ABSTRACT

We conducted a multi-wavelength 6-month campaign to observe the Seyfert Galaxy NGC 7469, using the space-based observatories HST, *Swift*, *XMM-Newton* and *NuSTAR*. We report the results of the spectral analysis of the seven simultaneous *XMM-Newton* and *NuSTAR* observations. The source shows significant flux variability within each observation, but the average flux is less variable among the different pointings of our campaign. Our spectral analysis reveals a prominent narrow neutral Fe $K\alpha$ emission line in all the spectra and weaker contributions from Fe $K\beta$, neutral Ni $K\alpha$, and ionized iron. We find no evidence for variability or relativistic effects acting on the emission lines, which indicates that they originate from distant material. In the joint analysis of *XMM-Newton* and *NuSTAR* data, a constant photon index is found ($\Gamma = 1.78 \pm 0.02$) together with a high energy cut-off $E_{\text{cut}} = 170_{-40}^{+60}$ keV. Adopting a self-consistent Comptonization model, these values correspond to an average coronal electron temperature of $kT = 45_{-12}^{+15}$ keV and, assuming a spherical geometry, an optical depth $\tau = 2.6 \pm 0.9$. The reflection component is consistent with being constant and the reflection fraction is in the range $R = 0.3\text{--}0.6$. A prominent soft excess dominates the spectra below 4 keV. This is best fit with a second Comptonization component, arising from a warm corona with an average $kT = 0.67 \pm 0.03$ keV and a corresponding optical depth $\tau = 9.2 \pm 0.2$.

Key words. galaxies: active – galaxies: Seyfert – quasars: general – X-rays: galaxies

1. Introduction

Active galactic nuclei (AGN) are among the brightest sources in the Universe and they account for a large percentage of the X-ray photons we observe in the sky. It is commonly accepted that AGN are powered by matter accreting onto a supermassive black hole (SMBH). In the innermost region of the host galaxy, a SMBH is surrounded by a disc of spiralling matter that is responsible for its optical-UV emission, while the physical origin of the higher energetic photons still remains elusive. According to the commonly accepted scenario, X-rays are produced in a region close to the central black hole (BH), the so-called hot corona (e.g. Haardt & Maraschi 1991, 1993; Haardt et al. 1994), in which seed optical-UV photons arising from the

accreting disc interact with hot thermal electrons through an inverse Compton process. This process reproduces the power law shape we commonly observe in AGN spectra (e.g. Guainazzi et al. 1999; Bianchi et al. 2009; Marinucci et al. 2014). Moreover, a high energy cut-off is observed in different AGN spectra (e.g. Perola et al. 2002; De Rosa et al. 2002; Guainazzi et al. 2010; Brenneman et al. 2014; Marinucci et al. 2014; Lohfink et al. 2015; Ursini et al. 2016; Tortosa et al. 2017, 2018a; Porquet et al. 2018), and this is another signature of the thermal Comptonization acting in the hot corona (Haardt & Maraschi 1991, 1993). Furthermore, the primary continuum emission can be modified by a Compton reflection from the disc, from farther material or by absorption from neutral or from ionized gas.

As an additional hallmark of AGN activity there is continuum variability. Flux variations are indeed observed on several timescales, from hours and days (e.g. Ponti et al. 2012) up to years and decades (e.g. Vagnetti et al. 2011, 2016; Middei et al. 2017). Rapid variability not only is of primary importance to investigate the X-ray emission, but it can be also used to estimate the SMBH mass (e.g. McHardy et al. 2006; Ponti et al. 2012) and as a luminosity distance estimator (La Franca et al. 2014).

Long multi-wavelength monitorings of single nearby AGN produced outstanding results (e.g. Kaastra et al. 2011, and the related series of papers on Mrk 509). The target of our observational campaign is NGC 7469, which is a luminous Seyfert galaxy ($L_{\text{bol}} \sim 10^{45}$ erg s $^{-1}$; Behar et al. 2017) at $z = 0.016268$ (Springob et al. 2005). Using reverberation mapping, Peterson et al. (2014) found that NGC 7469 hosts a BH with a mass of $1.1 \pm 0.1 \times 10^7 M_{\odot}$ and an Eddington ratio of the order of 0.3. In X-ray wavelengths, this Seyfert Galaxy was first observed by the *Uhuru* satellite (Forman et al. 1978) in the seventies, and it was subsequently studied by many other observatories that found this source to have a complex X-ray emission. Since the *EXOSAT* observation, we know that its X-ray spectrum displays an excess in the soft band (Barr 1986). Other authors (Turner et al. 1991; Brandt et al. 1993; Guainazzi et al. 1994; Nandra et al. 1998, 2000; De Rosa et al. 2002) analysed this source using data obtained by *Einstein*, ROSAT, ASCA, RXTE and *BeppoSAX*.

NGC 7469 was also studied more recently: Petrucci et al. (2004) investigated the UV/X-ray variability, Scott et al. (2005) analysed its simultaneous X-ray, far-ultraviolet, and near-ultraviolet spectra using *Chandra*, *FUSE* and *STIS*, while Patrick et al. (2011) studied this source taking advantage of *Suzaku* observations. Previous *XMM-Newton* data were analysed in Blustin et al. (2003) and De Marco et al. (2009), while some results from the 2015 observational campaign have been presented in Behar et al. (2017) and Peretz et al. (2018).

This paper focuses on the seven simultaneous *XMM-Newton* and *NuSTAR* observations of our campaign, and it is organized as follows. Section 2 presents the NGC 7469 temporal analysis. Section 3 focuses on the data reduction. Sections 4 and 5 report on the spectral analysis. Section 6 contains the discussion of the results, and in Sect. 7 a summary of this work is reported.

2. Observations and data reduction

The spectral analysis presented in this work is based on *XMM-Newton* (Jansen et al. 2001) and *NuSTAR* (Harrison et al. 2013) observations of NGC 7469 belonging to the multi-wavelength campaign first described by Behar et al. (2017). The two satellites observed the source simultaneously between June 12 and December 28, 2015. The seven observations are spaced by different time intervals, allowing us to study flux and spectral variations on different timescales, see Table 1.

XMM-Newton data were obtained using the EPIC cameras (Strüder et al. 2001; Turner et al. 2001) in the Small Window operating mode and they were processed taking advantage of the *XMM-Newton* Science Analysis System¹ (SAS, Version 15.0.0). Because of its larger effective area with respect to the two MOS cameras, we only report the results for the PN instrument. We extract spectra from circular regions of 50 arcsec radius for the background, and 40 arcsec radius for the source. These regions are selected by an iterative process that maximizes the signal-to-noise ratio (S/N; Piconcelli et al. 2004). All the spectra were

rebinned in order to have at least 30 counts for each bin and not to oversample the spectral resolution by a factor greater than three.

