ABSTRACT

Context. The abundance of deuterated molecules in a star-forming region is sensitive to the environment in which they are formed. Deuteration fractions, in other words the ratio of a species containing D to its hydrogenated counterpart, therefore provide a powerful tool for studying the physical and chemical evolution of a star-forming system. While local low-mass star-forming regions show very high deuteration ratios, much lower fractions are observed towards Orion and the Galactic centre. Astration of deuterium has been suggested as a possible cause for low deuteration in the Galactic centre.

Aims. We derive methanol deuteration fractions at a number of locations towards the high-mass star-forming region NGC 6334I, located at a mean distance of 1.3 kpc, and discuss how these can shed light on the conditions prevailing during its formation.

Methods. We use high sensitivity, high spatial and spectral resolution observations obtained with the Atacama Large Millimeter/submillimeter Array to study transitions of the less abundant, optically thin, methanol-isotopologues: $^{13}\text{CH}_3\text{OH}$, $\text{CH}_3^{18}\text{OH}$, CH_2DOH and CH_3OD , detected towards NGC 6334I. Assuming local thermodynamic equilibrium (LTE) and excitation temperatures of $\sim 120\text{--}330$ K, we derive column densities for each of the species and use these to infer $\text{CH}_2\text{DOH}/\text{CH}_3\text{OH}$ and $\text{CH}_3\text{OD}/\text{CH}_3\text{OH}$ fractions.

Results. We derive column densities in a range of $(0.8\text{--}8.3) \times 10^{17} \text{ cm}^{-2}$ for $^{13}\text{CH}_3\text{OH}$, $(0.13\text{--}3.4) \times 10^{17} \text{ cm}^{-2}$ for $\text{CH}_3^{18}\text{OH}$, $(0.03\text{--}1.63) \times 10^{17} \text{ cm}^{-2}$ for CH_2DOH and $(0.15\text{--}5.5) \times 10^{17} \text{ cm}^{-2}$ for CH_3OD in a $\sim 1''$ beam. Interestingly, the column densities of CH_3OD are consistently higher than those of CH_2DOH throughout the region by factors of 2–15. We calculate the CH_2DOH to CH_3OH and CH_3OD to CH_3OH ratios for each of the sampled locations in NGC 6334I. These values range from 0.03% to 0.34% for CH_2DOH and from 0.27% to 1.07% for CH_3OD if we use the ^{13}C isotope of methanol as a standard; using the ^{18}O -methanol as a standard, decreases the ratios by factors of between two and three.

Conclusions. All regions studied in this work show $\text{CH}_2\text{DOH}/\text{CH}_3\text{OH}$ as well as $\text{CH}_2\text{DOH}/\text{CH}_3\text{OD}$ values that are considerably lower than those derived towards low-mass star-forming regions and slightly lower than those derived for the high-mass star-forming regions in Orion and the Galactic centre. The low ratios indicate a grain surface temperature during formation ~ 30 K, for which the efficiency of the formation of deuterated species is significantly reduced. Therefore, astration of deuterium in the Galactic centre cannot be the explanation for its low deuteration ratio but rather the high temperatures characterising the region.

Key words. astrochemistry – methods: observational – stars: protostars – ISM: individual objects: NGC 6334I – submillimeter: ISM

1. Introduction

The abundance of deuterium (D) formed in the Big Bang sets the primordial D/H in the universe. As stars form and start processing D in their interiors, the deuterium abundance should drop if no other source of D exists. The best estimate of the cosmic D/H is therefore obtained by observing environments with little star formation and chemical processing such as the diffuse interstellar medium (ISM) for which D/H is $\sim (1.5\text{--}2.0) \times 10^{-5}$ (Linsky 2006; Prodanović et al. 2010). On the other hand, environments with high star-formation rates would be expected to show lower D/H fractionation ratios as a consequence of astration, that is the processing of D in stellar interiors, and

a generally higher temperature. This however, contradicts observations of molecules in both high and low-mass star-forming regions that not only show D/H values which are orders of magnitude higher than that of the ISM, but also display multiply deuterated species. An example of a source exhibiting such high deuterium fractionation is the well-studied low-mass protostellar binary IRAS 16293–2422 (hereafter IRAS 16293; van Dishoeck et al. 1995; Ceccarelli et al. 1998). This source is especially interesting because it was the first source towards which both doubly as well as triply-deuterated methanol was detected (Parise et al. 2002, 2004). More recently, IRAS 16293 has been studied by Jørgensen et al. (2017) who have characterised the isotope composition of a number of complex organic

molecules. They derived D/H values, that is the column density ratio of isotopologues with respect to their hydrogenated counterparts including the statistical correction for the location of the substituted deuterium, for all detected species in the range 2–8%. Specifically, the D to H ratio of methanol (CH_3OH) is found to be $\sim 2\%$. In addition, the detection of singly and doubly-deuterated formaldehyde (H_2CO) and methanol towards seven other low-mass protostars, with deuteration fractions similar to those observed towards IRAS 16293, is reported by [Parise et al. \(2006\)](#). For high-mass star-forming regions the most thorough studies of deuterated species have been carried out towards the hot cores located in the Galactic centre and the Orion Complex. For Sagittarius B2 (Sgr B2), [Belloche et al. \(2016\)](#) report D/H values of 0.38% for acetonitrile (CH_3CN) and (0.05–0.12)% for the tentative detections of $\text{CH}_3\text{CH}_2\text{CN}$, HC_3N and CH_3OH . Approximately the same low levels of deuteration were found by [Neill et al. \(2013\)](#), who studied ammonia (NH_3), formaldehyde and methanol towards Orion KL and find D/H $\sim (0.2\text{--}0.8)\%$ towards the compact ridge and hot core regions. Similar levels of deuterium in methanol are found by [Peng et al. \(2012\)](#).

While these observations clearly illustrate that deuterated species, including CH_3OH , are enhanced in star-forming regions, the explanation of how the various ratios came to be remains incomplete. For the low-mass objects, the high deuteration ratios can, for the most part, be explained by gas-grain astrochemical models where high densities and low dust temperatures allow simple deuterated species to build up rapidly in precursor dark cores ([Taquet et al. 2012](#)). In the case of Sgr B2 however, the low deuteration fractions are attributed to the combined effects of astration and a less efficient deuteration process at the high temperatures characterising the Galactic centre. In order to quantify which of these processes influence the deuteration fractionation more, observations of other high-mass star-forming regions, located away from the Galactic centre, are essential.

Deuterium fractionation of simple interstellar molecular species was first studied in detail by [Watson \(1976\)](#) who argued that the large D/H values, especially present in DCN and DCO^+ , can be understood as a result of ion-molecule exchange reactions in the gas and the difference in zero-point vibrational energies of the hydrogen versus deuterium-containing molecules. The observed deuterated species are then the end product of a chain of reactions starting with the formation of H_2D^+ from H_3^+ and HD, reacting with neutral molecules to form deuterated ions and subsequently recombining with electrons. This recombination also results in enhanced atomic D/H in the gas at low temperatures, which increases even more when CO, the main destroyer of H_3^+ and H_2D^+ , is frozen out on grains ([Roberts et al. 2003](#)). As pointed out by [Tielens \(1983\)](#), this enhanced atomic D/H in the gas can be transferred to those molecules that are primarily formed by hydrogenation on grain surfaces. Key examples are H_2CO and CH_3OH , which both result from the hydrogenation of CO. Thus, the abundances of these deuterated molecules are good tracers of the physical conditions in the gas.

The process of deuteration at low temperatures has also been studied in the laboratory. In particular, [Nagaoka et al. \(2005\)](#) have shown that grain-surface H-D abstraction-addition reactions in solid methanol can account for the methanol D/H values derived from observations. They also note that if the gaseous atomic D/H is higher than 0.1, deuterated methanol may be formed directly through successive hydrogenation or deuteration of CO.

The focus of this work is on methanol, especially its isotopologues $^{13}\text{CH}_3\text{OH}$, $\text{CH}_3^{18}\text{OH}$ and the two single deuterated species CH_2DOH and CH_3OD . As described above, methanol is formed primarily on the surface of dust grains ([Watanabe & Kouchi 2002](#);

[Geppert et al. 2005](#); [Fuchs et al. 2009](#)) and therefore presents a good tracer of the chemistry of interstellar ice. In addition, if formed in environments with high gaseous atomic D/H, methanol will be deuterated. Deuteration levels can therefore be considered a fossil record of the chemical composition not only of the ice, but also of the gas, characterising the region in which it was formed, with the highest ratios associated with the lowest temperatures. However, in order to deduce accurate deuteration ratios, it is critical that the transitions used to derive column densities are optically thin. If this is not the case, deuterium fractions are likely to be overestimated since the lines of the more abundant hydrogenated species are generally optically thick, resulting in underestimated values. To ensure transitions are optically thin, one generally needs to target lines that are weak, that is to say have low Einstein A_{ij} values. Observations of such weak lines have however presented a challenge since line surveys have, for the most part, been conducted using single dish telescopes which are, by and large, less sensitive when compared with interferometric observations. These observations have therefore mostly targeted the brightest lines which may in many cases be optically thick and therefore result in deuteration ratios which are higher than is actually the case. With the unique sensitivity and resolving power offered by the Atacama Large Millimeter/submillimeter Array (ALMA), this is changing. With ALMA it has become possible to probe molecular transitions that are both weaker and are emitted from objects less bright than ever before. Consequently, the field of molecular line surveys and analysis has entered a new epoch where column density determinations no longer, or to a much lesser extent, suffer from misinterpretation due to the increased access to transitions in the optically thin regime.

In this work we focus on NGC 6334I, a region of active high-mass star-formation in the giant molecular cloud complex NGC 6334, also referred to as the Cat's Paw Nebula. The complex is located in the Scorpius constellation in the southern hemisphere. The region constitutes six main dense cores, identified as discrete continuum sources in the far-infrared, labelled with Roman numerals I–VI ([McBreen et al. 1979](#)). Later, an additional, very low temperature source, NGC 6334I(N) was identified $\sim 2'$ north of NGC 6334I ([Gezari 1982](#)). The distance to the NGC 6334 site has commonly been cited as (1.7 ± 0.3) kpc ([Russeil et al. 2012](#)) but recent work on H_2O and CH_3OH masers associated with the star-forming complex, carried out by [Reid et al. \(2014\)](#) and [Chibueze et al. \(2014\)](#), place the region closer, at distances of 1.34 and 1.26 kpc respectively. Here we will assume a mean distance of 1.3 kpc, corresponding to a galactocentric distance, d_{GC} , of ~ 7.02 kpc. With a synthesised beam of the observations of $1''.00 \times 0''.74$, this allows us to probe NGC 6334I at scales of ~ 1300 AU. NGC 6334I is complex both in structure and composition and very rich in molecular lines ([McCutcheon et al. 2000](#)), but has the great advantage of lines with widths of only ~ 3 km s^{-1} (as compared to ~ 20 km s^{-1} for Sgr B2), reducing the problem of line confusion considerably. The molecular diversity of the region is demonstrated by [Zernickel et al. \(2012\)](#) who use the *Herschel* Space Observatory and Submillimeter Array (SMA) to investigate ~ 4300 emission and absorption lines belonging to 46 different molecules and their isotopologues.

NGC 6334I is comprised of multiple hot cores, some of which are themselves multiples. This multiplicity was shown by [Brogan et al. \(2016\)](#) who recently presented an in-depth, high-resolution continuum study of the morphology of the site. In addition to the four previously known millimetre sources associated with the region, labelled MM1–4 and identified

by Hunter et al. (2006), Brogan et al. (2016) identify six new sources: five at millimetre wavelengths, MM5-9, and one at centimetre wavelengths, CM2, all within a radius of $\sim 10''$ corresponding to 0.06 pc at the distance of the site. Another centimetre source, CM1, is identified $18''$ (~ 0.1 pc) west of the main cluster. In addition to molecular lines and the far-IR and radio continuum sources, indicative of cool, dense and dusty cores, NGC 6334I displays a variety of other star-formation tracers including ultra-compact HII regions and outflows (see e.g. Persi et al. 1996; Leurini et al. 2006; Qiu et al. 2011, and references therein).

The paper is structured in the following way: Sect. 2 introduces the observations, the data reduction process and the analysis method. In Sect. 3 the process of identifying and fitting individual lines and estimating molecular column densities is presented. Section 4 discusses the deuteration levels derived and compare these to those obtained for other objects as well as the predictions from astrochemical models. Finally, Sect. 5 summarises our findings.

2. Observations and analysis method

2.1. Observations

The observations have been described in detail in McGuire et al. (2017), while the analysis and reduction procedures are described in detail in Brogan et al. (2016) and Hunter et al. (2017), and as such only a brief discussion is presented here. Two sets of observations are used. The primary dataset (ALMA Project 2015.1.00150.S) was taken in Cycle 3 at $\sim 1''$ resolution (~ 1300 AU at the distance of NGC 6334I), centred on 302 GHz, and covering ~ 3 GHz of total bandwidth with an rms noise of ~ 500 mK. The second dataset (ALMA Project 2015.A.00022.T) was also observed in Cycle 3 but at $\sim 0''.2$ (260 AU) resolution, centred around four frequency windows at approximately 281, 293, 338, and 350 GHz each ~ 3.75 GHz wide, and with an rms noise of ~ 620 mK and ~ 900 mK in the lower and higher frequency ranges, respectively. In each case, the most line-free continuum channels were selected and used for both self calibration and continuum subtraction.

2.2. Analysis method

Nine spectra are extracted from the data cube. Each spectrum represents the average of a $1''.00 \times 0''.74$ region, equivalent to the area of the synthesised beam. The coordinates of the central pixel of each of the regions are summarised in Table 1 and the locations shown in Fig. 1. The positions are chosen so they present a fairly homogeneous sampling of the continuum sources MM1, located in the northern part of NGC 6334I, MM2, located in the western part of the region, and MM3, located in the southern part of the region, as well as their surroundings.

For our line analysis, the software package CASSIS¹ is used. CASSIS is a tool for spectral line identification and analysis which reads a list of line data, including rest frequency, ν , upper state energy, E_{up} , and Einstein A_{ij} coefficients. Once a line has been identified, the line analysis tool is used to produce a synthetic spectrum by providing CASSIS with a number of parameters: excitation temperature, T_{ex} [K], column density of the species, N_s [cm^{-2}], source velocity, v_{LSR} [km s^{-1}], line width, FWHM [km s^{-1}], and angular size of the emitting region (which is assumed to be equal to the area of the synthesised

Table 1. Summary of regions and column densities.

| Region | Location (J2000) | | v_{LSR} [km s^{-1}] | FWHM [km s^{-1}] | T_{ex}^a [K] | $^{13}\text{CH}_3\text{OH}$ [$\times 10^{17} \text{ cm}^{-2}$] | CH^{18}OH [$\times 10^{17} \text{ cm}^{-2}$] | CH_2DOH^b [$\times 10^{17} \text{ cm}^{-2}$] | CH_3OD [$\times 10^{17} \text{ cm}^{-2}$] |

Notes. Range of N_s corresponds to the range in column density, within the synthesised beam of $1''.00 \times 0''.74$, with and without blending. ^(a)Excitation temperature of the best-fit $^{13}\text{CH}_3\text{OH}$ model. ^(b)Numbers include the vibrational correction factor of 1.25 as well as the uncertainty on the line strength (see Sect. 2.2).

¹ <http://cassis.irap.omp.eu>

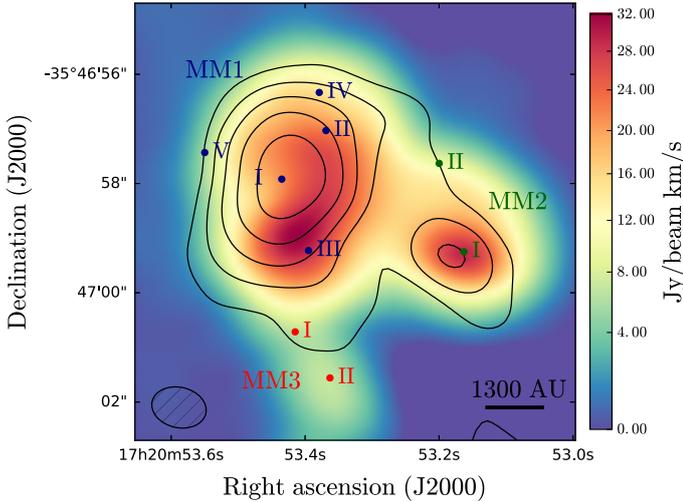

Fig. 1. Velocity integrated intensity map of the $^{13}\text{CH}_3\text{OH}$ transition at 303.692 GHz with the 1 mm continuum image overlaid in black contours (levels are [10, 20, 40, 80, 160] σ with $\sigma = 0.02 \text{ Jy beam}^{-1}$). The locations at which spectra have been extracted are marked in blue for MM1, green for MM2 and red for MM3. The synthesised beam ($\sim 1300 \times 962 \text{ AU}$) is shown in the bottom left corner.

beam), θ_s ["]]. For line input the Jet Propulsion Laboratory (JPL²) and Cologne Database for Molecular Spectroscopy (CDMS³) databases are used.

For the analysis of $^{13}\text{CH}_3\text{OH}$ and $\text{CH}_3^{18}\text{OH}$, the CDMS database is used. These entries include the ground and first vibrational states for $^{13}\text{CH}_3\text{OH}$ and the ground, first and second vibrational states for $\text{CH}_3^{18}\text{OH}$. For the analysis of CH_2DOH the JPL database is used. The line intensities in this list are based on the method described by Pearson et al. (2012). The JPL catalogue warns that extreme caution should be taken in determining columns (or concentrations) of CH_2DOH directly from b-type and c-type transitions as significant errors can occur, while the a-type transitions are more reliable⁴. The symmetry of the transitions are defined as follows: $\Delta K_a = \text{even}$, $\Delta K_c = \text{odd}$ for a-type, $\Delta K_a = \text{odd}$, $\Delta K_c = \text{odd}$ for b-type and $\Delta K_a = \text{odd}$, $\Delta K_c = \text{even}$ for c-type (Pearson et al. 2012). We optimise our CH_2DOH fit to the $12_{(2,11)} \rightarrow 12_{(1,12)}$ b-type transition at 301.514 GHz (see Sect. 3.3) and use an updated value for the base 10 logarithm of the integrated line intensity at 300 K for this transition of $-3.84 \pm 0.2 \text{ nm}^2 \text{ MHz}$ (John Pearson, priv. comm.). Also, since the CH_2DOH entry only includes the ground vibrational state, a vibrational correction factor of 1.25 has been applied to all listed values (Holger Müller, priv. comm.). To model CH_3OD we use the summary of CH_3OD frequencies reported by Walsh et al. (2000), the line strengths reported by Anderson et al. (1988, 1933) and the partition function of $\text{CH}_3^{18}\text{OH}$ (from the CDMS database) which includes the vibrational levels.

Because CH_3OH is a very abundant species in star-forming regions, the lines of the primary ^{12}C -isotope are optically thick and cannot be used to derive column densities and excitation temperatures. Fortunately, many lines of the isotopologues $^{13}\text{CH}_3\text{OH}$, $\text{CH}_3^{18}\text{OH}$, CH_2DOH and CH_3OD remain in the optically thin regime, making column density determination of these species possible. We identify a total of 15 transitions belonging to the methanol isotopologues in the covered frequency

range: eight of these belong to $^{13}\text{CH}_3\text{OH}$, four to $\text{CH}_3^{18}\text{OH}$, one to CH_2DOH and two to CH_3OD . The transitions are summarised in Table 2. Since the frequency range covered is limited to $\sim 3 \text{ GHz}$ (301.180–304.165 GHz) only a few transitions of each species are covered. This complicates the definite identification of lines, especially in the case of $\text{CH}_3^{18}\text{OH}$, CH_2DOH and CH_3OD for which many lines are either very weak or blended to an extent that it is impossible to distinguish the contribution from individual molecular species.

