting this into Eqs. (17) and (18), we obtain the stress tensor components

$$\begin{align*}
  S_{\phi \phi} &= \rho R \sin \theta \left[ (v_r \sin^2 \theta + v_z \cos^2 \theta) \frac{\partial \Omega}{\partial R} + (v_r - v_z) \frac{\cos \theta \sin \theta \frac{\partial \Omega}{\partial \theta}}{R} \right], \quad (19) \\
  S_{\theta \phi} &= \rho R \sin \theta \left[ \sin \theta \cos \theta (v_r - v_z) \frac{\partial \Omega}{\partial R} + (v_r \cos^2 \theta + v_z \sin^2 \theta) \frac{1 \frac{\partial \Omega}{\partial \theta}}{R} \right]. \quad (20)
  \end{align*}$$

As can be inferred from these equations, the relatively simple anisotropic relation in cylindrical coordinates leads to complex coupled equations in spherical coordinates with cross terms in the derivatives for $\Omega$. For the isotropic case we can set $v_r = v_z = v$ and obtain the standard relations for the stress tensor components in $R\theta$-coordinates (Tassoul 1978). Now it becomes clear why merely increasing the $\theta$ part of the viscosity in $R\theta$-coordinates did not yield the correct answer when compared to the VSI case. Using the full viscosity terms as described in Eqs. (19) and (20) in the numerical simulations yields the correct behavior. However, this comes with a serious drawback because in this case the numerical integration required much smaller time steps for numerical stability than the cylindrical simulation with the same viscosity coefficients. Performing multidimensional simulations of viscous disks mimicking the non-isotropic behavior of the VSI turbulence in $R\theta$-coordinates therefore requires a considerable numerical effort. One solution to this problem may be the usage of an implicit solver for the viscous terms.

5. Conclusions

From direct three-dimensional simulations of locally isothermal accretion disks we observed that the eddies introduced by the VSI generate stresses that are strongly anisotropic. Specifically, we found that the vertical $\phi\phi$-component of the Reynolds stress is enhanced by a factor of 650 over the standard $\phi\phi$-part. By performing viscous disk simulations using a non-isotropic viscosity with $\alpha_r$ highly enlarged over $\alpha_\theta$, we could obtain the same flow reversal as seen in the VSI disk, which verifies the non-isotropy of the viscosity. Hence, the reversal of the radial flow profile compared to the usual $\alpha$-model is a clear consequence of the anisotropy. This will have an effect on the dust migration processes (Stoll & Kley 2016) that need to be contrasted to the outward drift in the midplane viscous models (Takeuchi & Lin 2002). From this we can conclude that we need to be careful with turbulence models imposed on accretion disks when we adopt viscous models to describe them.

The meridional circulation of MRI-turbulent disks has been analyzed by Fromang et al. (2011), who found a similar mean flow dynamics in the disk but did not attribute it to a non-isotropic turbulence (with large $S_{\phi \phi}$) but rather to a radial variation in the magnitude of the viscosity. However, their turbulent $R_{\theta \phi}$ profile (in Fig. 5) indicates that it may be enhanced over the standard viscous value as well, which could also be a reason for the flow reversal.

Even though the analysis is performed for simplicity for a locally isothermal disk, our results are quite general as simulations for fully radiative disks show the same behavior although they have different radial and vertical temperature profiles. For this purpose, we reanalyzed our radiative simulations in Stoll & Kley (2016) and found a similar anisotropy. Concerning numerical resolution, simulations with double resolution show the same results as shown in Fig. 1. Nevertheless, further exploration needs to be done in order to check how the anisotropy factor varies for different disk parameters and to explore the possibility of anisotropic stresses in MRI models.