NuSTAR data were reduced taking advantage of the standard pipeline (*nupipeline*) in the *NuSTAR* Data Analysis Software (nustardas release: *nustardas_14Apr16_v1.6.0*, part of the *heasoft* distribution²), adopting the latest calibration database. The *NuSTAR* observatory carries in its focal plane two modules, A and B, corresponding to the hard X-ray detectors FPMA and FPMB. Spectra and light curves were extracted for both modules using the standard tool *nuproducts*. A circular region with radius of ~ 70 arcsec is used to extract the source counts while the background is obtained from a blank area with the same radius, close to the source. Similar to the *XMM-Newton* spectra, we binned *NuSTAR* spectra to have an S/N greater than five in each spectral channel, and to avoid oversampling the instrumental resolution by a factor greater than 2.5. The spectra of the two modules are in good agreement with each other, the cross-normalization constant for FPMB with respect to FPMA in all the fits being unity within 1%. Spectra were analysed with *XSPEC* 12.9 (Arnaud 1996). All errors reported in the plots account for 1σ uncertainty, while errors in text and tables are quoted at 90% confidence level, unless otherwise stated.

3. Temporal analysis

We started investigating the NGC 7469 temporal properties computing the light curves for all the observations. We used the standard command *epiclccorr* for the *XMM-Newton* data to compute corrected for the background light curves in the 0.5–2 keV and 2–10 keV bands, while, we used the *nuproducts* pipeline to compute the *NuSTAR* light curves in the 10–80 keV band. The *XMM-Newton* and *NuSTAR* light curves of all the observations of our campaign are shown in Fig. 1. The source shows a remarkable intra-observation flux variability (e.g. up to $\sim 60\%$ in the sixth observation for the *XMM-Newton* in the 0.5–2 and 2–10 keV bands) and has significant flux variations on timescales of a few ks. On longer timescales, flux variability appears to be less significant. The mean counts for each of the

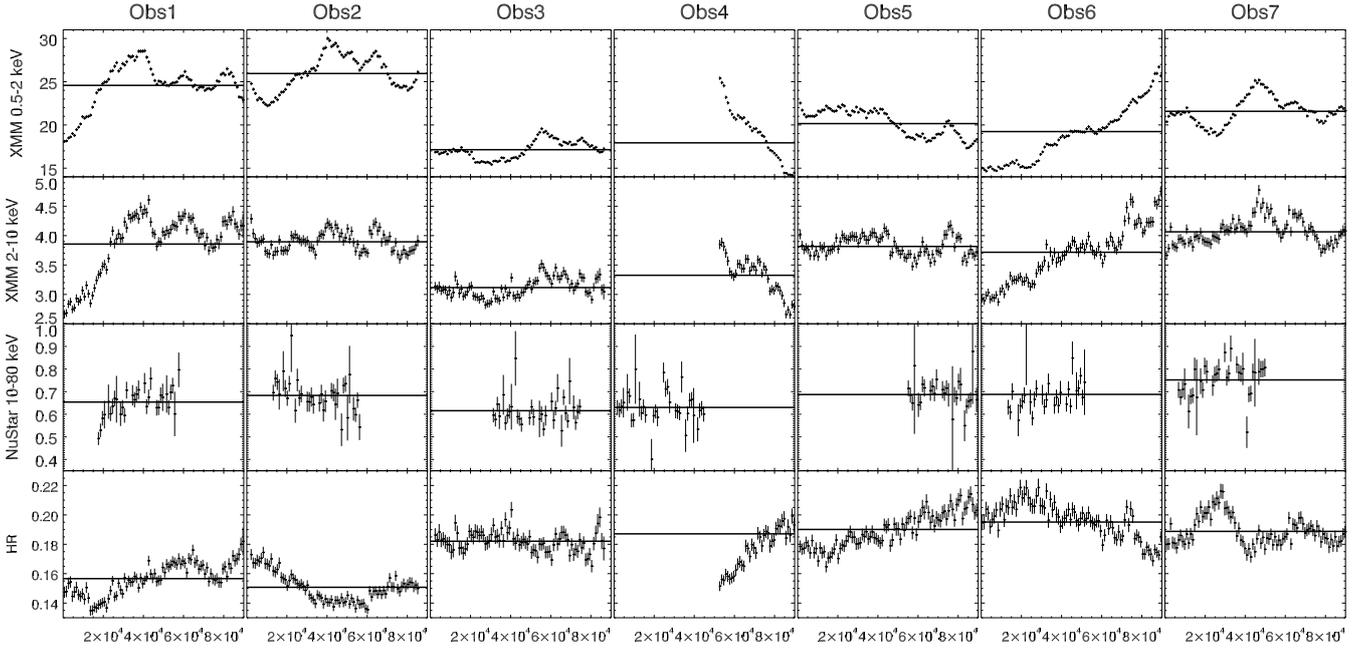

Fig. 1. Light curves corresponding to the seven simultaneous observations performed by *XMM-Newton* and *NuSTAR* for NGC 7469, in three different energy bands: 0.5–2 keV (*first row*), 2.0–10 keV (*second row*), and 10–80 keV (*third row*). The *fourth row* shows the ratio between the soft 0.5–2 keV and hard 2.0–10 keV light curves. The axis units are sec and counts for the *x*-axis and *y*-axis, respectively. The solid line overlapping all the light curves in each sub-panel represents the average of the counts for the specific light curve.

seven observations is observed to be, on average, weakly variable ($\sim 15\%$, $\sim 9\%$, and few per cent in the 0.5–2, 2–10, and 10–80 keV bands, respectively).

A convenient analysis tool for variability characterization is the so-called normalized excess variance (NXS). The NXS is defined as $\sigma_{\text{rms}}^2 = \frac{1}{N\mu^2} \sum_{i=1}^N (X_i - \mu)^2 - \sigma_i^2$, where μ is the unweighted count rate mean within the segment of the light curve, N is the number of the good time bins in that segment, and X_i represents the count rate with σ_i^2 as associated uncertainty. We computed the σ_{rms}^2 in the 2–10 keV band for all the observations of our campaign in the 20 ks time bin (see [Ponti et al. 2012](#) for more details), finding an average value $\sigma_{\text{rms}}^2 = 0.0021 \pm 0.0005$. A tight correlation between the X-ray variability of the source and its BH mass has been found by several authors (e.g. [Nandra et al. 1997](#); [Vaughan et al. 2003](#); [McHardy et al. 2006](#); [Ponti et al. 2012](#)). In particular, adopting the relation among σ_{rms}^2 and M_{BH} in [Ponti et al. \(2012\)](#), we are able to estimate the BH mass $M_{\text{BH}} = 1.1 \pm 0.1 \times 10^7 M_{\odot}$ for NGC 7469, in very good agreement with the reverberation mapping estimate by [Peterson et al. \(2014\)](#). The soft X-ray appears to be the most variable band, but hardness ratios do not display a large variation (however significant from a statistical point of view, see Sect. 6) both within and among the observations ($\sim 8\%$), see Fig. 1.

Therefore, we decided to use the average spectra of each observation in the following spectral analysis.