In order to verify the presence of these species in NGC 6334I, a second set of data, covering a larger range of frequencies, is also consulted (see Sect. 2). Based on transitions in these data the presence of the less abundant CH_3OH -isotopologues is confirmed. However, since these data are of higher angular resolution ($\sim 0''.2$) emission is resolved out and we are not able to constrain the column density of either of the deuterated species better than from our primary data set. The upper limits for CH_2DOH (which are similar for a- and b-type transitions covered) and CH_3OD as well as the column densities for $^{13}\text{CH}_3\text{OH}$ and $\text{CH}_3^{18}\text{OH}$ based on these data are consistent with the values derived based on our primary data set. The data are presented in Appendix A but will not be discussed further in the main manuscript.

For each methanol line candidate we carefully examine transitions belonging to other species (for which the spectroscopy is known and listed in either of the databases mentioned above) at similar frequencies to ensure lines are not incorrectly assigned. In the first step, all species which have not previously been detected in space are excluded. Secondly, species are excluded based on Einstein A_{ij} coefficient and upper state energy. For the remaining blending candidates we investigate if any additional transitions are covered in the data range and if so, whether these can provide additional constraints. If the blending candidates are isotopologues, we search for transitions belonging to the parent species and ensure that column densities are consistent. The process of line assignment and analysis of potential blended transitions will be discussed in detail in Sects. 3.1–3.4.

Assuming LTE and optically thin lines synthetic spectra are created for each methanol isotopologue. Firstly, the excitation temperatures and $^{13}\text{CH}_3\text{OH}$ column densities for each region are derived by creating a grid of models, with T_{ex} ranging between 50 and 350 K and N ranging between 5×10^{16} and $5 \times 10^{19} \text{ cm}^{-2}$, and selecting the model with the minimal χ^2 as the best fit. The $^{13}\text{CH}_3\text{OH}$ lines are fitted first because these lines are the most numerous and span the largest range of upper state energies. Secondly, the column densities of the remaining methanol isotopologues are optimised keeping the excitation temperature fixed at the value of the best-fit ^{13}C -methanol model. The transitions of each methanol isotopologue, as well as the blending species, are modelled separately, and summed to obtain a full spectrum for each of the nine regions. These spectra are shown in Figs. B.1–B.3.

Finally, to estimate the $^{12}\text{CH}_3^{16}\text{OH}$ column density used to calculate the deuterium fraction for each spectral region, a $^{12}\text{C}/^{13}\text{C}$ value of 62 and a $^{16}\text{O}/^{18}\text{O}$ value of 450 is adopted, both derived assuming $d_{\text{GC}} \sim 7.02 \text{ kpc}$ and the relations for $^{12}\text{C}/^{13}\text{C}$ and $^{16}\text{O}/^{18}\text{O}$ reported by Milam et al. (2005) and Wilson (1999) respectively.

3. Results

3.1. $^{13}\text{CH}_3\text{OH}$

Eight transitions of $^{13}\text{CH}_3\text{OH}$ are detected towards NGC 6334I. For each of these, a synthetic spectrum is created and optimised

Notes. $^{(a)}$ Quantum numbers for $^{13}\text{CH}_3\text{OH}$, $\text{CH}_3^{18}\text{OH}$ and CH_2DOH are $(J K_a K_c v)$ and quantum numbers for CH_3OD are $(J K P v)$ where $v = 0, 1, 2$ refers to the three sub-states e_0, e_1 and o_1 of the ground state respectively. $^{(b)}$ Walsh et al. (2000), and references therein.

simultaneously to obtain the best-fit values for T_{ex} and N . However, the same range of frequencies which host the ^{13}C -methanol lines are also known to be occupied by a number of methyl formate (CH_3OCHO) transitions. Especially the $^{13}\text{CH}_3\text{OH}$ transitions at 302.590, 302.882, 303.319 and 303.865 GHz are overlapping with transitions of CH_3OCHO . Fortunately, since many transitions of this species are covered in the spectral range, the column density of CH_3OCHO can be constrained to a range of $(0.6\text{--}2.5) \times 10^{17} \text{ cm}^{-2}$ in our beam for all regions. While the contribution from CH_3OCHO to the $^{13}\text{CH}_3\text{OH}$ line fits does not change the value of the best-fit $^{13}\text{CH}_3\text{OH}$ column density, likely because the upper state energy of these transitions are high, $\sim 700 \text{ K}$, as compared with those of the affected $^{13}\text{CH}_3\text{OH}$ lines, it is included for completeness. Figure 2 shows the synthetic spectra of the best fit models to $^{13}\text{CH}_3\text{OH}$, CH_3OCHO and the combination of the two for the transition at 302.590 GHz detected towards each of the regions. Despite this transition having the largest contribution from CH_3OCHO , it is evident that at the abundances of CH_3OCHO present in NCG 6334I, its effect on the $^{13}\text{CH}_3\text{OH}$ line is small and it is therefore reasonable to assume that the observed peak in the data at 302.590 GHz is due mainly to $^{13}\text{CH}_3\text{OH}$.

The best-fit column density and excitation temperature for $^{13}\text{CH}_3\text{OH}$ for each of the regions are listed in Table 1. The values range about an order of magnitude, with the lowest values associated with MM3 I and II, $(0.8\text{--}0.9) \times 10^{17} \text{ cm}^{-2}$, while the highest, $\sim 8.3 \times 10^{18} \text{ cm}^{-2}$, are found in MM1 I and III. For the remaining regions the values span a range of $(1.3\text{--}7.4) \times 10^{18} \text{ cm}^{-2}$.

Zoom-ins of the spectra showing the remaining $^{13}\text{CH}_3\text{OH}$ lines can be found in Appendix C. Generally the single- T_{ex} , single- N models reproduce the data well. It should be noted however, that the transition with the lowest $A_{ij} \sim 10^{-6} \text{ s}^{-1}$ at 303.865 GHz is consistently under produced by the models as compared with the data by factors of between three and six. The same is true for the line at 302.166 GHz towards the regions around MM1. The reason for this could either be uncertainties in the spectroscopic values for these particular transitions, or that the lines are blended with some unknown species, the spectroscopy of which is not included in either of the JPL or CDMS databases.

Alternatively, the explanation could be that some of the transitions which we assume to be optically thin are in fact slightly thick, resulting in underestimated column densities. To test this, we optimise the column density and excitation temperature to the transitions at 302.166 and 303.865 GHz. Doing so, we find that for the modelled spectra to reproduce the data at these frequencies, the column densities need to be higher by factors of between five and ten, as compared to the best-fit column density when fitting to all lines, resulting in the remaining transitions being largely saturated. To improve the fits the individual sources would need to be modelled using an excitation model taking both density and temperature gradients into account. Such a full excitation model would potentially make the saturated lines appear more Gaussian.

3.2. $\text{CH}_3^{18}\text{OH}$

Assuming a $^{12}\text{C}/^{13}\text{C}$ value of 62 and a $^{16}\text{O}/^{18}\text{O}$ value of 450 implies that the $^{13}\text{CH}_3\text{OH}$ to $\text{CH}_3^{18}\text{OH}$ column density ratio is approximately a factor of seven. Adopting this ratio and using the best-fit column density values for $^{13}\text{CH}_3\text{OH}$, the majority of the modelled $\text{CH}_3^{18}\text{OH}$ lines appear weaker as compared with the data by about a factor of two. Indeed, when optimising the $\text{CH}_3^{18}\text{OH}$ column density, assuming T_{ex} to be the same as for $^{13}\text{CH}_3\text{OH}$, the values are only factors of 2–3 lower than those of $^{13}\text{CH}_3\text{OH}$. This result suggests that the $^{13}\text{CH}_3\text{OH}$ lines, which are assumed to be optically thin, are in fact partially optically thick, and therefore the derived column densities may be slightly underestimated, as discussed above.

As in the case of $^{13}\text{CH}_3\text{OH}$, the $\text{CH}_3^{18}\text{OH}$ lines are also partly blended. Especially the line at 303.016 GHz overlaps with the transition from another molecular species: O^{13}CS , although the slight shift in frequency of the O^{13}CS line with respect to the line of $\text{CH}_3^{18}\text{OH}$ means that the observed peak in the data cannot be due purely to O^{13}CS . Unfortunately no other lines of O^{13}CS are covered in our frequency range and likewise only one line of the parent species, OCS , is in the data range. It is therefore

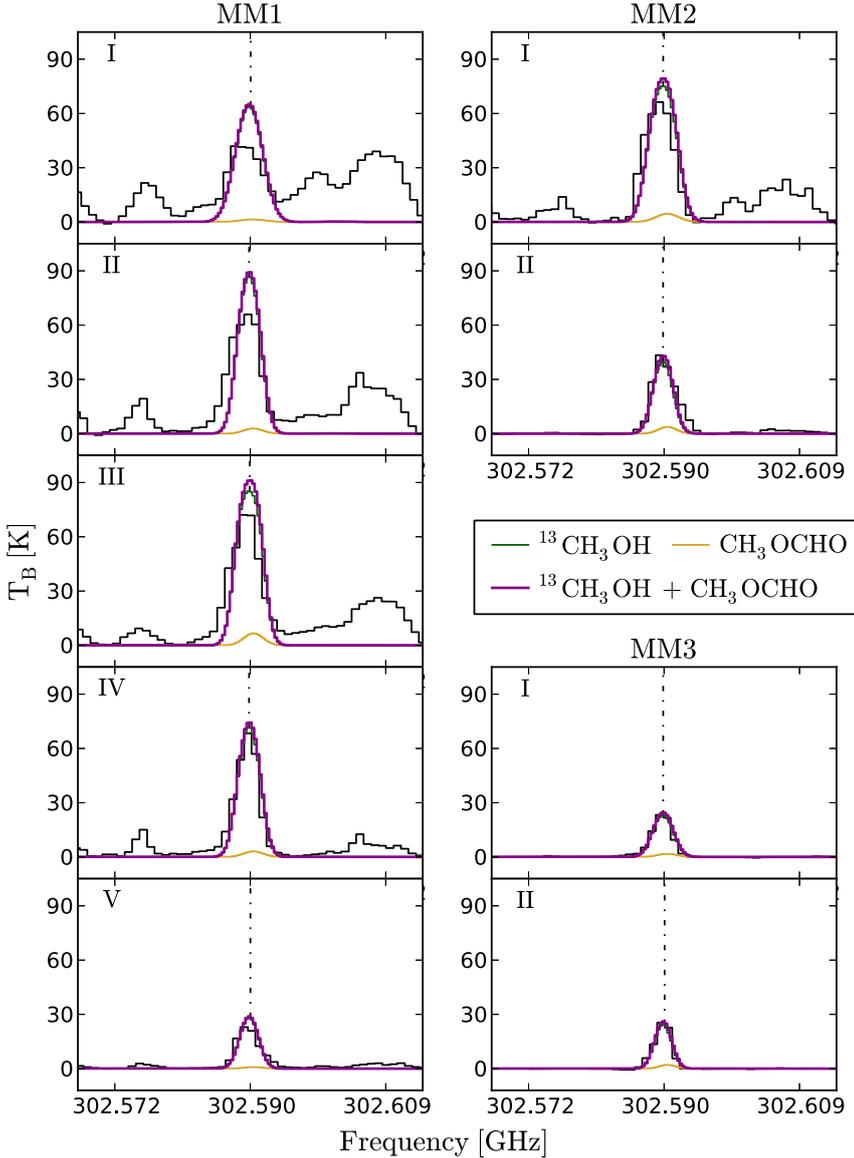

Fig. 2. $^{13}\text{CH}_3\text{OH}$ $10_{(0,10)} \rightarrow 9_{(1,8)}$ transition at 302.590 GHz (indicated by dash-dotted lines) detected towards each region. Frequencies are shifted to the rest frame of the individual regions. Green lines represent the modelled spectra of $^{13}\text{CH}_3\text{OH}$ without blending, i.e., excluding the contribution from CH_3OCHO (including the contribution from CH_3OCHO does not change the $^{13}\text{CH}_3\text{OH}$ column density of the best-fit model). Yellow lines represent the modelled spectra of CH_3OCHO and magenta lines represent the sum of the $^{13}\text{CH}_3\text{OH}$ and CH_3OCHO spectra.

difficult to constrain the contribution of O^{13}CS to the blend from the data itself. Instead the column density for OCS derived by Zernickel et al. (2012) of $1.2 \times 10^{18} \text{ cm}^{-2}$ (assuming a source size of $2.5''$) at $T_{\text{ex}} = 100 \text{ K}$ and the $^{12}\text{C}/^{13}\text{C}$ value of 62 is used to estimate a column density of O^{13}CS in NGC 6334I of $1.9 \times 10^{16} \text{ cm}^{-2}$. The modelled spectra of this transition as well as the data are shown in Fig. 3. A column density of O^{13}CS of $1.9 \times 10^{16} \text{ cm}^{-2}$ is also consistent with the data in Appendix A; however, while the O^{13}CS lines covered here are not overproduced at this column density, they cannot be better constrained due to blends. To derive the column density of $\text{CH}_3^{18}\text{OH}$ two sets of fits are performed: the first excludes the O^{13}CS -blended line and optimises the column density to the remaining three transitions (for which no known species listed in the databases contribute significantly to the data peaks), this value is used to set an upper limit for the column density. In the second fit, a contribution from O^{13}CS is included and the $\text{CH}_3^{18}\text{OH}$ column density is optimised to all lines. The O^{13}CS contribution is kept constant for all regions.

The column densities derived for $\text{CH}_3^{18}\text{OH}$ are listed in Table 1. For most regions, the difference between the fit purely considering $\text{CH}_3^{18}\text{OH}$ and the fit of $\text{CH}_3^{18}\text{OH}$ with a

contribution from O^{13}CS , is less than a factor of two. For regions MM1 III–V, MM2 II and MM3 however, the O^{13}CS column density derived from Zernickel et al. (2012) results in modelled spectra that overshoot the data at the specific frequency. For these regions only the value for the pure- $\text{CH}_3^{18}\text{OH}$ fit is reported. As is the case of $^{13}\text{CH}_3\text{OH}$, the derived $\text{CH}_3^{18}\text{OH}$ column densities are lowest in regions MM3 I and II, with values between $(1.3\text{--}1.4) \times 10^{16} \text{ cm}^{-2}$. Slightly higher values, $(0.32\text{--}1.5) \times 10^{17} \text{ cm}^{-2}$ and $(0.41\text{--}2.4) \times 10^{17} \text{ cm}^{-2}$, are derived for regions MM2 I and II and MM1 II–V respectively. The highest value is again associated with region MM1 I, $(2.0\text{--}3.4) \times 10^{17} \text{ cm}^{-2}$. Zoom-ins of all detected $\text{CH}_3^{18}\text{OH}$ transitions can be seen in Appendix D. Again, the single density and temperature models reproduce the data well, keeping in mind that the main contributor to the peak at 303.016 GHz is O^{13}CS .

3.3. CH_2DOH

For CH_2DOH , the $12_{(2,11)} \rightarrow 12_{(1,12)}$ transition at 301.514 GHz is detected. Unfortunately, this line too is blended. We constrain the column density of the blending species, CH_3NC , based on its characteristic double feature around 301.53 GHz, and derive

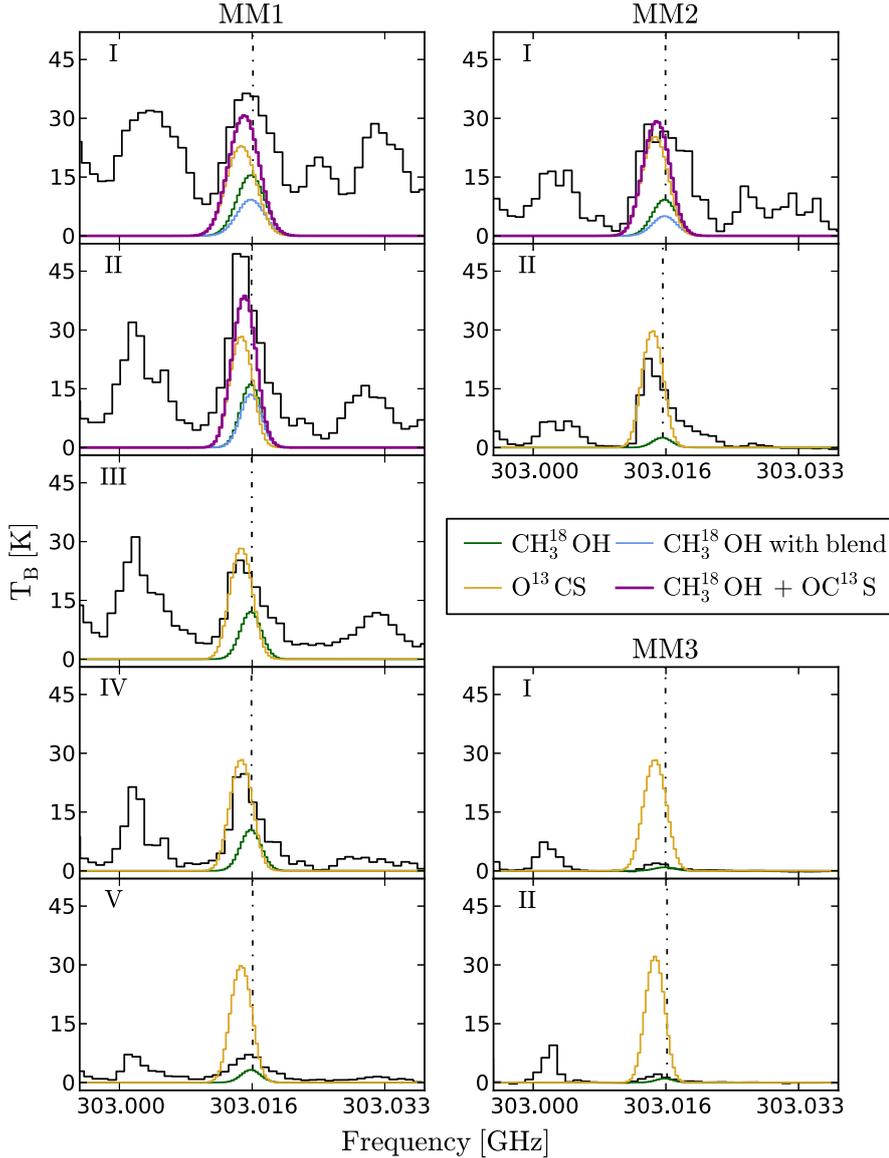

Fig. 3. $\text{CH}_3^{18}\text{OH}$ $16_{(1,16)} \rightarrow 15_{(2,14)}$ transition at 303.016 GHz (indicated by dash-dotted lines) detected towards each region. Frequencies are shifted to the rest frame of the individual regions. Blue and green lines represent the modelled spectra of $\text{CH}_3^{18}\text{OH}$ with and without blending, i.e., including and excluding the contribution from O^{13}CS , respectively. Yellow lines represent the modelled spectra of O^{13}CS , assuming a fixed column density of $1.9 \times 10^{16} \text{ cm}^{-2}$ for all regions, and magenta lines represent the sum of the spectra of $\text{CH}_3^{18}\text{OH}$ with blending and O^{13}CS .

values in the range $(1.1\text{--}2.0) \times 10^{14} \text{ cm}^{-2}$ for the regions MM1 I–IV and MM2 I. As in the case of O^{13}CS , these column densities are consistent with the data in Appendix A but cannot be further constrained. For the remaining regions, MM1 V, MM2 II and MM3 I–II, the data do not display any signs of CH_3NC . Figure 4 shows the modelled spectra of CH_2DOH , both with and without the contribution from the blending species, CH_3NC , as well as the sum of the spectra of CH_2DOH with blending and CH_3NC . For the regions where CH_3NC is detected, the difference between the values of the column density of CH_2DOH fitted with and without the contribution from CH_3NC is approximately a factor of three. No transitions of the more common isomer CH_3CN are covered by the data, so the ratio of $-\text{CN}/-\text{NC}$ cannot be constrained.

The column densities derived for CH_2DOH are listed in Table 1. We note that these include the vibrational correction and uncertainty on the line strength as discussed in Sect. 2.2. As regions MM1 V, MM2 II and MM3 I–II show no clear CH_3NC feature, only the value for the pure CH_2DOH fit is reported. As in the case of $^{13}\text{CH}_3\text{OH}$ and $\text{CH}_3^{18}\text{OH}$, the lowest CH_2DOH column densities are detected towards regions MM3 I and II, both with values in the range of $(3.0\text{--}6.0) \times 10^{15} \text{ cm}^{-2}$.

Region MM2 II also displays low values, $(4.0\text{--}9.0) \times 10^{15} \text{ cm}^{-2}$, while the values detected towards MM2 I are fairly high, $(0.45\text{--}1.38) \times 10^{17} \text{ cm}^{-2}$. The highest column density is again detected towards MM1 I, $(0.56\text{--}1.63) \times 10^{17} \text{ cm}^{-2}$, with the remaining regions extracted from the area around MM1 show column densities spanning a range of about an order of magnitude, $(0.08\text{--}1.10) \times 10^{17} \text{ cm}^{-2}$.

3.4. CH_3OD

In addition to the transitions of CH_2DOH , we have searched for lines belonging to CH_3OD , for which two transitions, one at 303.296 GHz and one at 303.904 GHz (see summary by Walsh et al. 2000), are covered. To derive a column density for this isotopologue, our fits were optimised to the transition at 303.296 GHz. No other transitions in either the JPL nor the CDMS databases are listed at this frequency so the line in the data is considered to be purely due to CH_3OD . The modelled spectra and data are shown in Fig. 5 and Appendix E and the derived column densities are listed in Table 1.

As in the case of CH_2DOH , the lowest column densities of CH_3OD are detected towards the regions MM3 I and II, with

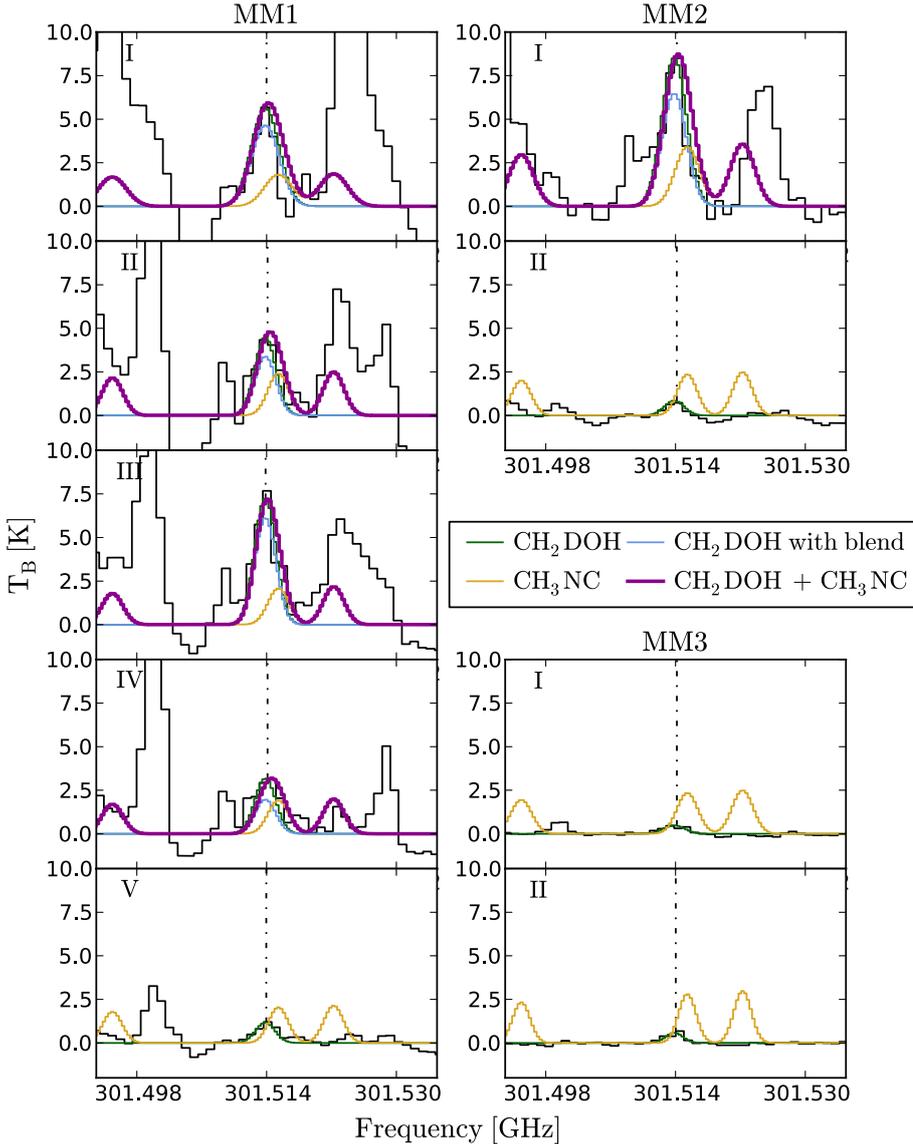

Fig. 4. CH_2DOH $12_{(2,11)} \rightarrow 12_{(1,12)}$ transition at 301.514 GHz (indicated by dash-dotted lines) detected towards each region. Frequencies are shifted to the rest frame of the individual regions. Blue and green lines represent the modelled spectra of CH_2DOH with and without blending, i.e., including and excluding the contribution from CH_3NC , respectively. Yellow lines represent the modelled spectra of CH_3NC and magenta lines represent the sum of the spectra of CH_2DOH with blending and CH_3NC .

values in the range of $(1.5\text{--}1.6) \times 10^{16} \text{ cm}^{-2}$. Regions MM2 II and MM1 V have similar column densities of 4.0 and $4.3 \times 10^{16} \text{ cm}^{-2}$ respectively. For the remaining regions, column densities in the range of $(1.7\text{--}5.5) \times 10^{17} \text{ cm}^{-2}$ are derived. The highest value is again associated with region MM1 I. It is very interesting to note that the column densities derived for CH_3OD are consistently higher than those derived for CH_2DOH in all regions.

4. Methanol deuteration fractions

In the following sections the $\text{CH}_2\text{DOH}/\text{CH}_3\text{OH}$ and $\text{CH}_2\text{DOH}/\text{CH}_3\text{OD}$ values derived for the nine regions in NGC 6334I, as well as those derived for a number of other sources, will be discussed. These are summarised in Fig. 6 and listed in Table 3.

4.1. NGC 6334I

Using the column densities derived from the $^{13}\text{CH}_3\text{OH}$, $\text{CH}_3^{18}\text{OH}$, CH_2DOH and CH_3OD transitions, we calculate the CH_2DOH to CH_3OH and CH_3OD to CH_3OH ratios for each

of the spectral regions. These are listed in Table 3. The $\text{CH}_2\text{DOH}/\text{CH}_3\text{OH}$ values range between $(0.03\text{--}0.34)\%$ and $(0.03\text{--}0.20)\%$ and the $\text{CH}_3\text{OD}/\text{CH}_3\text{OH}$ values range between $(0.27\text{--}1.07)\%$ and $(0.22\text{--}0.61)\%$, derived from $^{12}\text{C}/^{13}\text{C}$ and $^{16}\text{O}/^{18}\text{O}$ respectively. In the case of $\text{CH}_2\text{DOH}/\text{CH}_3\text{OH}$, both the lowest and the highest ratios are associated with region MM2, the lowest detected towards region MM1 II and the highest towards MM2 I. For the CH_3OD to CH_3OH ratio the lowest values are detected towards MM3 I and MM1 V while the highest is detected towards MM1 I. The mean values over all regions (including the vibrational correction and uncertainty on the line strength of CH_2DOH) are $0.13\% \pm 0.06\%$ and $0.53\% \pm 0.27\%$ based on the ^{13}C isotopologue and $0.08\% \pm 0.04\%$ and $0.32\% \pm 0.09\%$ based on the ^{18}O isotopologue, for $\text{CH}_2\text{DOH}/\text{CH}_3\text{OH}$ and $\text{CH}_3\text{OD}/\text{CH}_3\text{OH}$ respectively. Based on these means the average $\text{CH}_3\text{OD}/\text{CH}_3\text{OH}$ value is twice that of the average $\text{CH}_2\text{DOH}/\text{CH}_3\text{OH}$ value. The CH_2DOH to CH_3OH and CH_3OD to CH_3OH ratios derived based on the ^{13}C and ^{18}O isotopologues agree within factors of approximately two for all regions.

If the exchange of D into the CH_3 and OH functional groups of methanol is equally efficient, the column density ratio

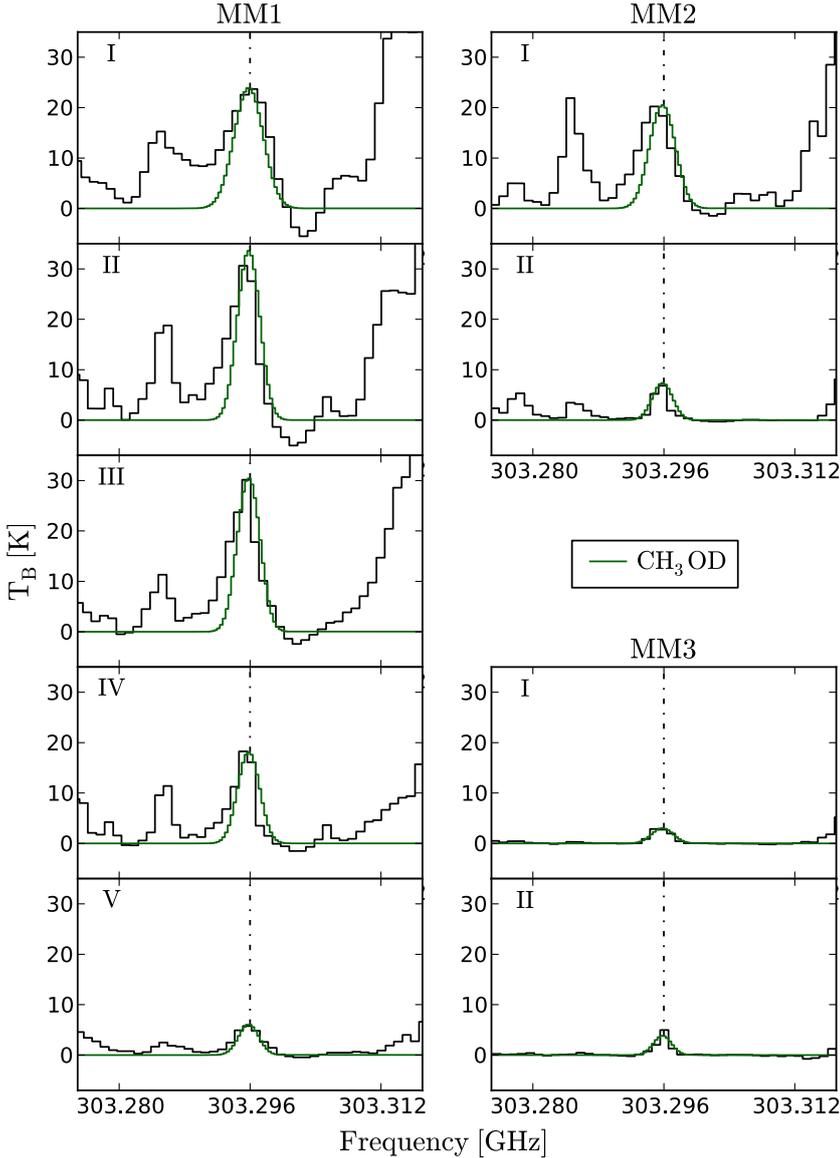

Fig. 5. $\text{CH}_3\text{OD } 7_{(2+)} \rightarrow 7_{(1,-)}$ transition at 303.296 GHz (indicated by dash-dotted lines) detected towards each region. Frequencies are shifted to the rest frame of the individual regions. Green lines represent the modelled spectra of CH_3OD .

of CH_2DOH to CH_3OD is expected to be equal to three. Interestingly, this is not the case for the regions presented here. Instead, we derive CH_2DOH to CH_3OD column density ratios of the order ~ 0.3 (not including the statistical correction factor which would further decrease the ratio by a factor of 3), lower by a factor of six as compared with the lower limit derived by Belloche et al. (2016) for Sgr B2 and factors of four and two as compared with the values derived for Orion KL by Neill et al. (2013) and Peng et al. (2012) respectively. This very low $\text{CH}_2\text{DOH}/\text{CH}_3\text{OD}$ value is just opposite to values found for pre-stellar cores and low-mass protostars, where $\text{CH}_2\text{DOH}/\text{CH}_3\text{OD}$ values up to ten are found (Bizzocchi et al. 2014; Parise et al. 2006), although consistent with the trend of lower ratios inferred for high mass protostars (Ratajczak et al. 2011). The low CH_2DOH to CH_3OD ratio implies that the deuteration of the OH functional group is more efficient than that of the CH_3 group, or that D is more easily abstracted from the CH_3 group rather than from the OH group.

Various chemical processes in the gas and ice that can cause the CH_2DOH to CH_3OD ratio to deviate from the statistical ratio of three are described in Ratajczak et al. (2011) and in Faure et al. (2015). In the gas phase these processes include

protonation and dissociative recombination reactions which destroy CH_3OD more efficiently than CH_2DOH since all recombinations of $\text{CH}_2\text{DOH}_2^+$ lead to CH_2DOH while CH_3OHD^+ can recombine to either CH_3OH or CH_3OD with an equal branching ratio (Charnley et al. 1997). However the timescale needed to significantly alter the CH_2DOH to CH_3OD ratio through these reactions is likely too long, that is more than 10^5 years, when compared with the typical lifetime of a hot core. In the solid state, experiments carried out by Nagaoka et al. (2005) have shown that H/D substitution in solid CH_3OH forms CH_2DOH but no CH_3OD . Also in the solid state, experiments by Ratajczak et al. (2009) and Faure et al. (2015) have shown that H/D exchanges can occur between water and methanol in warm ices ($T \sim 120$ K), but only on the OH functional group of methanol and not on the CH_3 group. The processes mentioned above favour the formation of CH_2DOH over that of CH_3OD and consequently lead to an increase in $\text{CH}_2\text{DOH}/\text{CH}_3\text{OD}$ rather than decrease. The low observed ratio therefore remains unexplained.

It should be noted however, that because the spectroscopy of CH_2DOH is not well understood, the $\text{CH}_2\text{DOH}/\text{CH}_3\text{OD}$ value derived may be higher. To better constrain the ratio, future

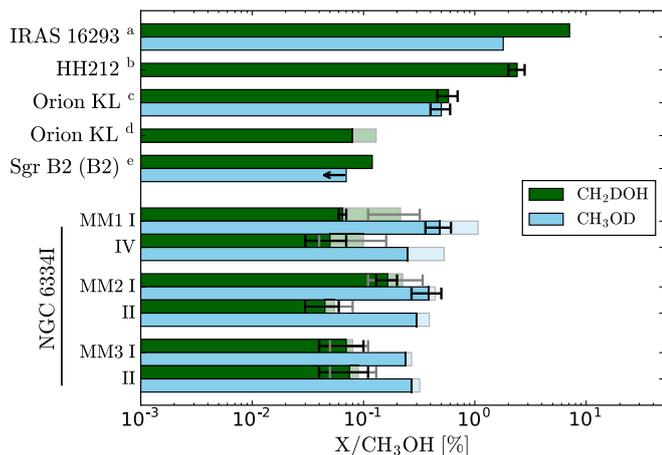

Fig. 6. Column density ratio of CH_2DOH to CH_3OH (green) and CH_3OD to CH_3OH (blue) for NGC 6334I and other objects. For Orion KL the shaded bar indicates the range of ratios derived by Peng et al. (2012). For NGC 6334I shaded and filled bars indicate the ratios derived using the ^{13}C and ^{18}O isotopologues as base respectively. Error bars indicate the range of ratios derived with and without blending. For NGC 6334I MM1 only the region with the lowest (MM1 IV) and highest (MM1 I) ratios are plotted. **References.** ^(a)Jørgensen et al. (2017). ^(b)Bianchi et al. (2017). ^(c)Neill et al. (2013). ^(d)Peng et al. (2012). ^(e)Belloche et al. (2016).

studies are well-advised to target only a-type CH_2DOH -transitions rather than b- or c-type transitions, for which the uncertainties on the line strength are not well-constrained, in addition to preferring weak, low A_{ij} transitions, to ensure that lines are optically thin. A refinement of the accuracy of the column density of CH_2DOH , will make it possible to investigate the coupling of $\text{CH}_2\text{DOH}/\text{CH}_3\text{OD}$ with environment and chemical evolution. Therefore it may be advantageous to focus future observations on narrow bands with high spectroscopic resolution covering a few well-chosen transitions, rather than broader bands which, albeit potentially covering more lines, might make identification and analysis difficult due to uncertainties in spectroscopic values or blending with features of other species which may not be resolved.

As discussed in Sect. 2.2, the excitation temperature for each region is determined based on a minimal χ^2 technique comparing a grid of models with the spectra. The excitation temperatures of the best-fit models range between ~ 120 and 330 K, the warmest regions associated with the MM1 core and the coldest with the MM3 core. We investigate the effect of varying the excitation temperature on the derived column densities and plot the ratios of CH_2DOH to CH_3OH and CH_3OD to CH_3OH as function of T_{ex} in Fig. 7. From this analysis, it is evident that the spread in $\text{CH}_2\text{DOH}/\text{CH}_3\text{OH}$ and $\text{CH}_3\text{OD}/\text{CH}_3\text{OH}$ ascribed to different excitation temperatures (over all regions) is within a factor of two of the value derived for $T_{\text{ex}} = 200$ K. For the individual regions, the variations in $\text{CH}_2\text{DOH}/\text{CH}_3\text{OH}$ and $\text{CH}_3\text{OD}/\text{CH}_3\text{OH}$ over the full range of excitation temperatures are within factors of between two and four. Therefore, it is reasonable to assume that the lines used to optimise our fits are optically thin at excitation temperatures of 100 – 400 K and consequently that our derived $\text{CH}_2\text{DOH}/\text{CH}_3\text{OH}$ and $\text{CH}_3\text{OD}/\text{CH}_3\text{OH}$ values do not depend critically on an exact determination of T_{ex} . For each value of T_{ex} we also calculate the ratio of the ^{13}C - and ^{18}O -methanol column densities. These ratios differ by less than a factor of two for MM2 and MM3 and a factor of four for MM1, verifying that the transitions are excited under similar conditions. The vibrational

correction factor applied to CH_2DOH has only little effect on this result.