4. Spectral analysis: data above 4 keV

4.1. *XMM-Newton*: iron line energy band

We start our spectral analysis adopting a simple power law model for all our *XMM-Newton* data. This crude fit leaves strong residuals in the soft X-rays. This soft excess extends up to 4 keV and is shown in the top left panel of Fig. 2; this value is obtained by fitting the data above 4 keV and then plotting

the best-fit model with the whole spectrum, i.e. extending the model into the soft X-ray band. Therefore, as a first step for our analysis, we decided to characterize the limited energy band 4–10 keV. The residuals in this energy band are dominated by strong emission features, readily identified with the $K\alpha$ lines from neutral and H-like iron, and the possible presence of weaker contributions from neutral Nickel, Fe $K\beta$, and ionized iron (see Fig. 3).

We therefore adopted the following model to fit the 4–10 keV spectra: $\text{zshift} \times (\text{pexrav} + \text{zgauss} + \text{zgauss})$. The *pexrav* code ([Magdziar & Zdziarski 1995](#)) is adopted to model the primary emission and any reflected component likely associated with the fluorescent emission line from neutral iron model by the first Gaussian line, while the second Gaussian line accounts for the Fe XXVI $\text{Ly}\alpha$ at 6.966 keV. The *zshift* component is used to correct the well-known *XMM-Newton* calibration issue affecting the EPIC pn (a detailed discussion on this topic can be found in [Cappi et al. 2016](#)). Within this paper, a *zshift* correction of about -8×10^{-3} (corresponding to ~ 50 eV at 6.4 keV), will always be applied for all the *XMM-Newton* spectra. To model the data, we let free to vary among the observations the normalizations of both the Fe $K\alpha$ and the Fe XXVI $\text{Ly}\alpha$ lines, the reflection parameter and the photon index in *pexrav*, and its normalization. The iron abundance is also free to vary but tied among the different observations. This simple model leads us to a very good best fit in the 4–10 keV band ($\chi^2 = 586$ for 567 *d.o.f.*); see top right side panel of Fig. 2.

The Fe $K\alpha$ and Fe XXVI $\text{Ly}\alpha$ lines are both statistically significant (>99.9 per cent according to the F-test), and have a constant flux (3σ level) during the seven observations of our campaign with average values of 3×10^{-5} and 4×10^{-6} ph $\text{cm}^{-2} \text{s}^{-1}$, respectively, corresponding to equivalent widths of ~ 90 and ~ 20 eV (see Fig. 4 for the Fe $K\alpha$ line); however, [De Marco et al. \(2009\)](#) analysing previous *XMM-Newton* data found possible hints of variability in the Fe XXVI $\text{Ly}\alpha$ component. We found both the Fe $K\alpha$ and Fe XXVI $\text{Ly}\alpha$ lines are narrow and their intrinsic line

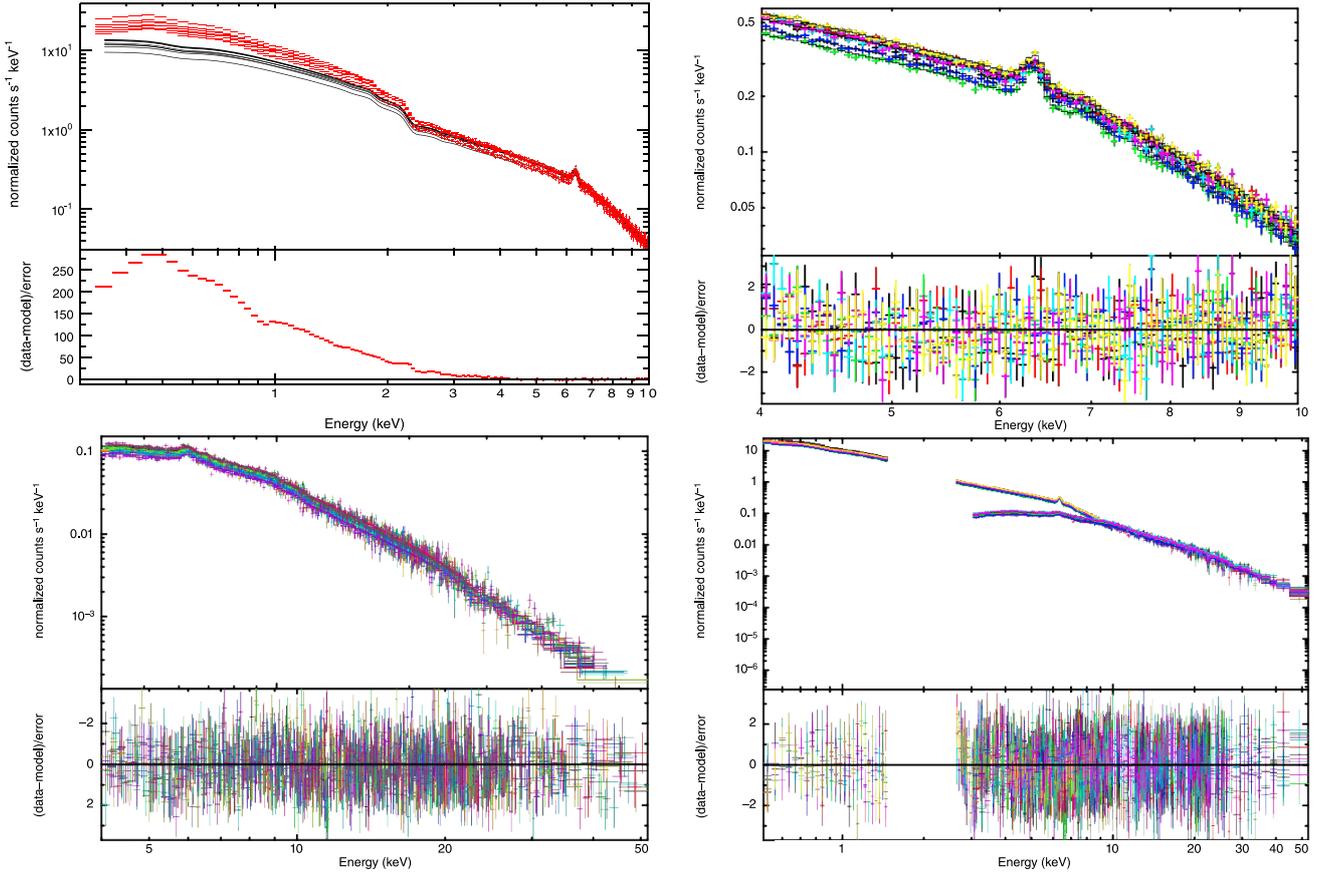

Fig. 2. *Top left panel:* seven *XMM-Newton* spectra shown in red; the best-fit model to the data above 4 keV shown in black. *Bottom panel:* the residuals of the seven spectra that are grouped using in *Xspec* the command ‘setplot group’. A secondary component clearly extends up to 4 keV. *Top right panel:* best fit to the seven *XMM-Newton* data and corresponding residuals shown with the basic model (i.e. $zshiftr(x)(pexrav+zgauss+zgauss)$), to which we added other Gaussian lines when weaker emission lines were found in the observation. *Bottom left panel:* best fit for all *NuSTAR* spectra above 4 keV is shown; *top subpanel* shows the best fit obtained adopting the model that employs *xillver* (see Sect. 4.2), while the *bottom subpanel* refers to the corresponding residuals. In the last panel, the best fit ($\chi^2 = 3041$ for 2765 d.o.f.) for the NGC 7469 *XMM-Newton* and *NuSTAR* spectra; see Sect. 5 for the model details.