4.2. Comparison with other sources

Using ALMA, Belloche et al. (2016) investigated the deuterium fractionation of complex organic molecules towards the high mass star-forming region Sgr B2 in the Galactic central region. With the high spatial resolution observations, $\sim 1.4''$, they probe scales down to 0.06 pc ($\sim 11\,620$ AU assuming a distance ~ 8.3 kpc). They report a tentative detection of CH_2DOH and derive a deuteration fraction for $\text{CH}_2\text{DOH}/\text{CH}_3\text{OH}$ of 0.12% . Including the statistical weight of the location of the substituted deuterium this value becomes 0.04% . CH_3OD is not detected, but an upper limit of 0.07% for $\text{CH}_3\text{OD}/\text{CH}_3\text{OH}$ is reported. This is translated into a lower limit on the CH_2DOH to CH_3OD ratio of 1.8 . Their CH_3OH column density is based on LTE modelling of both the ^{13}C and ^{18}O methanol isotopologues. The authors note that the $\text{CH}_2\text{DOH}/\text{CH}_3\text{OH}$ value they derive is lower than what is predicted by the chemical models of Taquet et al. (2014) and Aikawa et al. (2012) but may be explained by the high temperature that characterises the Galactic centre or result from an overall low abundance of deuterium in this region due to the high star formation rates.

For the high-mass star-forming regions in Orion, $\text{CH}_2\text{DOH}/\text{CH}_3\text{OH}$ values are of the same order as for Sgr B2, ranging between $(0.08\text{--}0.58)\%$, equivalent to $(0.03\text{--}0.19)\%$ when the statistical weights are accounted for. These values are derived by Peng et al. (2012), using observations from the IRAM Plateau de Bure Interferometer, and Neill et al. (2013), using data from *Herschel*/HIFI. In addition, Neill et al. (2013) report a $\text{CH}_3\text{OD}/\text{CH}_3\text{OH}$ value of $0.5 \pm 0.1\%$ and a $\text{CH}_2\text{DOH}/\text{CH}_3\text{OD}$ value of 1.2 ± 0.3 . A slightly lower $\text{CH}_2\text{DOH}/\text{CH}_3\text{OD}$ value of 0.7 ± 0.3 is reported by Peng et al. (2012). To derive CH_3OH column densities Neill et al. (2013) and Peng et al. (2012) use slightly different approaches: Neill et al. (2013) assume a $^{12}\text{C}/^{13}\text{C}$ value of 60 and derive the CH_3OH density based on transitions of $^{13}\text{CH}_3\text{OH}$, while Peng et al. (2012) detect a number of E-type methanol transitions and derive the total CH_3OH density assuming an A/E-type abundance of 1.2 . Both studies of Orion KL probe scales which are smaller than those studied in Sgr B2: $\sim 10''$ and $\sim 2''$, corresponding to ~ 4140 AU and ~ 830 AU at the distance of Orion KL (~ 414 pc), for Neill et al. (2013) and Peng et al. (2012) respectively. However, since the beam dilution factor is higher in these studies, meaning that the area over which the emission is averaged is larger, the column density derived, assuming the total emission to be the same, is lower. Also, observations with larger beam sizes, which are more sensitive to large scale structures, generally probe regions of lower temperature, meaning that some molecules may be locked up in icy grain mantles, resulting in lower gas phase abundances. This combination of effects means that the derived column densities, as well as the inferred deuteration ratios, for Orion KL may in fact be higher, if derived from observations with higher angular resolution.

An example of such high-resolution observations are presented by Bianchi et al. (2017) who use $0.15''$ -resolution ALMA observations to study the Sun-like class 0 protostar HH 212, located in the Orion B cloud, on scales of ~ 70 AU. From transitions of $^{13}\text{CH}_3\text{OH}$ and CH_2DOH they derive a $\text{CH}_2\text{DOH}/\text{CH}_3\text{OH}$ value of $(2.4 \pm 0.4)\%$, equivalent to $(0.8 \pm 0.1)\%$ after accounting for statistical weights, assuming a $^{12}\text{C}/^{13}\text{C}$ value of 70 . This deuteration ratio is higher than what has been derived for high-mass star-forming regions but lower by an order of magnitude

Notes. Ranges of CH₂DOH/CH₃OH and CH₃OD/CH₃OH correspond to the range in column density of ¹³CH₃OH, CH₃¹⁸OH and CH₂DOH with and without blending. All CH₂DOH/CH₃OH values include the vibrational correction of 1.25 as well as the uncertainty in the line strength. ^(a)Corrected for statistical weight of the location of the substituted deuterium. For CH₂DOH this value is 3, for CH₃OD it is 1. ^(b)Ratios do not include statistical correction factors. ^(c)Belloche et al. (2016). ^(d)Neill et al. (2013). ^(e)Peng et al. (2012). ^(f)Mean ratio over central region. ^(g)Jørgensen et al. (2017). ^(h)Bianchi et al. (2017). ⁽ⁱ⁾Includes vibration correction factor for CH₂DOH of 1.457 at 300 K (see Sect. 2.2 of Jørgensen et al. 2017).

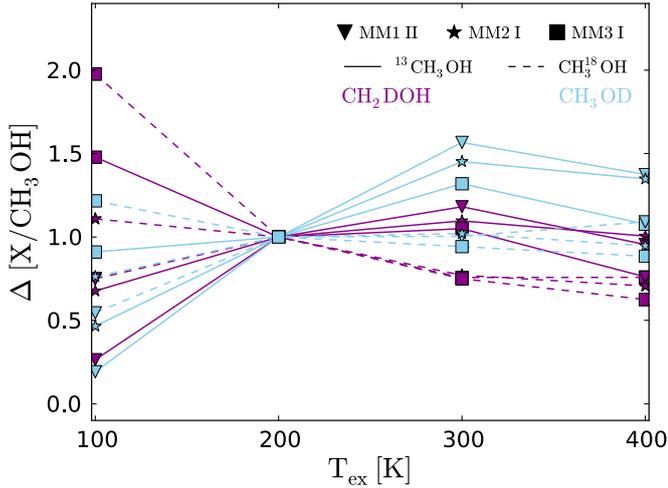

Fig. 7. Column density ratio as function of excitation temperature. Ratios are normalised to the value derived for $T_{\text{ex}} = 200$ K. Magenta and blue lines represent the CH_2DOH to CH_3OH and CH_3OD to CH_3OH column density ratios respectively, while solid and dashed lines indicate the values derived assuming $^{12}\text{C}/^{13}\text{C} = 62$ and $^{16}\text{O}/^{18}\text{O} = 450$ respectively. Different regions are indicated by different markers.

as compared with observations (carried out with single dish telescopes) towards protostars in Perseus. Bianchi et al. (2017) argue that the lower deuteration ratio they find is consistent with the dust temperature of the Orion region being higher than that of the Perseus cloud.

Similarly to HH 212, the low-mass protostellar binary system IRAS 16293, located in the ρ Ophiuchi cloud complex, exhibits a CH_2DOH to CH_3OH ratio which is much higher than that of the high-mass star-forming regions. With the ALMA-PILS survey (see Jørgensen et al. 2016 for full PILS overview), sampling spatial scales of the order $0.5''$, corresponding to 60 AU at the distance of the source (~ 120 pc), Jørgensen et al. (2017) derive a CH_2DOH to CH_3OH ratio of 7.1%, equivalent to 2.4% after corrections for statistical weights, assuming a ^{16}O to ^{18}O isotope ratio of 560 to estimate the CH_3OH abundance, and a CH_3OD to CH_3OH ratio of 1.8% resulting in a $\text{CH}_2\text{DOH}/\text{CH}_3\text{OD}$ value of 3.9.

Because of the comparable resolution and methods used, the methanol deuteration ratios derived for IRAS 16293, HH 212 and Sgr B2, may be directly compared to the ratios derived in this study. When doing so, the low levels of deuterium fractionation associated with the regions in NGC 6334I, as compared with the low-mass star-forming regions IRAS 16293 and HH 212, become very apparent (Table 3). It is also interesting to note that while our inferred $\text{CH}_2\text{DOH}/\text{CH}_3\text{OH}$ values for NGC 6334I are similar to what has been derived by Bellocche et al. (2016) for Sgr B2, the $\text{CH}_3\text{OD}/\text{CH}_3\text{OH}$ values are higher by up to an order of magnitude as compared with the lower limit reported for Sgr B2.

4.3. Comparison with models

In an effort to better understand the observed variety of deuterated species and their column density ratios, a number of astrochemical models have been put forward, among these the GRAINOBLE model. This code has been described in detail in previous studies (Taquet et al. 2012, 2013, 2014) and here we give only a brief presentation before discussing how the model compares with the levels of deuteration we find in the regions of NGC 6334I.

GRAINOBLE follows the gas-ice interstellar chemistry through a three-phase (gas, ice surface, ice bulk) rate equations approach initially developed by Hasegawa & Herbst (1993). The model takes into account a number of gas-grain processes including the accretion of species onto the grains, desorption back into the gas-phase and reactions between particles at the ice surface and in the ice mantle. The gas-phase chemical network is described in Taquet et al. (2014) and includes the spin states of H_2 , H_2^+ , and H_3^+ , as well as the deuterated isotopologues of hydrogenated species with four or less atoms and molecules involved in the chemistry of water, methanol, ammonia, and formaldehyde. The ice chemical network follows the formation and the deuteration of the main ice species, following a series of laboratory experiments, and complex organic molecules through radical-radical recombination reactions. Specifically, the pathways for formation and deuteration of methanol include both addition reactions involving atomic D and hydrogenation of solid CO and H_2CO at cold ($T = 10\text{--}15$ K) temperatures as well as abstraction reactions, as shown by Hidaka et al. (2009).

We investigated the effect of the dust and gas temperatures, T , assumed to be equal, and the total density, n_{H} , on the methanol deuteration. For this purpose, a series of pseudo-time dependent simulations in which the chemistry evolves over time whilst the temperature and density remain constant were run. Figure 8 shows the final ice abundances of CO, H_2O , and CH_3OH , the deuteration in ices of methanol and the gas phase atomic D to H ratio and the CH_2DOH to CH_3OD ratio as a function of temperature. Models are shown for three different densities, $n_{\text{H}} = 10^4$, 10^5 and 10^6 cm^{-3} , with respective ages of 2×10^7 , 2×10^6 , and 2×10^5 years.

It is evident that both the ice composition and the methanol deuteration are highly dependent on the considered temperature and total density. The barrierless reactions which form water from atomic oxygen mean that this species is the least dependent on T and n_{H} . Methanol and its deuterated isotopologues are, on the other hand, formed through hydrogenation and/or deuteration of CO and H_2CO , which are thought to have high activation barriers. As a consequence, methanol formation can be inhibited at high densities, decreasing the CO hydrogenation, or at high temperatures where CO no longer efficiently freezes-out onto grains. Despite the lower residence time of H and CO on the grains at temperatures above ~ 20 K, limiting the formation of H_2CO and later CH_3OH , significant deuteration of methanol occur in the model. This is due to the long timescales considered which enhance the probability that the CO and H or D particles meet on the dust grain and recombine. Also, since it is formed through hydrogenation and/or deuteration processes, the methanol deuteration is governed by the atomic D/H in the gas phase.

Specifically, the strong decrease of the methanol deuteration with temperature, up to three orders of magnitudes with an increase of T from 10 to 40 K, is due to the decreased efficiency of deuterium chemistry in the gas phase with increasing temperature. Atomic D is mostly formed via electronic recombination of H_3^+ isotopologues, formed through exothermic reactions between H_3^+ (or with its isotopologues) and HD. Because the efficiency of the backward reactions increase with an increase in temperature, the deuteration of H_3^+ and therefore the production of atomic D is limited at high temperatures. However, the solid CH_2DOH to CH_3OH ratio does not always scale with the final atomic gas phase D/H. Figure 8 shows how the CH_2DOH to CH_3OH ratio decreases more efficiently with temperature at high densities but remains fairly constant for $n_{\text{H}} = 10^4$ cm^{-3} .

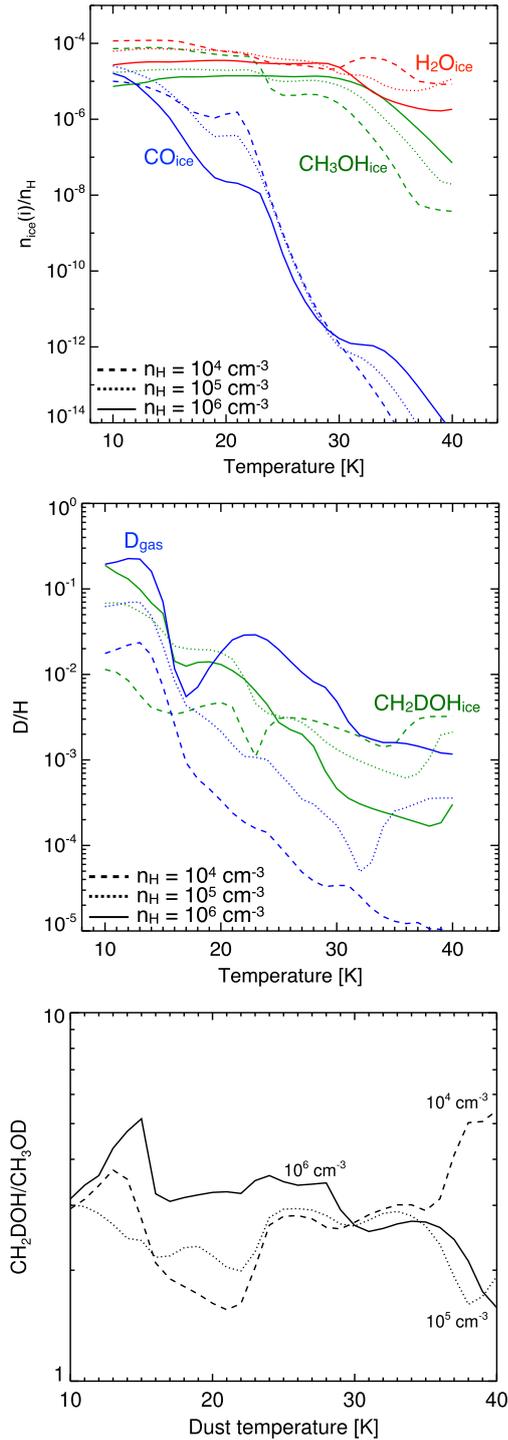

Fig. 8. *Top panel:* final abundances of H₂O (red lines), CO (blue lines), and CH₃OH (green lines) in ices as a function of temperature. *Middle panel:* final CH₂DOH to CH₃OH abundance ratio in ices (green lines) and final atomic D/H in the gas phase (blue lines) as a function of temperature. *Bottom panel:* final CH₂DOH to CH₃OD abundance ratio as a function of temperature. In all panels three densities are considered: $n_{\text{H}} = 10^4$ (dashed), 10^5 (dotted), and 10^6 (solid) cm^{-3} .

The model distinguishes the formation of CH₂DOH from that of CH₃OD. As seen in Fig. 8, the ratio remains close to three throughout the temperature range. This is due to the three reaction channels that form CH₂DOH compared with the single channel that forms CH₃OD. Also, it is important to note that while the observations trace the methanol deuteration in

the gas phase of the hot core surrounding the forming massive protostars, the model describes the predicted deuteration of ices formed during the precursor pre-stellar phase. Therefore, the analysis is implicitly based on the assumption that the gas phase composition around the hot cores reflects the composition of the ices in the pre-stellar phase. As discussed in Sect. 4.1, a number of processes may alter the ice methanol deuteration. Some of these processes are already accounted for in the model, for example the formation of CH₂DOH via abstraction reactions, shown experimentally by Nagaoka et al. (2005), is included in the model but contributes little to the overall abundance of CH₂DOH. Others, like the H/D exchanges shown to occur between water and methanol in warm ices (Ratajczak et al. 2009; Faure et al. 2015) still need to be implemented and could potentially contribute significantly to the decrease of the CH₃OD/CH₃OH abundance resulting in a higher CH₂DOH to CH₃OD ratio in contrast to the low ratios derived for the regions in NGC 6334I.

Based on the model predictions, our inferred deuterium fractionation of methanol in the NGC 6334I regions, indicate a temperature during formation around 30 K. A similar dust temperature of the precursor dense core is reported by Russeil et al. (2013) who use data from *Herschel* to derive a dust temperature map of the NGC 6334 star-forming region and show that the area is dominated by temperatures $\sim 25\text{--}35$ K. Such a warm pre-stellar cloud could be the result of heating from a nearby earlier phase of star formation, potentially associated with NGC 6334E a region located between I and I(N) and hosting an O-type star and associated large shell-like HII region (Carral et al. 2002). The small variation in deuterium fractions found towards the individual regions of NGC 6334I may reflect local differences in n_{H} .

5. Summary and conclusion

In this paper we analyse the level of deuterium fractionation in methanol towards the high-mass star-forming region NGC 6334I. We use high spectral resolution observations carried out with ALMA and extract spectra from nine individual locations across the MM1, MM2, and MM3 regions. Based on these, we identify a total of 15 transitions belonging to the isotopologues of methanol. Assuming excitation temperatures of $\sim 120\text{--}330$ K for the individual regions, we derived column densities for each of the species ¹³CH₃OH, CH₃¹⁸OH, CH₂DOH and CH₃OD and calculate CH₂DOH/CH₃OH and CH₃OD/CH₃OH. These range from 0.03% to 0.34% and 0.03% to 0.20% for the ratios of CH₂DOH to CH₃OH and from 0.27% to 1.07% and 0.22% to 0.61% for the ratios of CH₃OD to CH₃OH, using the ¹³C and ¹⁸O isotopologues to derive the column density of ¹²CH₃¹⁶OH respectively. The highest levels of deuterium fractionation are associated with the regions MM1 I and MM2 I, which are also the brightest regions in the continuum image, while the lowest are detected towards the regions MM2 II and MM3 I both associated with less bright continuum regions. The derived deuterium fractionation ratios only vary by factors of between two and four with excitation temperatures between 100 and 400 K.

The derived CH₂DOH/CH₃OH values are consistently low throughout NGC 6334I with a mean CH₂DOH/CH₃OH value over all regions of $0.13 \pm 0.06\%$ and $0.08 \pm 0.04\%$ based on the ¹³C and ¹⁸O isotopologues respectively. This homogeneity of the CH₂DOH to CH₃OH ratios derived for the different cores indicate that they formed from the same precursor cloud. The levels are also similar to those derived towards Sgr B2 in the Galactic centre (Belloche et al. 2016) as well as those derived for the high-mass star-forming regions in Orion by Peng et al. (2012),

but lower by factors of a few when compared with the values derived by Neill et al. (2013) for the same region. Because of the similar values, the low deuterium fractionation found in the Galactic centre is likely not due to astration but rather the high temperatures characterising the region. The methanol deuterium fractionation levels derived for the low-mass systems HH 212 and IRAS 16293 are higher by up to two orders of magnitude when compared with the values inferred for NGC 6334I, clearly illustrating the differences in physical and chemical environment prevailing in high- and low-mass star-forming regions.

Based on the chemical model of Taquet et al. (2014), the CH₂DOH to CH₃OH ratios detected towards the regions of NGC 6334I indicate a dust temperature at the time of the systems formation ~30 K. This temperature is higher than what is predicted for low-mass star-forming regions where the levels of deuterium in simple molecular species indicate a dust temperature at the time of formation below 20 K.

In addition to CH₂DOH, CH₃OD is unambiguously detected towards all nine regions of NGC 6334I allowing CH₂DOH to CH₃OD ratios to be derived. These range from 0.10 to 0.50, the highest value associated with the region MM2 I and the lowest with MM1 II. Our CH₂DOH/CH₃OD values towards NGC 6334I are lower than what is expected from statistics, assuming the CH₃ and OH functional groups of methanol to be equally likely to be deuterated. While CH₂DOH to CH₃OD ratios of the order of unity have been detected towards high-mass star-forming regions previously, the low levels derived here have not been seen before and may hint at a favoured formation of CH₃OD or destruction of CH₂DOH in this region which has yet to be explained by models or experiments.