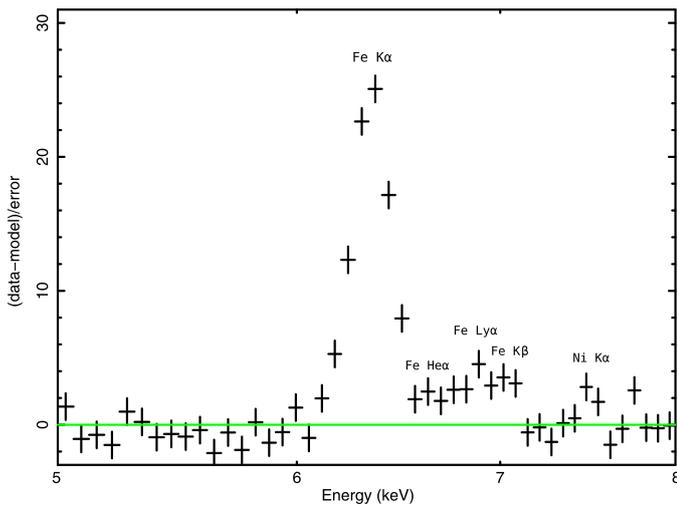

Fig. 3. Residuals (in the observer frame) to a simple power law fit to the *XMM-Newton* spectra in the energy range 5–8 keV. Emission lines are clearly present. The residuals of the seven spectra are grouped for plotting purposes.

width is consistent with zero in all the observations. In particular, the line profiles do not show any evidence for the relativistic

effects (see Fig. 3) expected to occur in the innermost regions of the accretion disc.

The residuals in Fig. 3 suggest the presence of the Fe XXV He α , Fe K β , and the Ni K α emission lines expected at 6.64–6.7, 7.06 and 7.47 keV, respectively, so we tried to fit these lines adding three further Gaussian lines to our best-fit model. However, the inclusion of these lines does not improve the χ^2 of the fit significantly. In fact, these three lines are very weak: the Fe K β flux is only an upper limit in all the spectra, the nickel line is a detection only in two observations with an average flux of $\sim 4.6 \times 10^{-6}$ ph cm $^{-2}$ s $^{-1}$, and Fe XXV He α is detected just in three observations with an average flux $\sim 4.0 \times 10^{-6}$ ph cm $^{-2}$. Indeed, none of these lines is more significant than 98 per cent, according to the F-test. The best-fit normalizations, or their upper limits, are reported in Table 2 for all the emission lines discussed in this section.

4.2. *NuSTAR*: the 4–80 keV spectra

Our preliminary analysis on the 4–10 keV *XMM-Newton* data shows a non-variable and narrow neutral iron line, likely produced by Compton-thick gas far from the central SMBH. For the *NuSTAR* data we adopted the self-consistent model *xillver* (García & Kallman 2010; García et al. 2013) to fit both the neutral iron line and the associated reflection continuum;

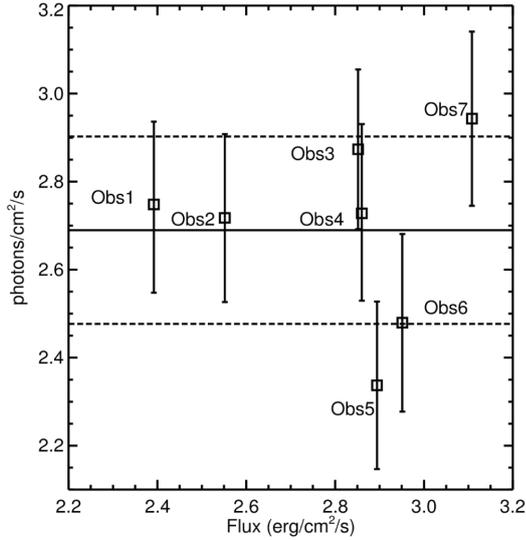

Fig. 4. Fe $K\alpha$ line flux vs. 2–10 continuum flux for the seven *XMM-Newton* observations. The average line flux is shown together with the standard deviation (dashed lines).

Table 2. Best-fit normalizations for the emission lines observed in the *XMM-Newton* observations.

Obs	Fe $K\alpha$	Fe XXVI Ly α	Fe XXV He α	Fe $K\beta$	Ni $K\alpha$
1	$28.7^{+1.8}_{-1.8}$	$4.3^{+1.6}_{-1.7}$	<3.12	<5.2	<3.3
2	$24.7^{+2.0}_{-2.0}$	$3.5^{+2.0}_{-2.0}$	<1.7	<6.3	$4.3^{+2.8}_{-3.0}$

6	$27.2^{+2.0}_{-1.9}$	$4.4^{+2.0}_{-2.0}$	<4.2	<6.9	<4.0
7	$29.4^{+2.0}_{-1.9}$	$4.7^{+2.0}_{-2.0}$	$3.9^{+2.8}_{-2.8}$	<5.5	<6.4

Notes. The normalizations are in units of 10^{-6} ph cm^{-2} .

we use *xillver* with its ionization parameter fixed to zero. A Gaussian emission line is included to model the observed emission line at 6.966 keV and a second Gaussian line is used for the Fe XXV He α lines. Strong soft excess features also appear in *NuSTAR* spectra; thus, similar to what we already performed for *XMM-Newton*, we preliminary cut *NuSTAR* spectra below 4 keV. The reflection fraction, the high energy cut-off, normalizations, and the inter-calibration constant are free to vary, while the iron abundance is free to vary but tied among the observations. Following this approach, we obtained the best fit to the data ($\chi^2 = 1762$ for 1665 d.o.f.), and this best fit is plotted in the bottom left panel of Fig. 2. The values of the best-fit parameters are reported in Table 3.

This best-fit model requires a super-solar iron abundance $A_{\text{Fe}} = 2.8 \pm 0.6$. The photon index is consistent with being constant between the observations and has average value of 1.78 ± 0.02 (see Fig. 5, top left panel, showing contour plots). A high energy cut-off is well constrained only in two observations, with values around 150 keV, and there are some indications of

Table 3. Values from the best-fit model for all the *NuSTAR* spectra analysed in the 4–78 keV band using the best-fit model *xillver+zgauss+zgauss* ($\chi^2 = 1762$ for 1665 d.o.f.).

Notes. The 10–78 keV flux is in units of 10^{-11} erg cm^{-2} s^{-1} , and the iron abundance was let free to vary but tied among the observations.

variability up to higher values in other observations (see same panel in Fig. 5). However, fitting the *NuSTAR* spectra tying the high energy cut-off among the seven observations yields a value of 170^{+60}_{-40} keV with a $\chi^2 = 1775$ for 1671 d.o.f. very similar to the previous one in which the high energy cut-off was untied. Some hints of variability are also found for the reflection fraction in the range 0.3–0.6 (see Fig. 5, top right-hand panel, showing contour plots). The flux of the reflection component is consistent with being constant when the primary continuum varies, which is in agreement with an origin from distant matter; we obtained larger reflection components for lower flux states.

Although the iron $K\alpha$ line does not present any broadening of its profile, we tested for the presence of a relativistic reflection component. Therefore, we added a further reflection component to the best-fit model, accounting for the relativistic effects arising in matter in the innermost regions of the accretion disc. We used *relxill* (e.g. García et al. 2014; Dauser et al. 2016). The photon index and the high energy cut-off are tied between *relxill* and *xillver*, while the *relxill* ionization parameter ξ and its normalization are free to vary in all the observations. No significant improvement in terms of $\chi^2/\text{d.o.f.}$ is found: $\Delta\chi^2 = 30$ for 18 d.o.f. less, corresponding to 80% confidence level according to F-test. No relativistic reflection is required by the *NuSTAR* data: indeed, in all but three of the observations, the normalization of *relxill* is consistent with zero.

According to the standard scenario, hard X-rays are produced by Comptonization, thus as a further investigation, we decided to model the *NuSTAR* spectra using a self-consistent Comptonization model. In our model we substitute *xillver* with *xillvercp* (García et al. 2014; Dauser et al. 2016). This different code accounts for the primary emission produced by *nthcomp* (Zdziarski et al. 1996) and a non-relativistic reflection. The parameters of this new model are treated as in the previous fit and the hot corona electron temperature is free to vary. The best fit obtained ($\chi^2 = 1768$ for 1658 d.o.f.) adopting *xillvercp* shows larger values for the photon index with respect to the previous best-fit model with *xillver* (on average 0.08). On the other hand, the parameters of the reflection

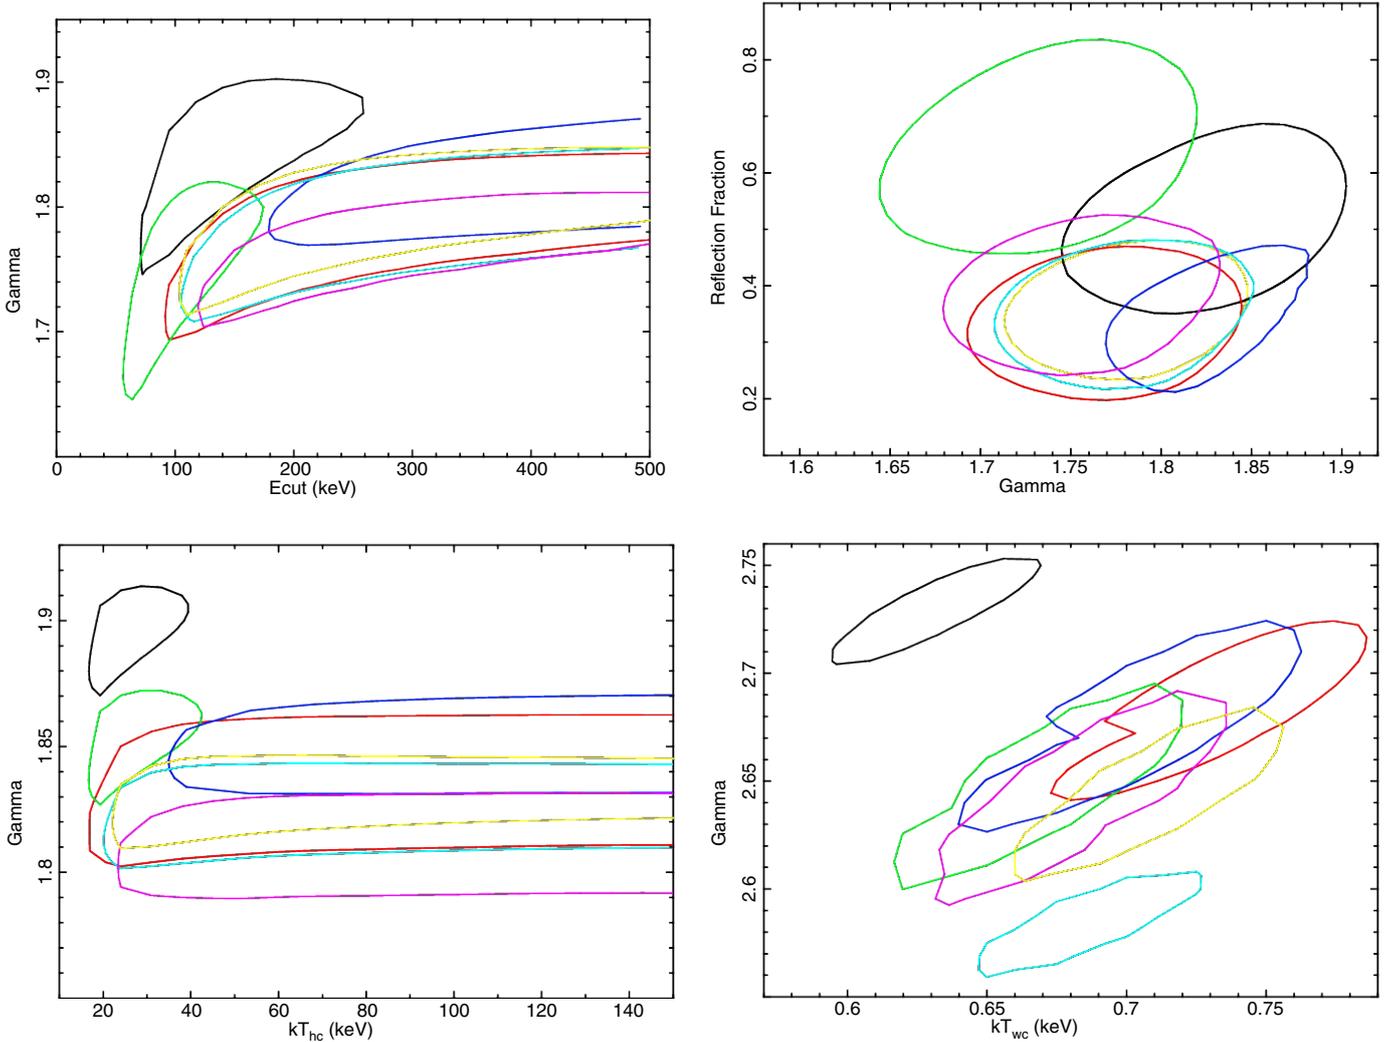

Fig. 5. Contours for the high energy cut-off and photon index for all the *NuSTAR* observations in the *top left panel*. These contours account for the data analysed with *xillver* and above 4 keV. The best-fit parameters are shown in Table 3. *Top right plot*: best-fit values for the reflection fraction as a function of the photon index for the various observations. The contours are computed on the *NuSTAR* data above 4 keV adopting the model with *xillver*. *Bottom left panel*: contour plots for the photon index and hot electron temperature computed on the *NuSTAR* data above 4 keV with *xillvercp*. *Last panel*: contour plots for the warm corona parameters for all the observations of our campaign.

component are in agreement with the values previously quoted. The best-fit values for the parameters of this fit are shown in Table 4.