Acknowledgements. A special thanks to Dr. Holger Müller for valuable discussions of the spectroscopy of deuterated methanol. We acknowledge data reduction support from Allegro, the European ALMA Regional Center node in the Netherlands, and Dr. Luke Maud in particular for expert advice. We thank the anonymous referee for constructive comments that improved our manuscript. Support for B.A.M. was provided by NASA through Hubble Fellowship grant #HST-HF2-51396 awarded by the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., for NASA, under contract NAS5-26555. This paper makes use of the following ALMA data: ADS/JAO.ALMA#2015.1.00150.S and #2015.A.00022.T. ALMA is a partnership of ESO (representing its member states), NSF (USA) and NINS (Japan), together with NRC (Canada) and NSC and ASIAA (Taiwan) and KASI (Republic of Korea), in cooperation with the Republic of Chile. The Joint ALMA Observatory is operated by ESO, AUI/NRAO and NAOJ. This work is based on analysis carried out with the CASSIS software and JPL: <http://spec.jpl.nasa.gov/> and CDMS: <http://www.ph1.uni-koeln.de/cdms/> spectroscopic databases. CASSIS has been developed by IRAP-UPS/CNRS (<http://cassis.irap.omp.eu>).

Appendix A: ADS/JAO.ALMA#2015.A.00022.T

This appendix summarises the additional data set introduced in Sect. 2. The data confirm the presence of CH₃¹⁸OH, CH₂DOH and CH₃OD in NGC 6334I but do not constrain the column den-

sities of O¹³CS and CH₃NC better than the primary data set. This is due to blending with other species and, in the case of O¹³CS, a limited number of lines covered. The column densities of O¹³CS and CH₃NC derived from the primary data set are consistent with the data in this appendix.

Table A.1. Summary of data set ALMA#2015.A.00022.T.

| Location (J2000) | | v_{LSR} | $FWHM$ | N_s | | | |
|------------------|---------------|-----------------------|-----------------------|--|--|--|--|
| RA | Dec | | | ¹³ CH ₃ OH | CH ₃ ¹⁸ OH | CH ₂ DOH ^a | CH ₃ OD |

Notes. For CH₂DOH only the least blended lines are listed. ^(a)QNs for ¹³CH₃OH, CH₃¹⁸OH and CH₂DOH are ($J K_a K_c v$) and QNs for CH₃OD are ($J K P v$) where $v = 0, 1, 2$ refers to the three sub-states e_0, e_1 and o_1 of the ground state respectively. ^(b)Walsh et al. (2000), and references therein.

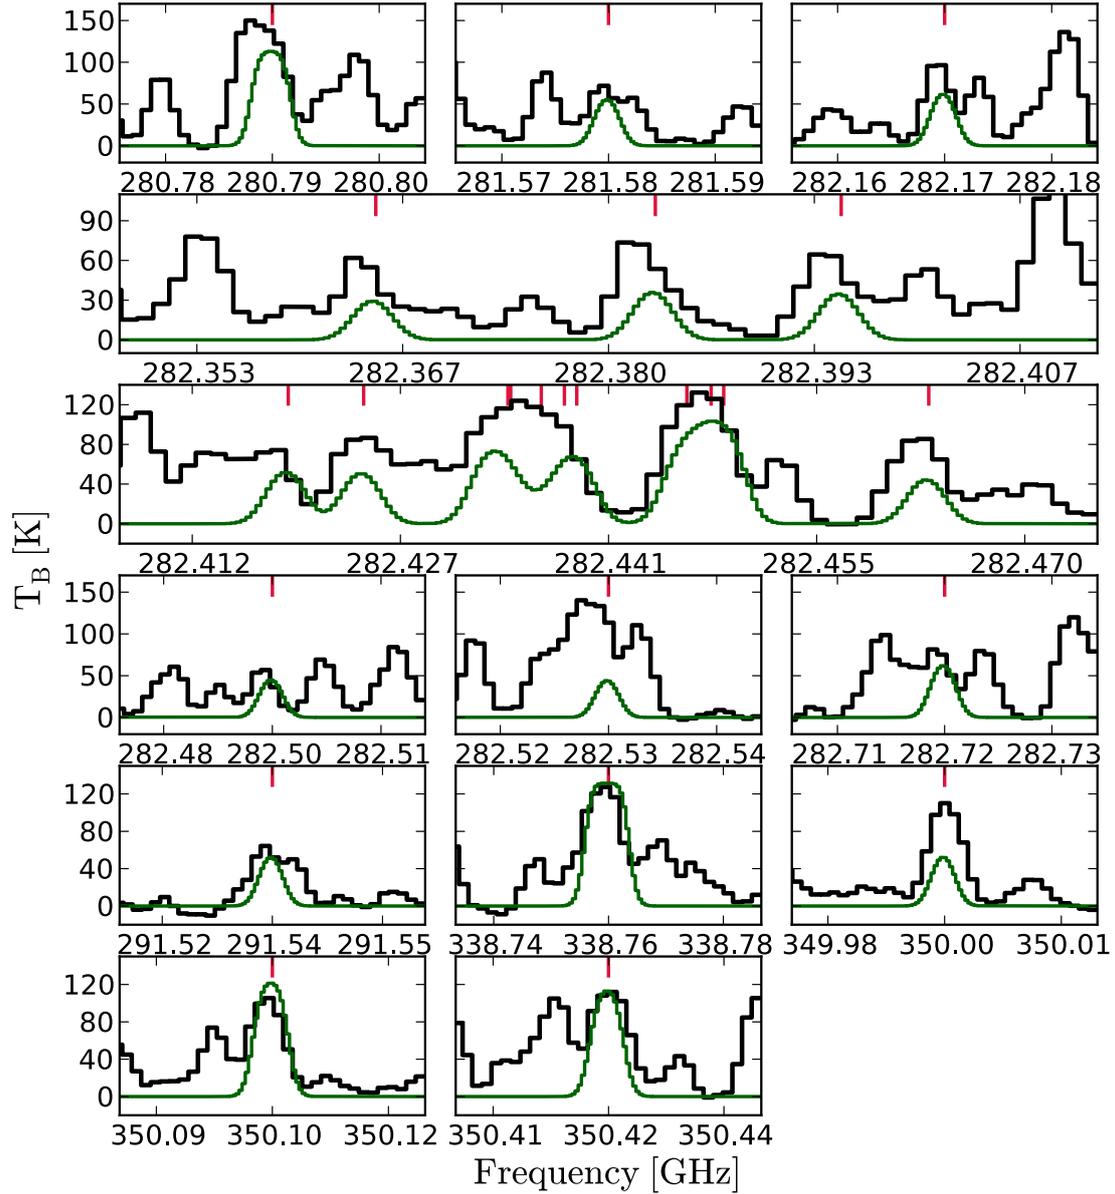

Fig. A.1. $^{13}\text{CH}_3\text{OH}$ transitions with $T_{\text{ex}} < 600$ K and $A_{ij} > 10^{-5}$ s $^{-1}$ detected towards NGC 6334I. Frequencies are shifted to the rest frame of the region. The data and model are shown in black and green respectively. Rest frequencies of individual lines are indicated in red.

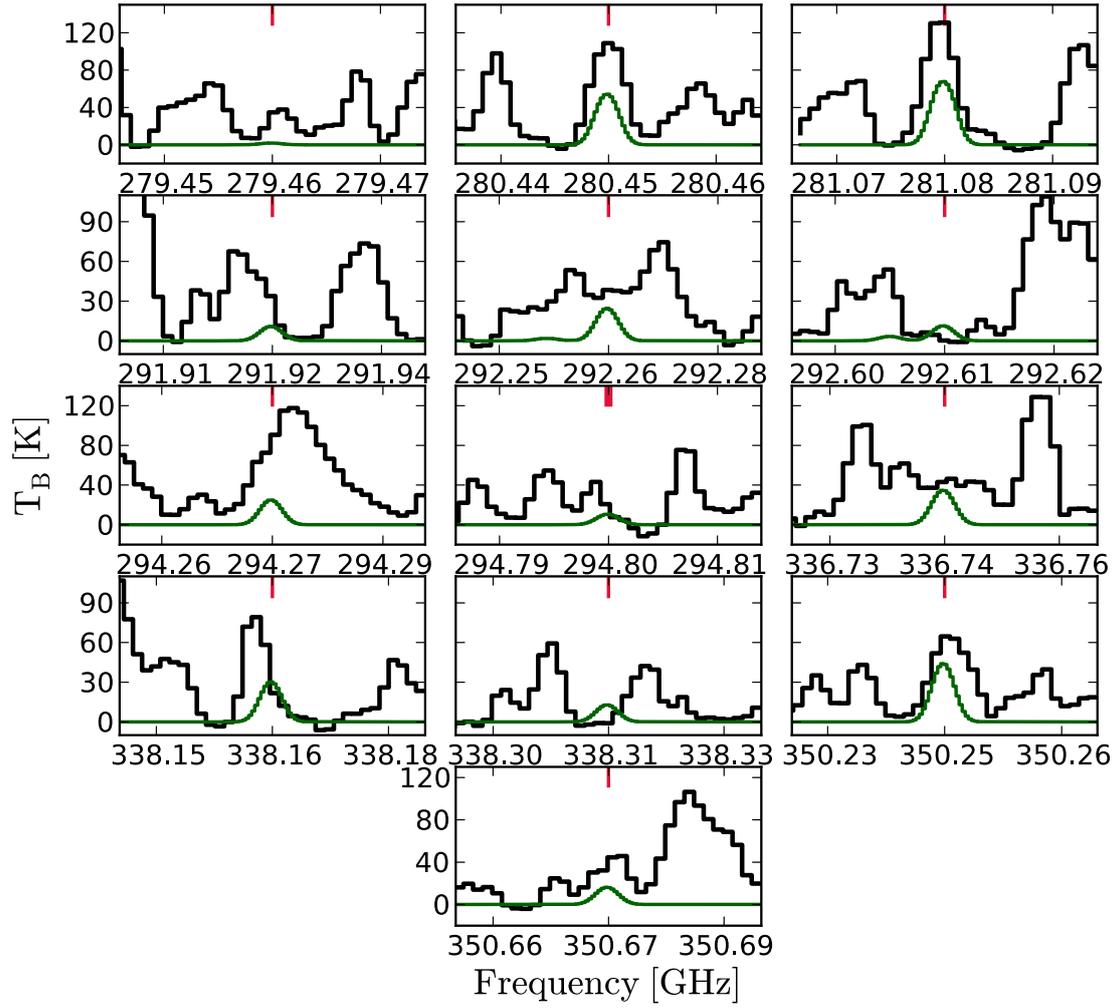

Fig. A.2. $\text{CH}_3^{18}\text{OH}$ transitions with $T_{\text{ex}} < 600$ K and $A_{ij} > 10^{-5}$ s $^{-1}$ detected towards NGC 6334I. Frequencies are shifted to the rest frame of the region. The data and model are shown in black and green respectively. Rest frequencies of individual lines are indicated in red.

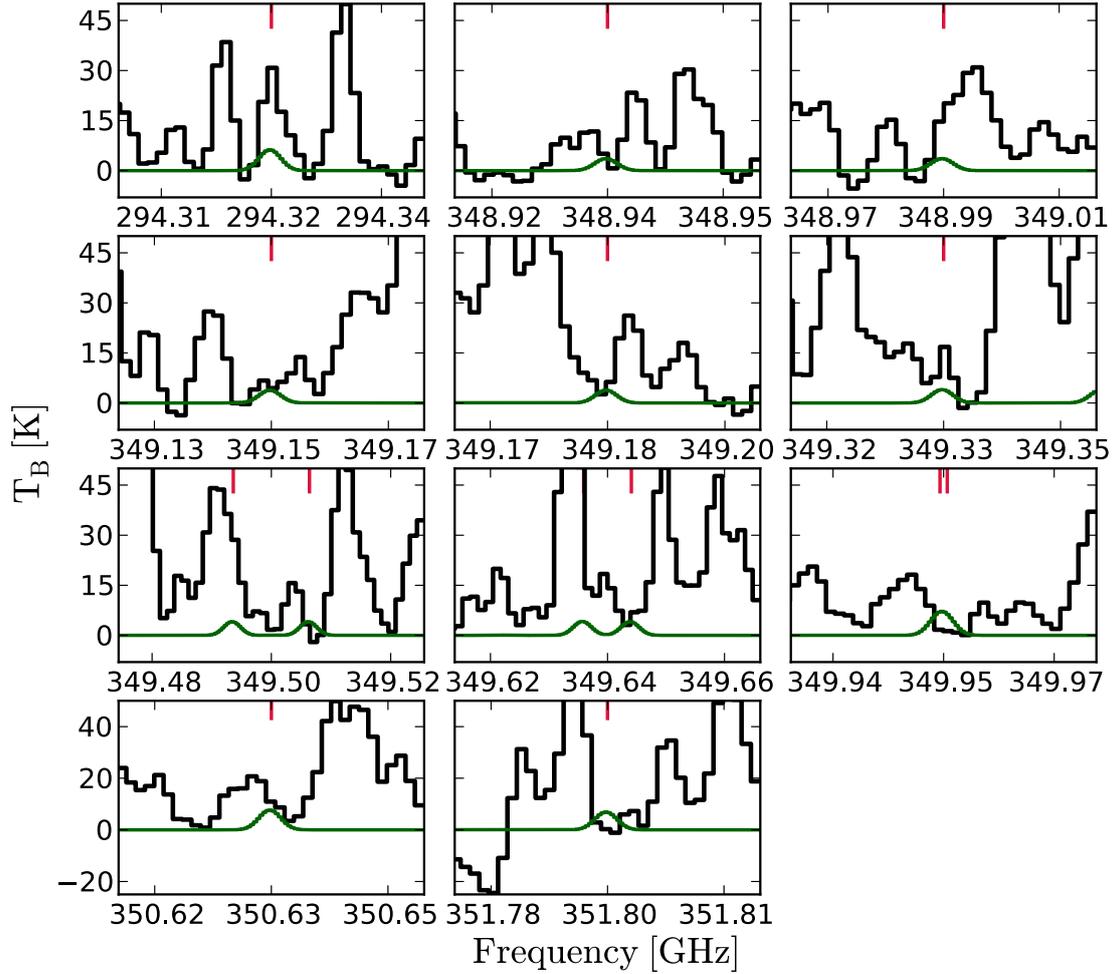

Fig. A.3. Selection of CH_2DOH transitions with $T_{\text{ex}} < 400$ K and $A_{ij} > 10^{-4} \text{ s}^{-1}$ detected towards NGC 6334I. Frequencies are shifted to the rest frame of the region. The data and model are shown in black and green respectively. Rest frequencies of individual lines are indicated in red.

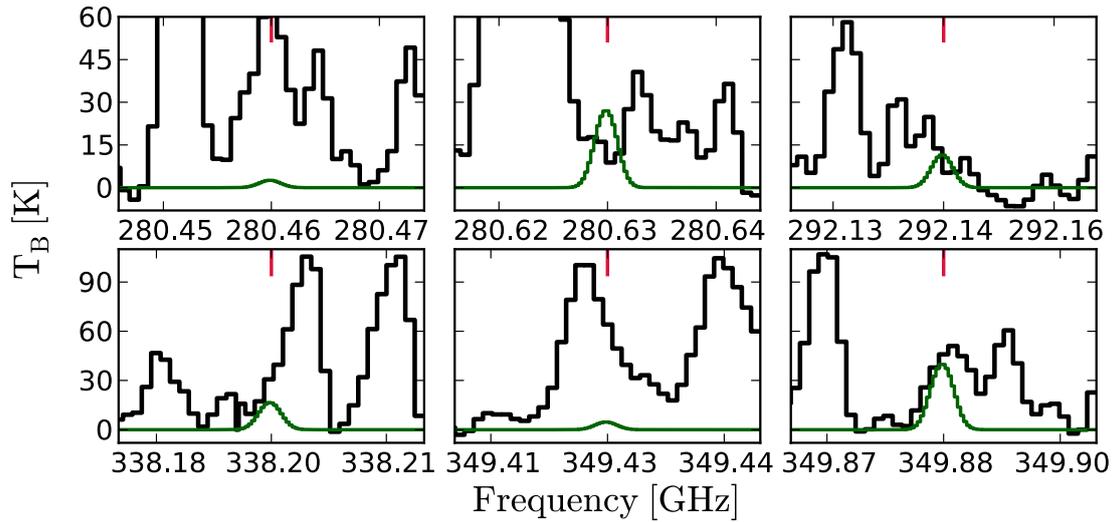

Fig. A.4. CH_3OD transitions detected towards NGC 6334I. Frequencies are shifted to the rest frame of the region. The data and model are shown in black and green respectively. Rest frequencies of individual lines are indicated in red.

Appendix B: Full spectra

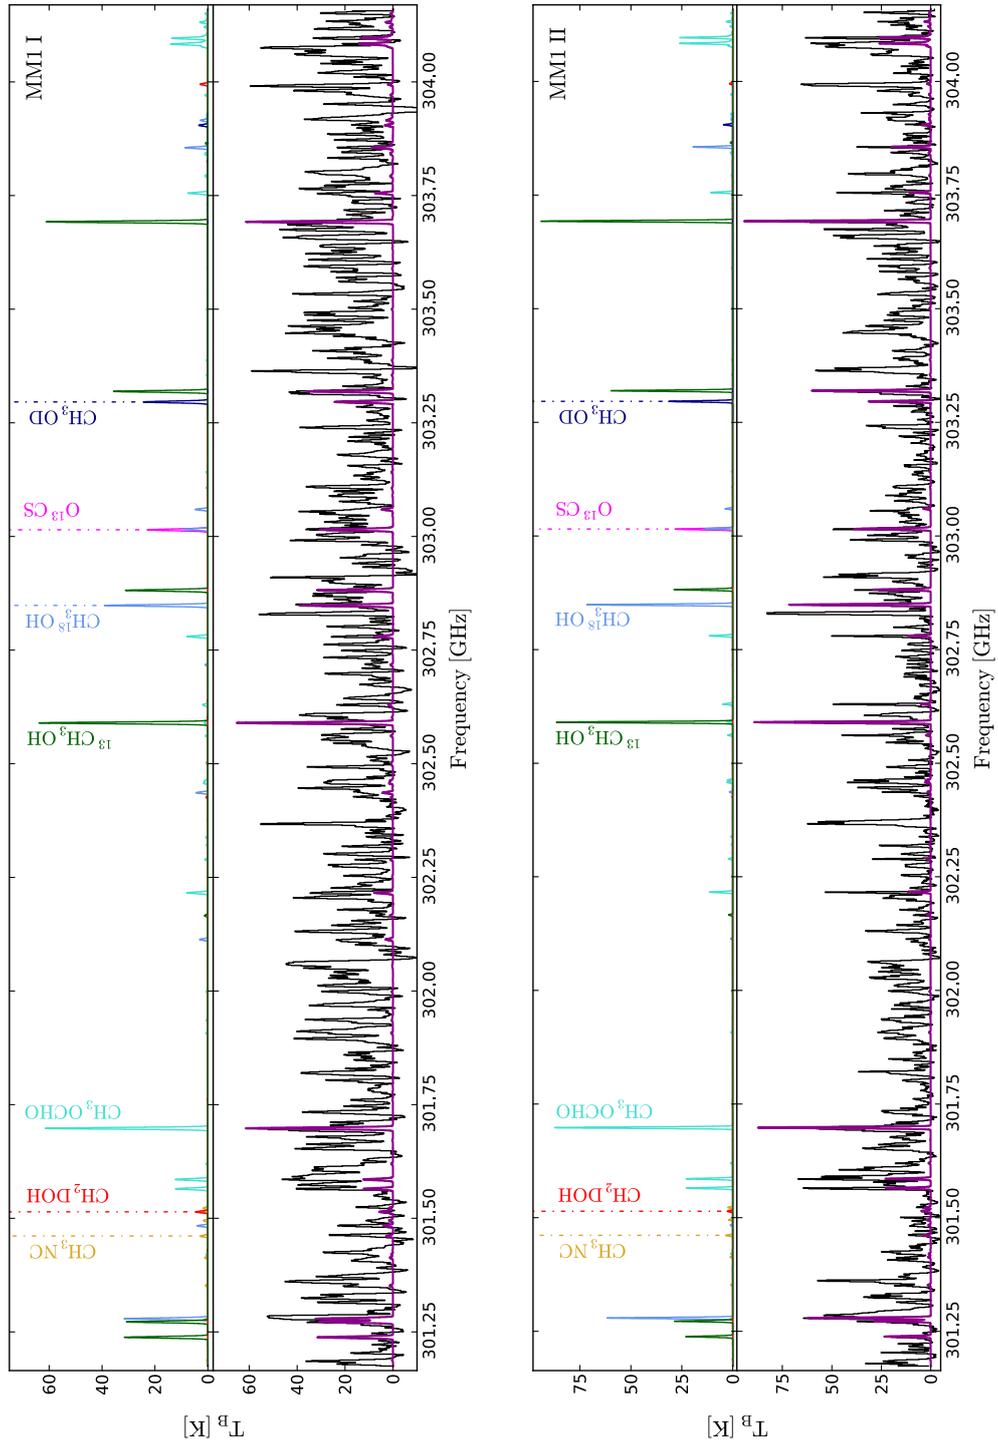

Fig. B.1. MM1 I–V. *Top panels:* model components. *Bottom panels:* data (black) and full model (magenta), i.e., the linear combination of the synthetic spectrum for each species. Frequencies are shifted to the rest frame of the individual regions.