In the bottom left panel of Fig. 5, the contour plots for the photon index and hot electron temperature are reported. Weak variations in the photon index are observed, while the electron temperature has a more constant behaviour. To test the variability of the hot electron temperature, similar to what we already performed for the high energy cut-off, we fit the *NuSTAR* spectra tying the electron temperature among the observations of this campaign. This yielded a measure of $kT = 45^{+15}_{-12}$ keV corresponding to a best fit ($\chi^2 = 1773$ for 1664 d.o.f.) very similar to the previous value.

5. Spectral analysis: 0.5–80 keV band

As shown in Sect. 4.1 (see also Fig. 2, top left hand panel) the data below 4 keV are characterized by a strong soft excess. In order to properly model the continuum emission associated with this excess, we first characterize any discrete emitting and

absorbing feature expected in the 0.5–4 keV band. On one side, these are features that can be directly attributed to the detector systematic calibration uncertainties, i.e. issues on its quantum efficiency at the Si K-edge (1.84 keV), and on the mirrors effective area at the Au M-edge (~ 2.4 keV). To avoid these issues, we ignored the spectral bins in the energy range 1.7–2.6 keV (see e.g. [Kaastra et al. 2011](#); [Di Gesu et al. 2015](#); [Ursini et al. 2015](#); [Cappi et al. 2016](#)). We then included all the emission and absorption features (e.g. due to the warm absorbers) derived from the analysis of the *XMM-Newton* *RGS* spectra of our campaign by [Behar et al. \(2017\)](#). Since none of these components displayed significant variability during our campaign ([Behar et al. 2017](#); [Peretz et al. 2018](#)), we kept all their parameters fixed in our following fits to the values found from the *RGS* data (see [Behar et al. 2017](#), for a detailed description of all the components). Some line-like features still remained in the pn spectra, and even if very weak, they result significant in terms of χ^2 , as a consequence of the high number of counts in the soft band. Two narrow Gaussian lines untied and free to vary among the observations at ~ 0.75 keV and ~ 1 keV are enough to correct

Table 4. Values and errors for the best-fit parameters of all the *NuSTAR* spectra analysed in the 4–78 keV band adopting *xillvercp*.

Notes. Optical depth estimates are obtained following Beloborodov (1999), see Sect. 5 for details. The iron abundance is free to vary but tied among the observations.

these residual narrow features (see also e.g. Kaastra et al. 2011; Di Gesu et al. 2015; Ursini et al. 2015; Cappi et al. 2016).

At first, we model the soft X-ray emission with a phenomenological continuum model, such as a power law or a black body. However, in both cases we do not get an acceptable fit, obtaining $\chi^2 = 3542$ for 2793 d.o.f. and $\chi^2 = 7430$ for 2793 d.o.f., respectively. We then tried to reproduce the soft excess via two self-consistent models: blurred relativistic reflection arising from the innermost regions of the accretion disc, and Comptonization from a warm corona.

There are a number of reasons (e.g. high BH spin and high ionization parameters) that could lead to a weak broad iron line, but still a prominent relativistic reflection continuum, particularly in the soft X-rays. Indeed, Walton et al. (2013), analysing *Suzaku* data, found a good fit modelling the NGC 7469 soft excess using a relativistic reflection model. Thus, even if our previous analysis failed to find significant signatures from relativistic effects in the hard X-ray band (and, notably, in the iron line profile), we tested for a relativistic origin for the soft excess in this source.

To perform this test, we again added *relxill* to the model, similar to what previously had been carried out in the *NuSTAR* data alone, leaving the ionization parameter, coronal emissivity, BH spin, and the normalization free to vary among the observations, while the photon index and high energy cut-off are linked to those in *xillver*. We get parameters ($\xi = 2.4 \pm 0.2$, $i = 45^\circ$, emissivity = 4.8 ± 0.3 , $a > 0.996$) consistent with those found by Walton et al. (2013), but our fit is not statistically acceptable ($\chi^2 = 6036$ for 2788 d.o.f.). This discrepancy is likely due to the much higher S/N of our data (especially in the soft X-rays) with respect to that used by Walton et al. (2013).

We finally tried *nthcomp* (Zdziarski et al. 1996; Życki et al. 1999), accounting for a Comptonized continuum from a warm corona, as discussed by Petrucci et al. (2013), Róžańska et al. (2015), and Petrucci et al. (2018). For this model we untie and let free to vary the electron temperature and seed photons temperature among the observations. For each observation, all the parameters among *XMM-Newton* and *NuSTAR* are tied during the fit, however we need to allow for different values

Table 5. Best-fit parameters for the soft excess, where kT_{wc} is the electron temperature of the warm corona.

Obs.	Γ_{soft}	kT_{wc} [keV]	τ_{wc}	Norm _{nthcomp} (10^{-3})
1	$2.73^{+0.02}_{-0.02}$	$0.63^{+0.04}_{-0.03}$	$8.8^{+0.5}_{-0.5}$	$5.77^{+0.01}_{-0.01}$
2	$2.66^{+0.02}_{-0.02}$	$0.71^{+0.04}_{-0.03}$	$8.7^{+0.7}_{-0.6}$	$5.42^{+0.01}_{-0.01}$
3	$2.62^{+0.02}_{-0.02}$	$0.65^{+0.04}_{-0.03}$	$9.4^{+0.8}_{-0.6}$	$4.24^{+0.01}_{-0.01}$
4	$2.65^{+0.02}_{-0.02}$	$0.68^{+0.03}_{-0.03}$	$9.0^{+0.5}_{-0.4}$	$4.10^{+0.01}_{-0.01}$
5	$2.58^{+0.02}_{-0.02}$	$0.68^{+0.03}_{-0.05}$	$9.6^{+0.3}_{-0.7}$	$5.11^{+0.01}_{-0.01}$
6	$2.61^{+0.02}_{-0.02}$	$0.65^{+0.04}_{-0.03}$	$9.5^{+0.6}_{-0.6}$	$4.56^{+0.01}_{-0.01}$
7	$2.62^{+0.02}_{-0.02}$	$0.69^{+0.03}_{-0.03}$	$9.2^{+0.6}_{-0.6}$	$5.15^{+0.01}_{-0.01}$

Notes. The obtained seed photons temperature is ~ 3 eV with no signature of any variability among the observations. The best-fit parameters for the hard X-ray model components are consistent, within the errors, with those obtained in the 4–78 keV band, and are not reported here for the sake of simplicity.

of photon index between *XMM-Newton* and *NuSTAR* in every observation. *XMM-Newton* slopes are harder than the *NuSTAR* derived slopes and this discrepancy, likely due to residual inter-calibration issues, is, on average, of the order of $\Delta\Gamma \sim 0.17$ (see e.g. Cappi et al. 2016, and Appendix A for more details). In this paper, we report values of the photon index derived from *NuSTAR* data.

Following this procedure, we obtained a very good fit to the whole dataset, with $\chi^2 = 3041$ for 2765 d.o.f. (see Fig. 2, bottom right-hand side panel). The parameters of the hard X-ray components are fully compatible with those obtained from the fit of the data above 4 keV (Sect. 4.2 and Table 2). We report the best fit values for the parameters describing the soft excess in Table 5. Most of the observed variability can be attributed to the *nthcomp* normalization that varies among all the observations. On the other hand, the electron temperature is found consistent with being constant, while for the photon index marginal variations are observed; see bottom right-hand side panel of Fig. 5. The measured warm corona temperature (kT_{wc}) is found to be, on average, 0.67 ± 0.03 KeV.

The obtained electron temperature can be used to estimate the optical depth τ for the warm corona. Following Beloborodov (1999), and using his Eq. 13 and the average values for the kT_{wc} and Γ reported in Table 5, we estimate the NGC 7469 warm corona τ_{wc} to be 9.2 ± 0.2 .

6. Discussion

6.1. Two-corona scenario

The broad-band X-ray spectrum of NGC 7469 shows the presence of two main components, the primary power law at high energies and a strong soft excess which starts dominating below ~ 4 keV. This is commonly found in Seyfert galaxies (e.g. Piconcelli et al. 2005; Bianchi et al. 2009; Scott et al. 2012).

The high energy X-ray spectrum can be phenomenologically characterized by a cut-off power law with average spectral index $\Gamma = 1.78 \pm 0.02$ and high energy cut-off $E_{\text{cut}} = 170^{+60}_{-40}$ keV.

These parameters are consistent with being constant among all the observations, with only some marginal evidence of variability of the cut-off energy. The latter value is compatible within the errors with measures based on *Suzaku* data ($E_{\text{cut}} = 119^{+65}_{-31}$ keV; Patrick et al. 2011) and *BeppoSAX* ($E_{\text{cut}} \sim 150$ keV; De Rosa et al. 2002). On the other hand, the rapid Γ variability reported by Nandra et al. (2000) could be due to the contamination from the soft excess, which could not be properly modelled in RXTE data. Indeed, it is clear from our monitoring that the soft X-ray energy part of the spectrum varies more than the high energy part, generating variations of the hardness ratio, which could mimic a photon index variability if the two spectral components are not properly modelled separately (see e.g. Figs. 1 and 2, top left panel). However, the rapid Γ variability reported by Nandra et al. (2000) could also be due to a different state of NGC 7469 at the epoch of the IUE/RXTE campaign. In fact, a comparison between our data and those studied by the authors reveals that the source was in a more variable state compared to 2015.

The cut-off power law that reproduces the high energy spectrum of NGC 7469 can be naturally ascribed to Comptonization of the accretion disc photons onto a corona of hot electrons. Adopting a self-consistent Comptonization model, we recovered an average electron temperature of $kT_{\text{hc}} = 45^{+15}_{-12}$ keV and, under the assumption of a spherical geometry, an optical depth $\tau_{\text{hc}} = 2.6 \pm 0.9$. These values are within ranges generally found in other Seyfert galaxies (e.g. Petrucci et al. 2013, 2018; Tortosa et al. 2018b) and are consistent with being constant among the observations of our monitoring campaign, which is in agreement with what found with phenomenological models. Interestingly, the coronal parameters measured in NGC 7469 lie along the $kT_e - \tau$ anti-correlation found by Tortosa et al. (2018b) in a sample of Seyfert galaxies observed by *NuSTAR*. As discussed in their paper, this anti-correlation is suggestive of variations in the heating-cooling ratio of the corona, as a result of different disc-corona geometries and/or intrinsic disc emission. The soft excess cannot be satisfactorily modelled by simple phenomenological models, such as a steep power law or a black body, as often found in large samples of objects and/or low S/N spectra (Bianchi et al. 2009; Matt et al. 2014; Ursini et al. 2015). Moreover, a self-consistent model in terms of blurred relativistic reflection is also statistically unacceptable for reproducing this soft excess.

An additional Comptonized spectral component provides a good representation of the soft excess in this source. Assuming the same seed photons as for the hot corona (i.e. those arising from the accretion disc), the temperature of the electron cloud responsible for the Comptonization of the spectrum is on average $kT_{\text{wc}} = 0.67 \pm 0.03$ keV and the optical depth $\tau_{\text{wc}} = 9.2 \pm 0.2$, again with marginal evidence for variability among the observations of our campaign. These values are well in agreement with those found in a sample of Seyfert galaxies, within the framework of the so-called two-corona model (e.g. Petrucci et al. 2013, 2018; Mehdipour et al. 2015; Róžańska et al. 2015). According to this model, the soft X-ray emission is produced by Comptonization of the disc photons by a warm optically thick and extended medium (the warm corona), which is different from the compact, optically thin, and hot medium (the hot corona) that is responsible for the high energy emission. The ranges of the coronal values found for the warm corona in Seyfert galaxies (including NGC 7469) are consistent with the warm corona covering a large percentage of a quasi-passive accretion disc, whose intrinsic emission is negligible because most of the accretion power is released in the warm corona itself

(Petrucci et al. 2018). It is important to note that this two-corona scenario for NGC 7469 is also consistent with the observed optical-UV emission of this object by HST and *Swift* UVOT, as quantitatively shown by Mehdipour et al. (2018).

6.2. Reprocessed components

Along with the main continuum components discussed in the previous section, all the *XMM-Newton* and *NuSTAR* spectra of our campaign on NGC 7469 are characterized by the presence of a prominent emission line that was readily identified as a neutral Fe $K\alpha$ fluorescent line. We find that this line is unresolved, has no evidence of any broadening and a flux compatible with being constant among all the observations, and with the past *XMM-Newton* observation in 2000 (Blustin et al. 2003). As expected if originating in Compton-thick matter, the iron line is associated with a reflection component whose flux is also consistent with being constant among the observations of our campaign. Consequently, its reflection fraction with respect to the primary continuum is slightly variable (R being in the range 0.3–0.6), and higher values are measured when the primary flux is lower. Self-consistent reflection models agree with a scenario in which both the iron line and reflection component arise from Compton-thick matter far from the accretion disc, as commonly found in the X-ray spectra of Seyfert galaxies (e.g. Bianchi et al. 2009; Cappi et al. 2016; Tortosa et al. 2017).