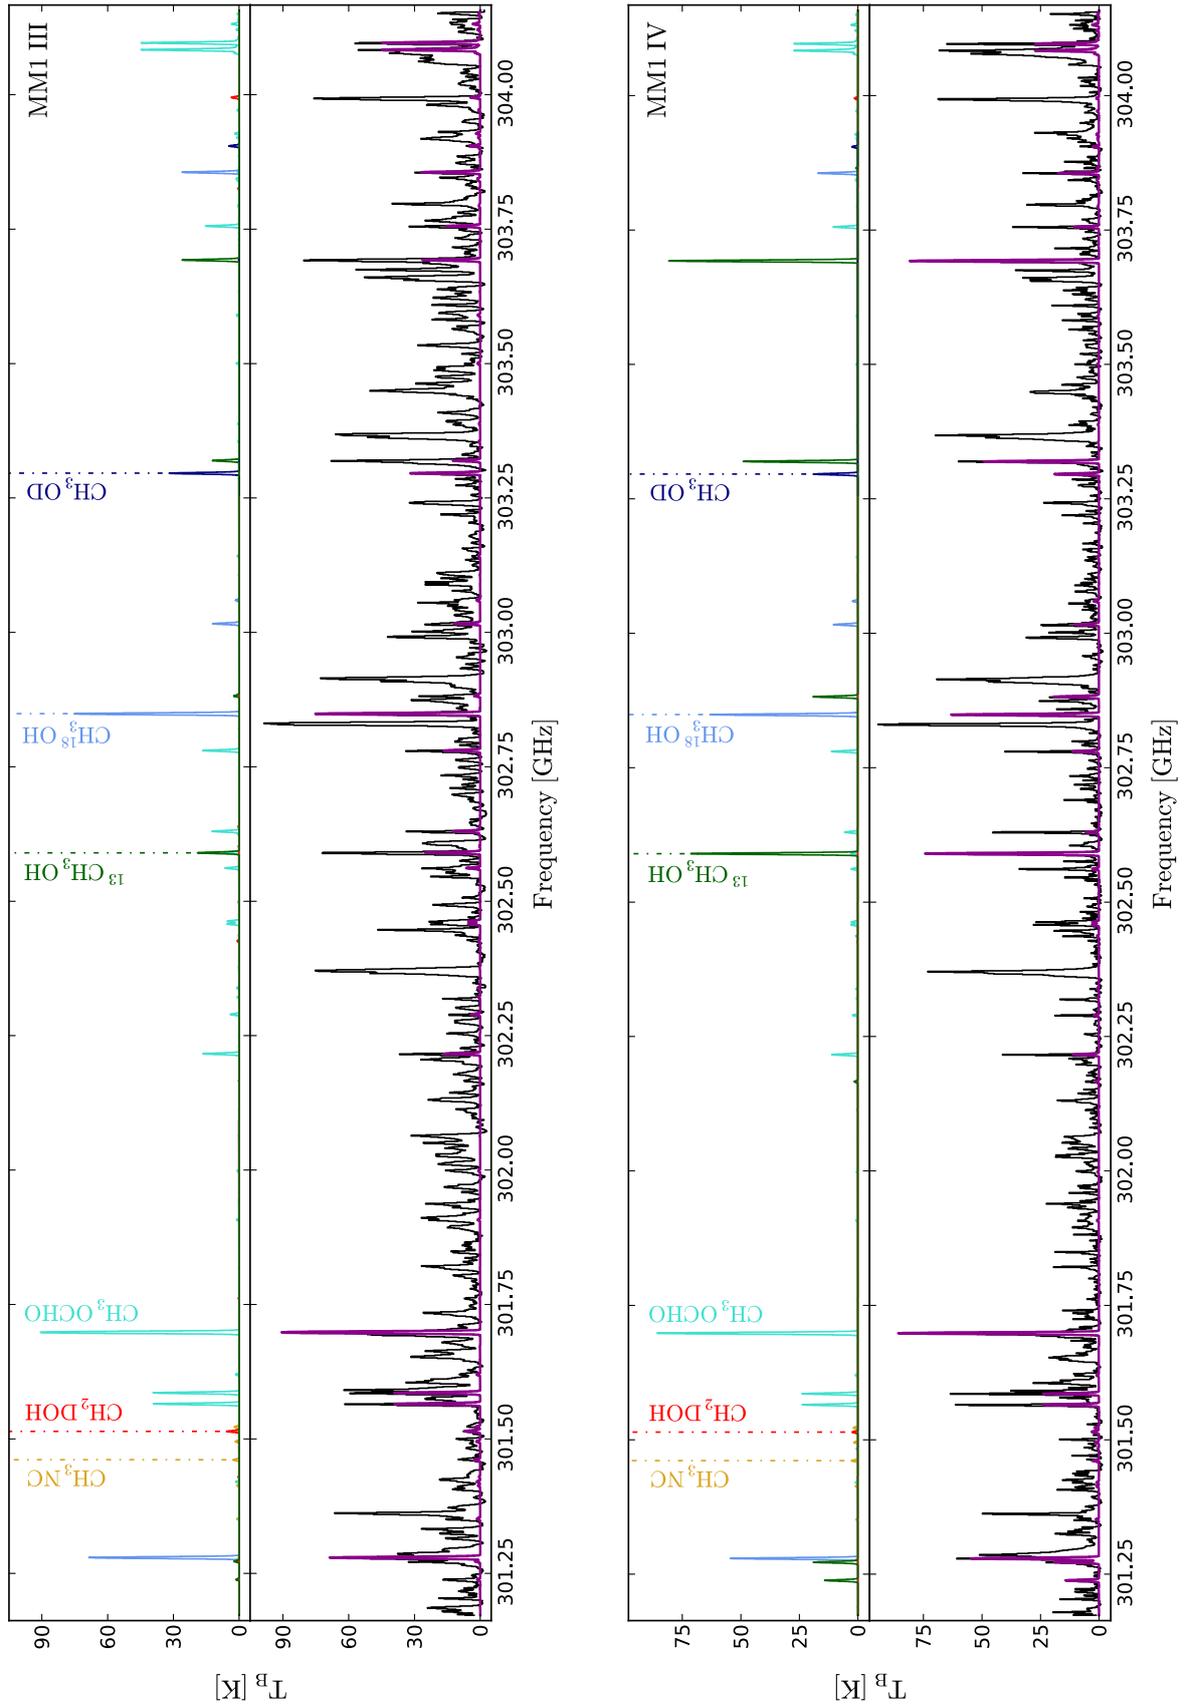

Fig. B.1. Continued.

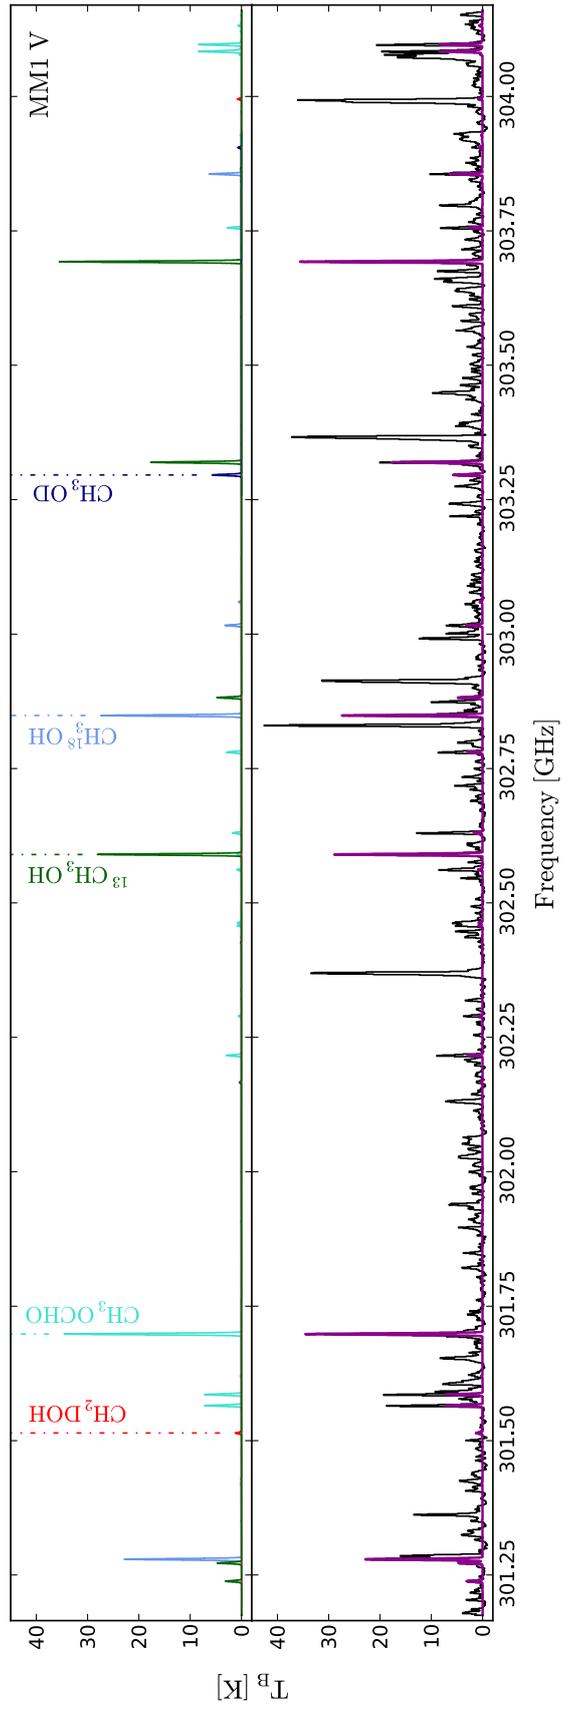

Fig. B.1. Continued.

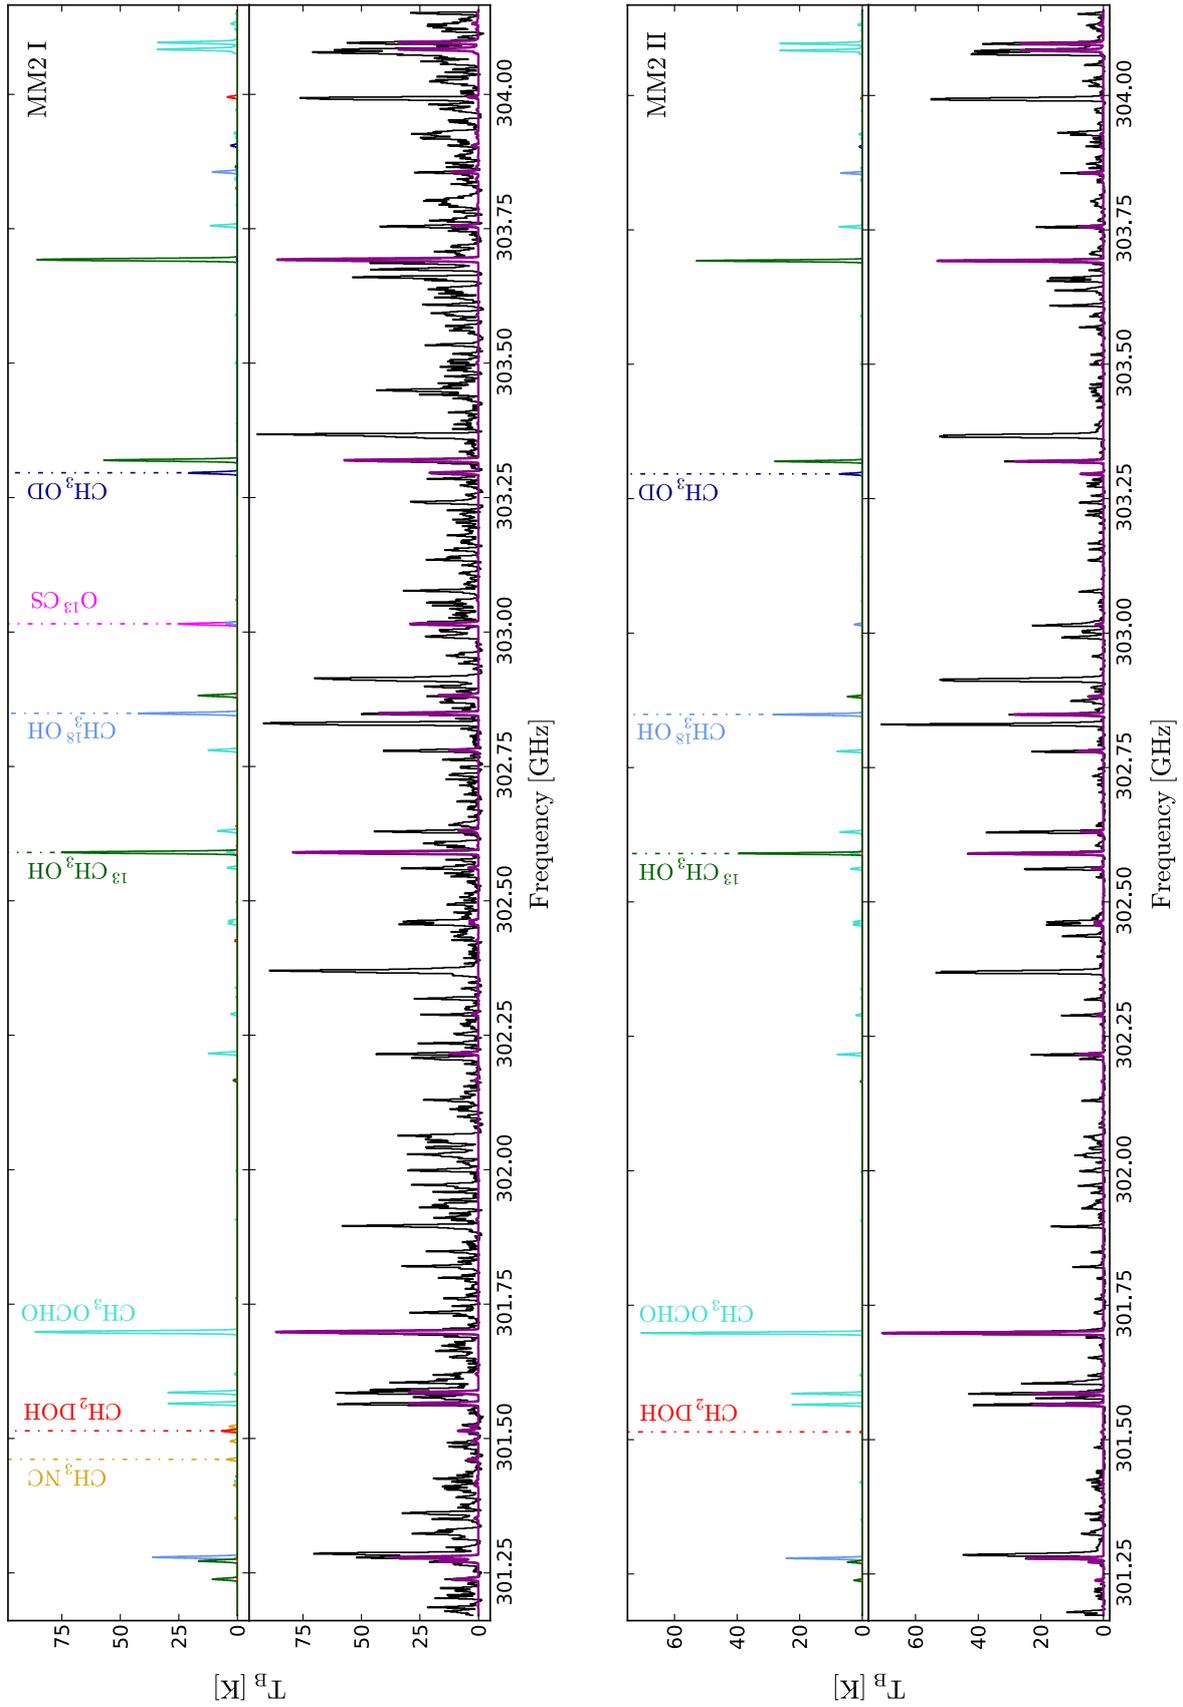

Fig. B.2. MM2 I–II. *Top panels:* model components. *Bottom panels:* data (black) and full model (magenta), i.e., the linear combination of the synthetic spectrum for each species. Frequencies are shifted to the rest frame of the individual regions.