As already noted, we find no evidence for relativistic effects in the iron line profile of NGC 7469. However, it has to be compared with the rich literature for this source. Guainazzi et al. (1994) found the Fe $K\alpha$ line to be narrow in a 40 ks ASCA spectrum. In particular, the authors estimated the line-emitting region to be at several tens of Schwarzschild radii from the central engine of the galaxy. This result was confirmed by Nandra et al. (1997) with the same dataset. Subsequently, Blustin et al. (2003) working on *XMM-Newton* data observed the Fe $K\alpha$ line to be narrow, and they modelled it with a single narrow Gaussian line. On the other hand, the analysis of *BeppoSAX* data by De Rosa et al. (2002), pointed to a relativistically broadened component of the line, together with an unresolved core. The presence of a relativistic component was confirmed, albeit marginally, by *Suzaku* (Patrick et al. 2011; Mantovani et al. 2016).

Although we cannot exclude the presence of a broad component of the iron line in past observations, we may speculate that the narrow core we observe in *XMM-Newton* data may be contaminated by other emission lines in spectra with lower spectral resolution and/or S/N. Indeed, other emission features are clearly present in the *XMM-Newton* spectra, as shown in Fig. 3: a strong Fe XXVI Ly α emission line, which was significantly detected in all the observations of our campaign, and weaker emission lines such as Fe XXV He α , neutral Fe $K\beta$ and Ni $K\alpha$, which were not always significant. While the latter two emission lines are expected to accompany the neutral Fe $K\alpha$ emission, and therefore share the same origin, the other lines must arise in a much more ionized plasma. Such lines are often observed both in Seyfert 1s and in Seyfert 2s and are likely produced in a Compton-thin, photoionized material illuminated by the nuclear continuum (e.g. Bianchi & Matt 2002; Bianchi et al. 2005; Costantini et al. 2010).

7. Conclusions

In this paper we reported the spectral analysis of seven simultaneous *NuSTAR* and *XMM-Newton* observations of the Seyfert Galaxy NGC 7469 performed from June 2015 to December 2015

in the context of a multi-wavelength campaign. In the following, we summarize the results of our analysis:

- NGC 7469 displayed a significant flux variability during this observational campaign with intra-observation variability at a timescales of few ks. We quantified this variability using the normalized excess variance estimator (e.g. [Ponti et al. 2012](#)) $\sigma_{\text{rms}}^2 = 0.0021 \pm 0.0005$; this also allowed us to estimate the BH mass to be $M_{\text{BH}} = 1.1 \pm 0.1 \times 10^7 M_{\odot}$, which is in agreement with the measure based on reverberation mapping ([Peterson et al. 2014](#)).
- The high energy spectrum can be phenomenologically characterized by a cut-off power law with average spectral index $\Gamma = 1.78 \pm 0.02$ and high energy cut-off $E_{\text{cut}} = 170_{-40}^{+60}$ keV. These parameters are consistent with being constant among all the observations, with only some marginal evidence of variability of the cut-off energy. Using a realistic Comptonization model, the derived coronal parameters are $kT_{\text{hc}} = 45_{-12}^{+15}$ keV and $\tau_{\text{hc}} = 2.6 \pm 0.9$ for a spherical geometry.
- A strong soft excess is observed in all the observations, extending up to 4 keV. The best description for this component is through another Comptonized spectrum that is produced by a warm corona with $kT_{\text{wc}} = 0.67 \pm 0.03$ keV and $\tau_{\text{wc}} = 9.2 \pm 0.2$, again with only marginal evidence for variability among the observations of our campaign. Indeed, most of the observed variability of the soft X-ray data may be simply ascribed to variations of the normalization of this component. The overall scenario is consistent with the so-called two-corona model (e.g. [Petrucci et al. 2013, 2018](#); [Rózańska et al. 2015](#)), where most of the accretion power is released in a warm optically thick and extended medium instead of the accretion disc.
- A neutral Fe $K\alpha$ emission line is present in all the observations. The line is found to be narrow, with no indications for relativistic broadening, and consistent with being constant. An accompanying Compton reflection component is also found to be constant among the observations, which is in agreement with a scenario in which both components arise from Compton-thick matter located far away from the central BH. Weak neutral Fe $K\beta$ and Ni $K\alpha$ emission lines, which were only detected in some observations, have the same origin.
- A Fe XXVI Ly α emission line is significantly detected in all the observations of this campaign, and is likely to arise in a photoionized material illuminated by the central continuum, together with a weaker Fe XXV He α emission line.

Appendix A: Γ discrepancy between *XMM-Newton* and *NuSTAR*

We reported in our analysis that our simultaneous *XMM-Newton* and *NuSTAR* data yielded photon indexes differing on average of ~ 0.17 . In this appendix, we report our investigations concerning a plausible origin for this issue.

- *Different energy band*: the energetic range of *NuSTAR* is different with respect to that of *XMM-Newton*, thus we performed a simple analysis on the same observational band for both the satellites. For the whole sample of observations, we try to fit the spectra with a simple power law model in

the common energy band 4–10 keV. The measurements for the photon indexes we obtained were still discrepant of the same amount.

- *Pile-up*: our *XMM-Newton* spectra could, at least marginally, suffer from pile-up. According to the *XMM-Newton* hand guide³, pile-up can affect pn observations performed in Small Window mode, when a total count rate of ~ 25 c/s is exceeded. Therefore, at least the first and second *XMM-Newton* observations could suffer from pile-up problems.
- We thus tried to extract the spectra from source annular regions, using different values for the annulus inner radius (from 50 up to 200 pixels). However, our tests show that any choice of the inner annular radius improves the $\Delta\Gamma$ discrepancy between the *XMM-Newton* and *NuSTAR* spectra.
- *Intrinsic variability*: *XMM-Newton* observations are longer with respect to those performed by *NuSTAR*, thus the difference in the two Γ could be due to the not truly simultaneity of the observations. To verify this hypothesis we extracted *XMM-Newton* spectra exactly in the same temporal range of those obtained using *NuSTAR*⁴. As in the previous cases, analysing these truly simultaneous spectra does not affect the $\Delta\Gamma$ discrepancy.

We therefore conclude that the most likely origin for the spectral index discrepancy has to be found in residual inter-calibration issues between *XMM-Newton* and *NuSTAR*⁵, whose significance may vary from observation to observation, and whose impact on the analysis is larger for high S/N data. We estimate that the results in this paper are not qualitatively affected by this issue, but a systematic uncertainty in the reported best-fit parameters should be taken into account.

⁴ For the fourth observation, the two satellites do not observe NGC 7469 simultaneously so that we cannot perform this test on it.

⁵ A new SAS version was released when we were finalizing this paper (SAS version 16.1). We performed several tests to check if this could affect our results, but found that the reported $\Delta\Gamma$ between *XMM-Newton* and *NuSTAR* is not significantly improved.