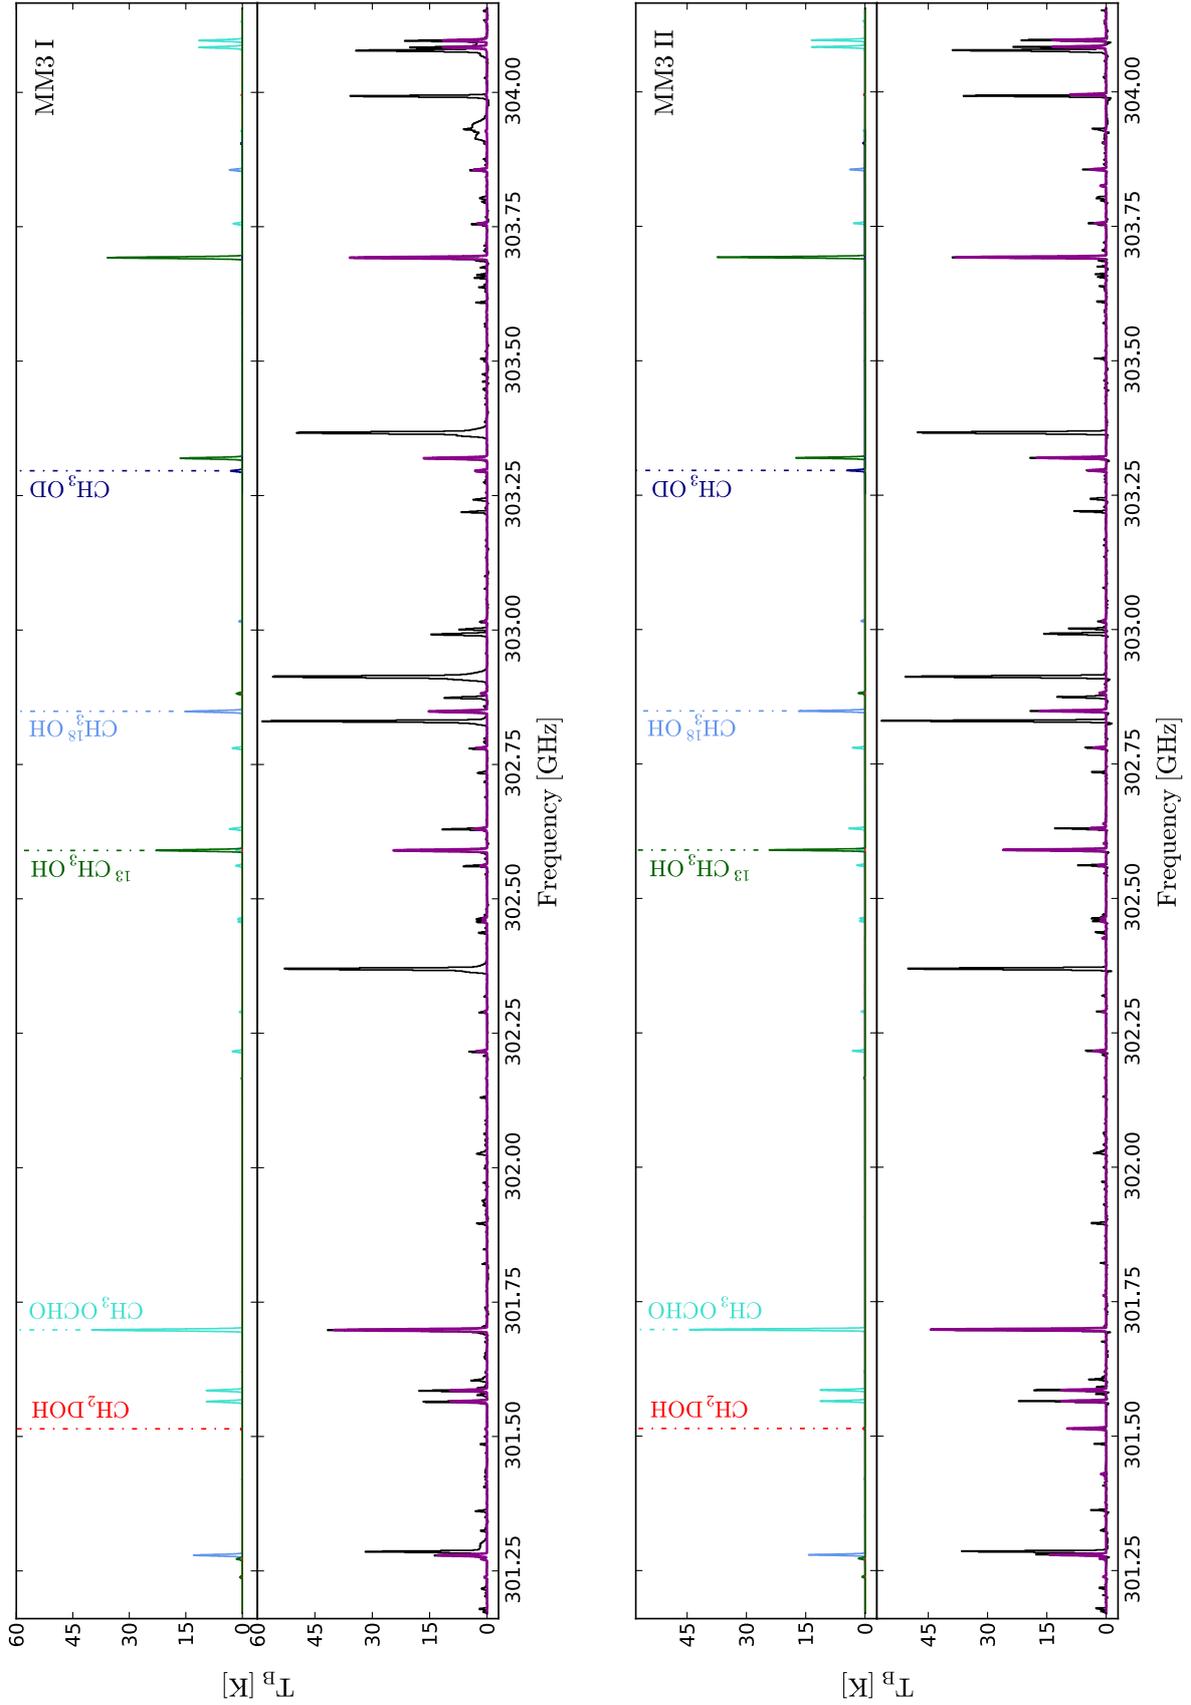

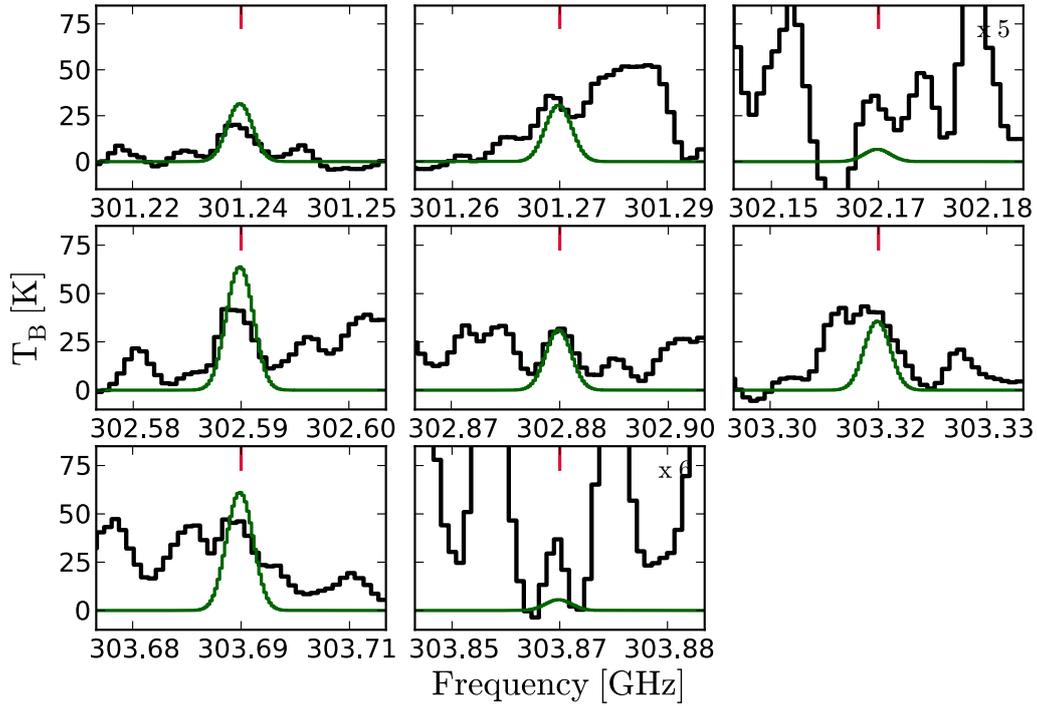

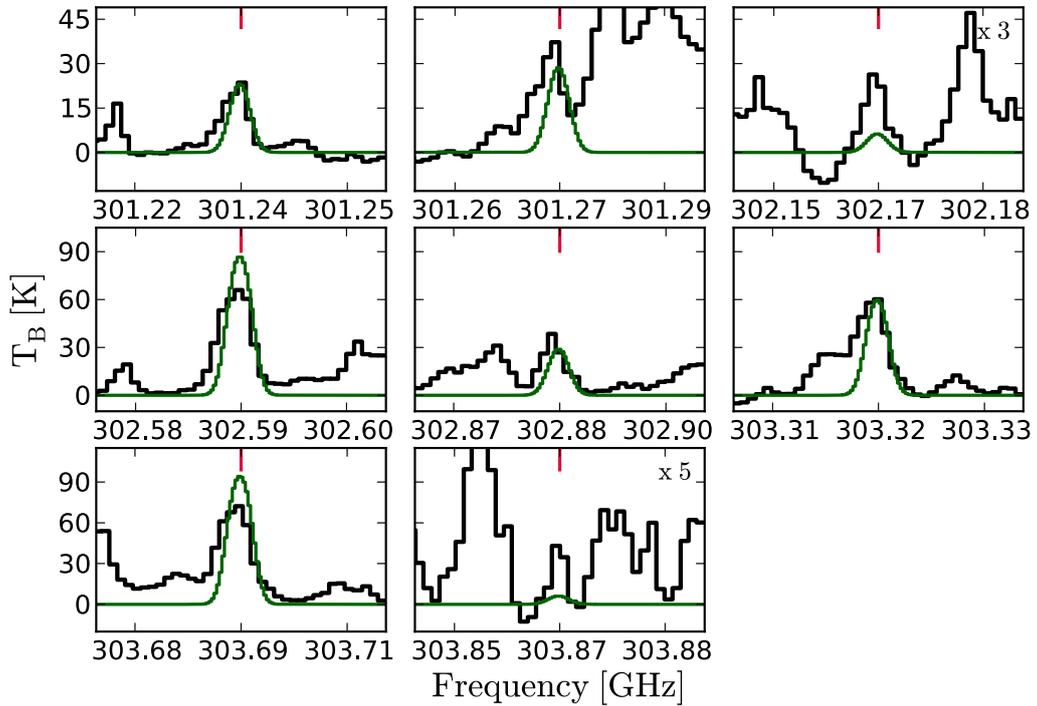

Fig. B.3. MM3 I–II. *Top panels:* model components. *Bottom panels:* data (black) and full model (magenta), i.e., the linear combination of the synthetic spectrum for each species. Frequencies are shifted to the rest frame of the individual regions.

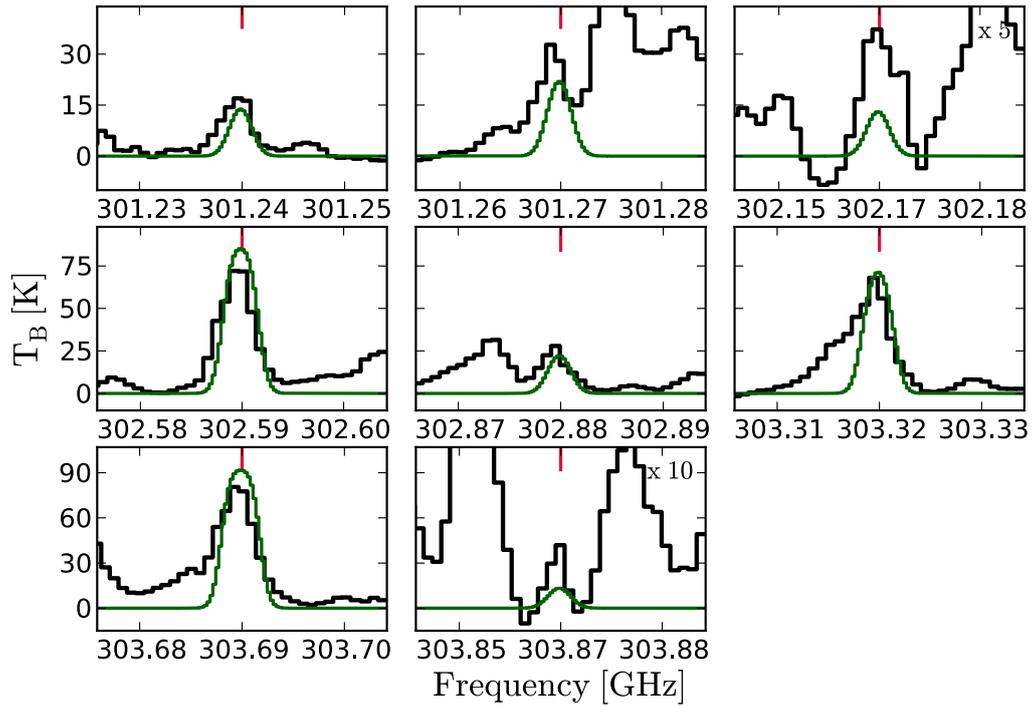

Appendix C: $^{13}\text{CH}_3\text{OH}$ transitions

(a) MM1 I

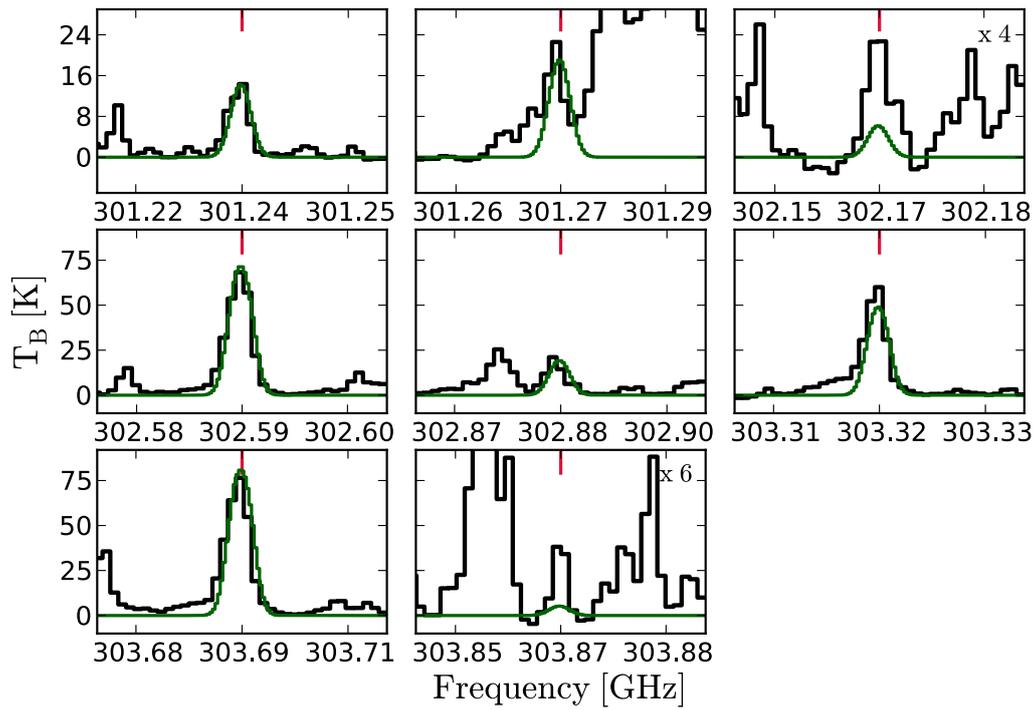

(b) MM1 II

Fig. C.1. All $^{13}\text{CH}_3\text{OH}$ lines detected towards NGC 6334I MM1 I–V. Frequencies are shifted to the rest frame of the individual regions. Green lines represent the modelled spectra of $^{13}\text{CH}_3\text{OH}$ without blending, i.e., excluding the contribution from CH_3OCHO (including the contribution from CH_3OCHO does not change the $^{13}\text{CH}_3\text{OH}$ column density of the best-fit model). To enhance the readability of some panels, both data and model have been scaled up by the factor in the top right corner of the respective panel.

(c) MM1 III

(d) MM1 IV

Fig. C.1. Continued.

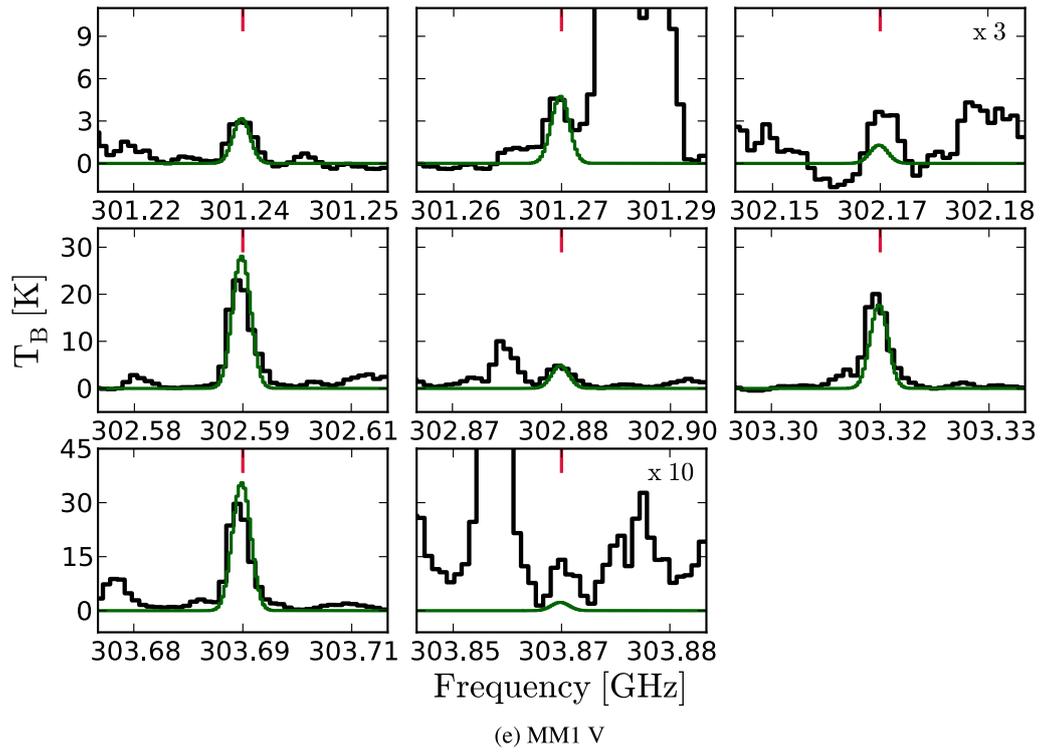

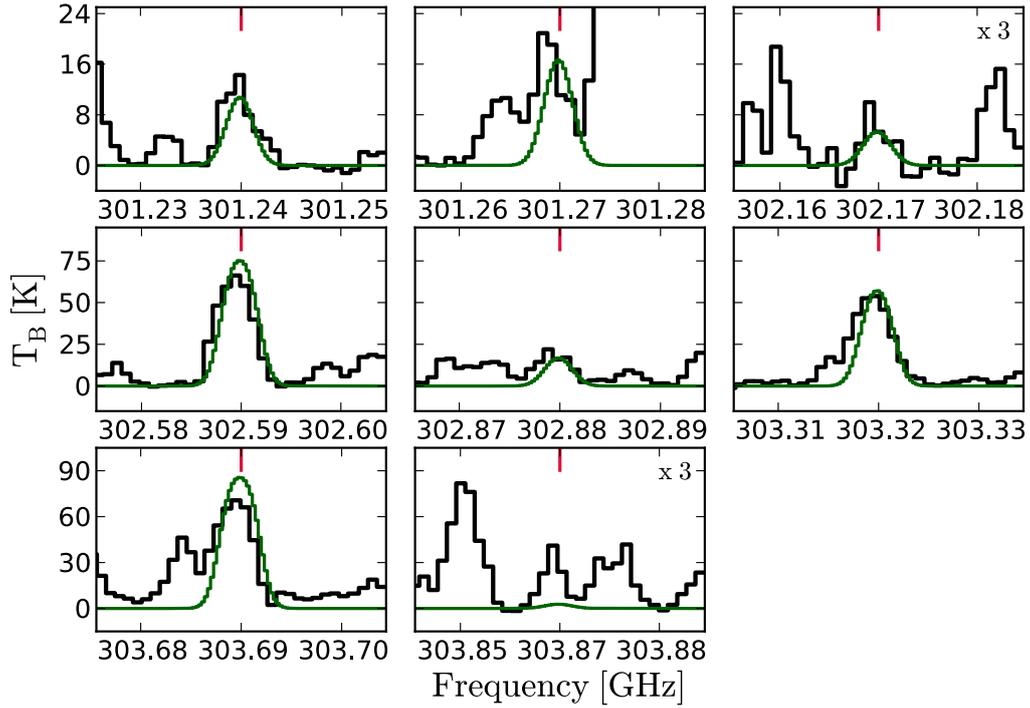

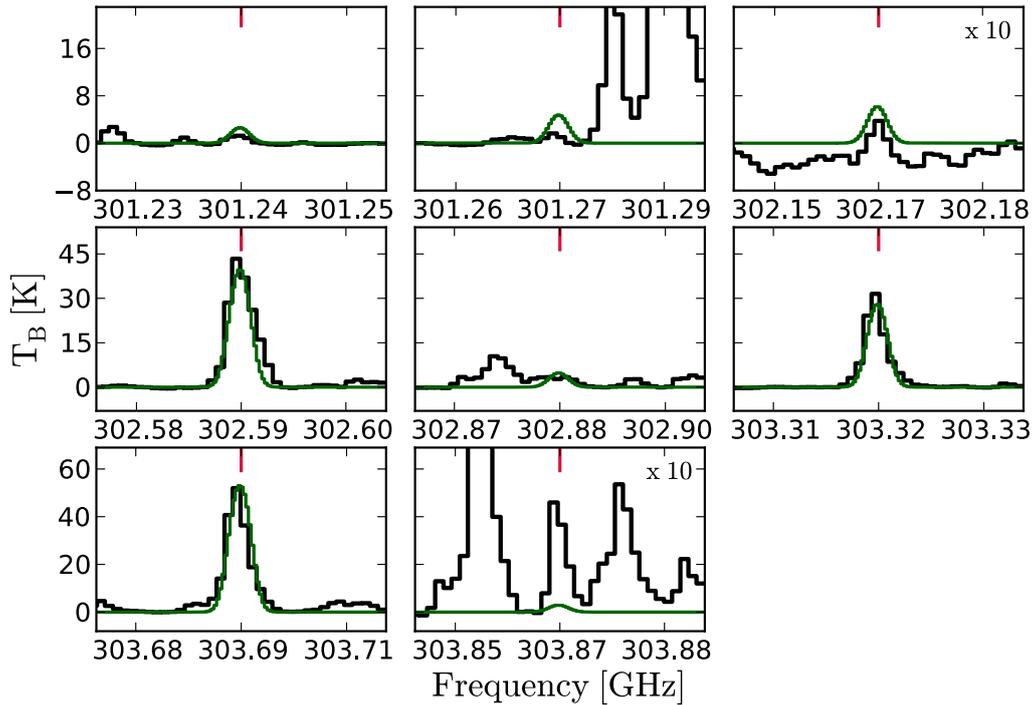

Fig. C.1. Continued.

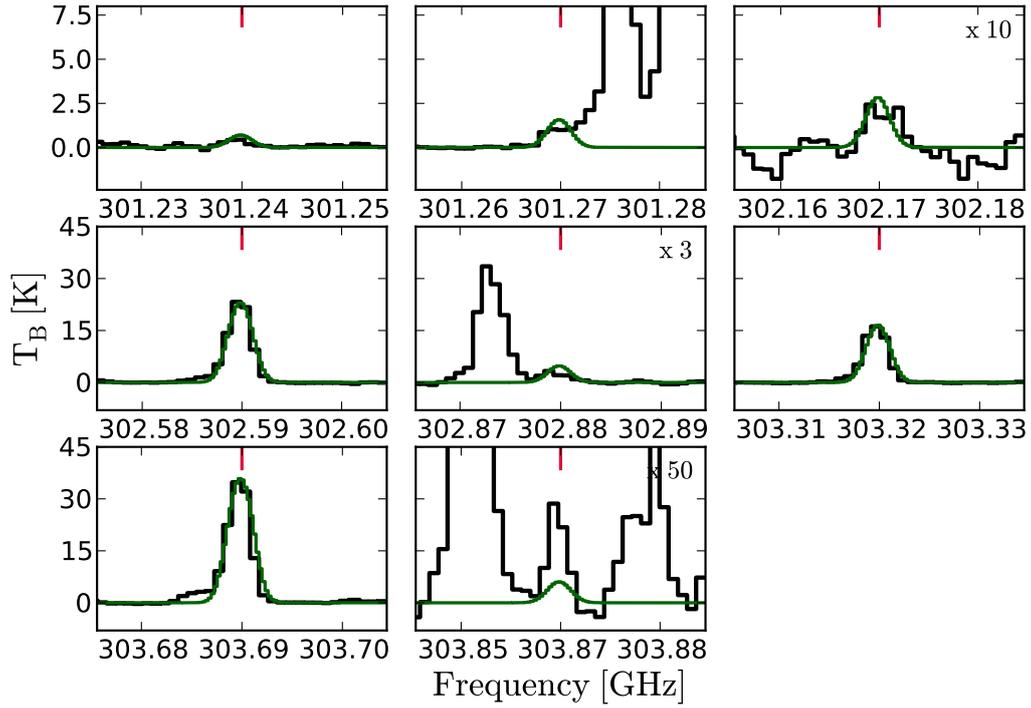

(a) MM2 I

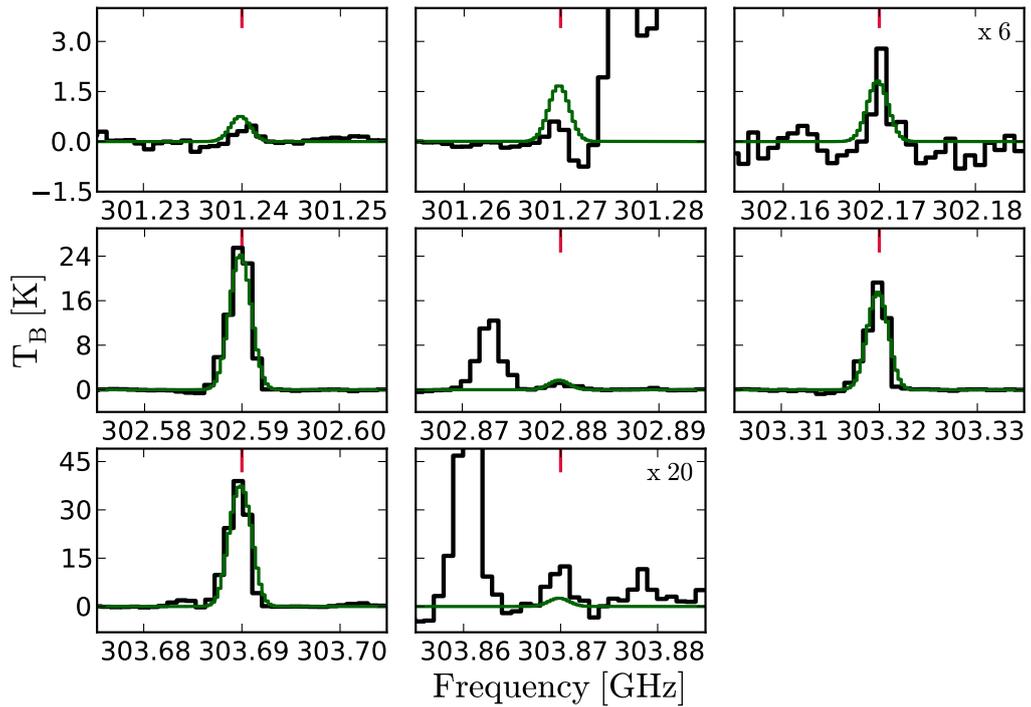

(b) MM2 II

Fig. C.2. All $^{13}\text{CH}_3\text{OH}$ lines detected towards NGC 6334I MM2 I–II. Frequencies are shifted to the rest frame of the individual regions. Green lines represent the modelled spectra of $^{13}\text{CH}_3\text{OH}$ without blending, i.e., excluding the contribution from CH_3OCHO (including the contribution from CH_3OCHO does not change the $^{13}\text{CH}_3\text{OH}$ column density of the best-fit model). To enhance the readability of some panels, both data and model have been scaled up by the factor in the top right corner of the respective panel.

(a) MM3 I

(b) MM3 II

Fig. C.3. All $^{13}\text{CH}_3\text{OH}$ lines detected towards NGC 6334I MM3 I–II. Frequencies are shifted to the rest frame of the individual regions. Green lines represent the modelled spectra of $^{13}\text{CH}_3\text{OH}$ without blending, i.e., excluding the contribution from CH_3OCHO (including the contribution from CH_3OCHO does not change the $^{13}\text{CH}_3\text{OH}$ column density of the best-fit model). To enhance the readability of some panels, both data and model have been scaled up by the factor in the top right corner of the respective panel.

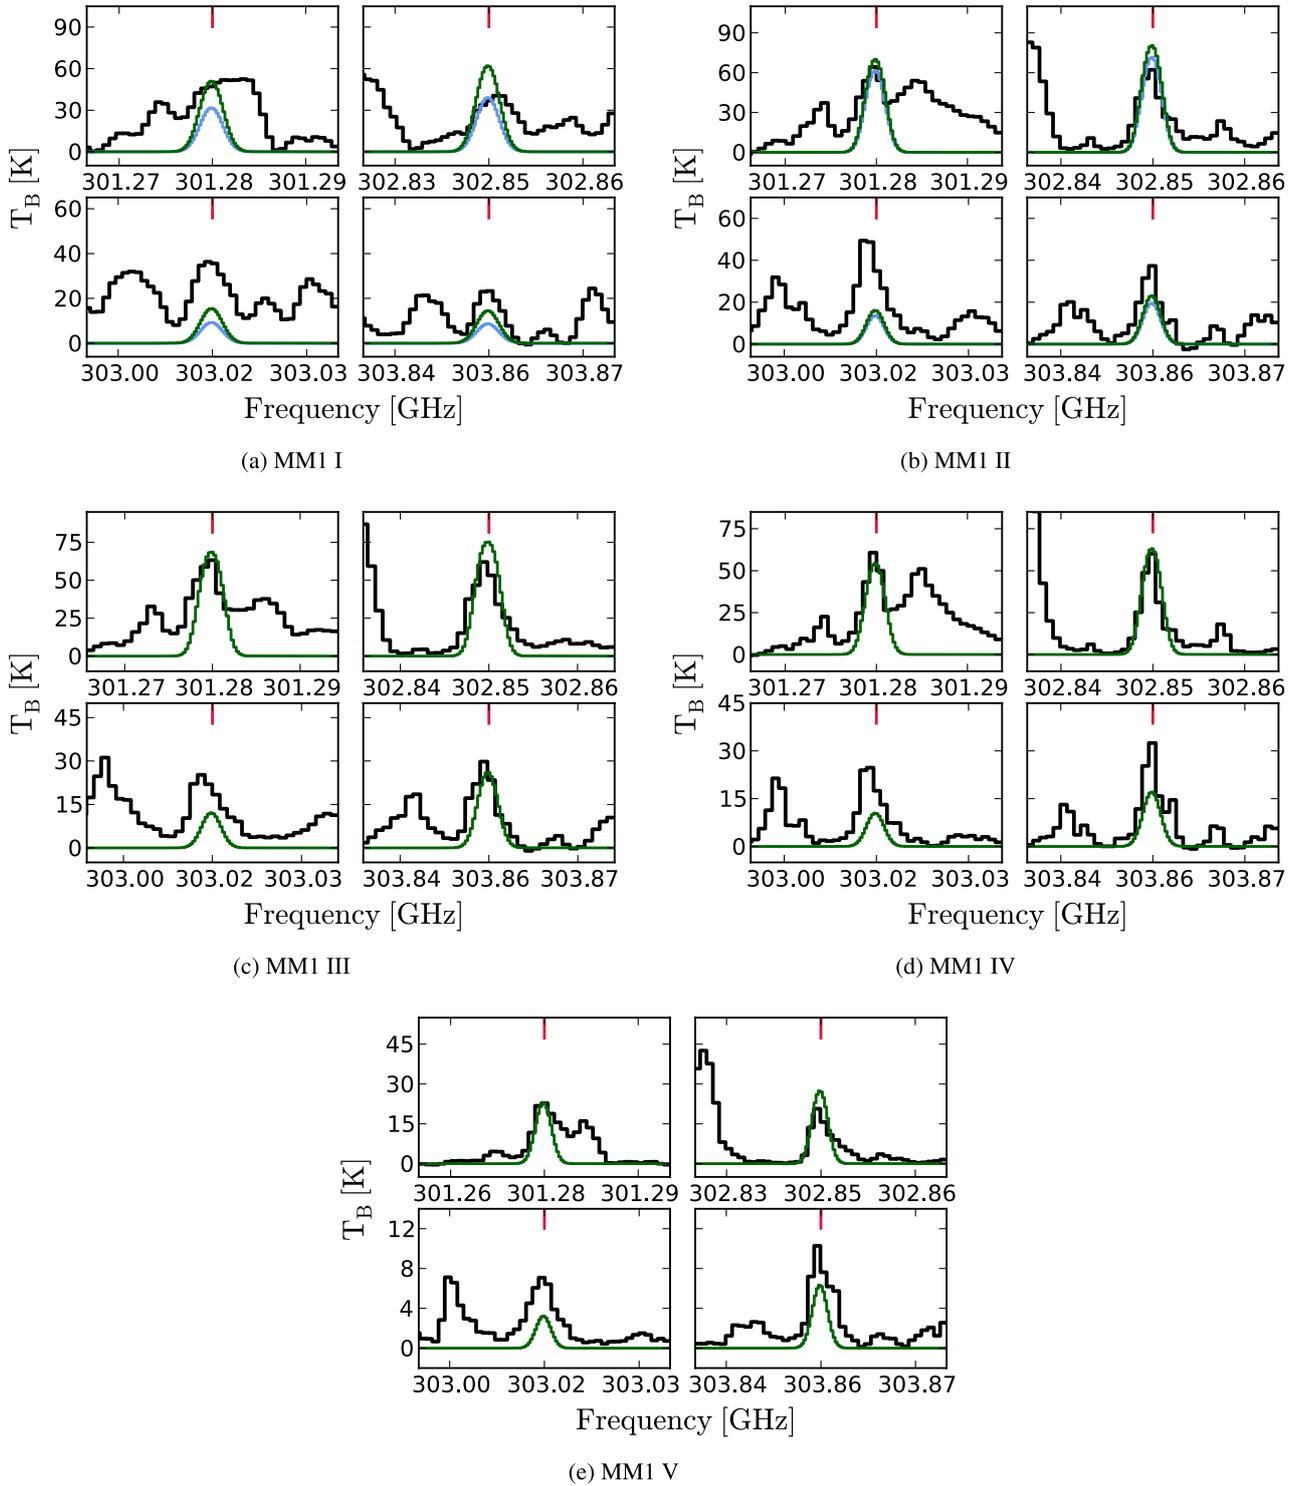

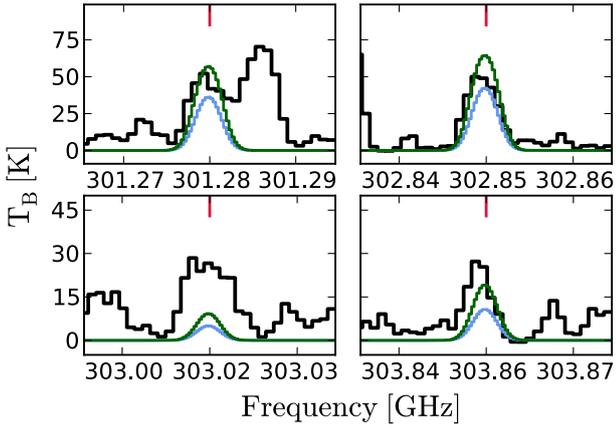

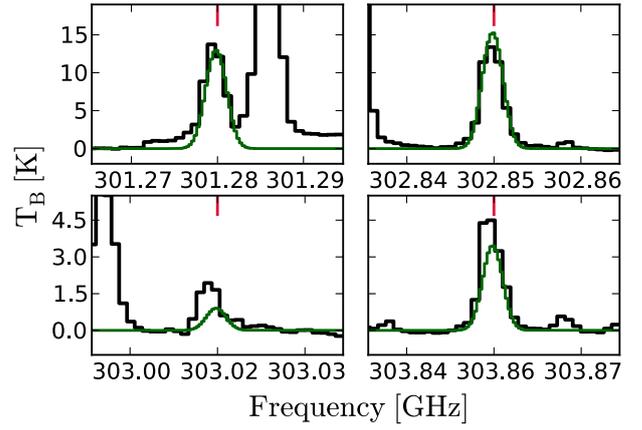

Appendix D: CH₃¹⁸OH transitions

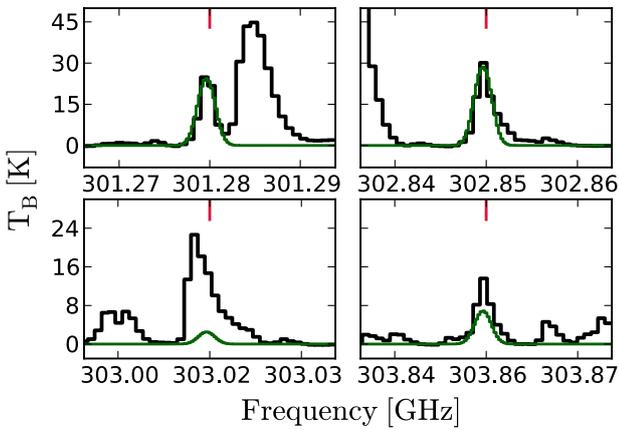

Fig. D.1. All CH₃¹⁸OH lines detected towards NGC 6334I MM1 I–V. Frequencies are shifted to the rest frame of the individual regions. Blue and green lines represent the modelled spectra of CH₃¹⁸OH in each region with and without blending, i.e., including and excluding the contribution from O¹³CS, respectively. For regions MM1 III–V only the pure-CH₃¹⁸OH fits are shown.

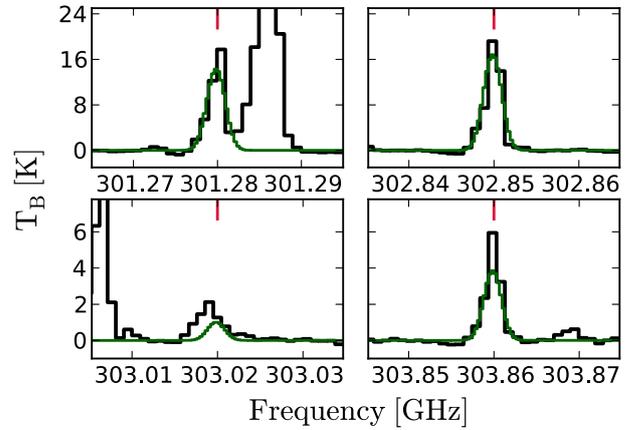

(a) MM2 I

(a) MM3 I

(b) MM2 II

(b) MM3 II

Fig. D.2. All $\text{CH}_3^{18}\text{OH}$ lines detected towards NGC 6334I MM2 I–II. Frequencies are shifted to the rest frame of the individual regions. Blue and green lines represent the modelled spectra of $\text{CH}_3^{18}\text{OH}$ in each region with and without blending, i.e., including and excluding the contribution from O^{13}CS , respectively. For regions MM2 II only the pure- $\text{CH}_3^{18}\text{OH}$ fits are shown.

Fig. D.3. All $\text{CH}_3^{18}\text{OH}$ lines detected towards NGC 6334I MM3 I–II. Frequencies are shifted to the rest frame of the individual regions. Green lines represent the modelled spectra of $\text{CH}_3^{18}\text{OH}$ in each region with and without blending, i.e., including and excluding the contribution from O^{13}CS .

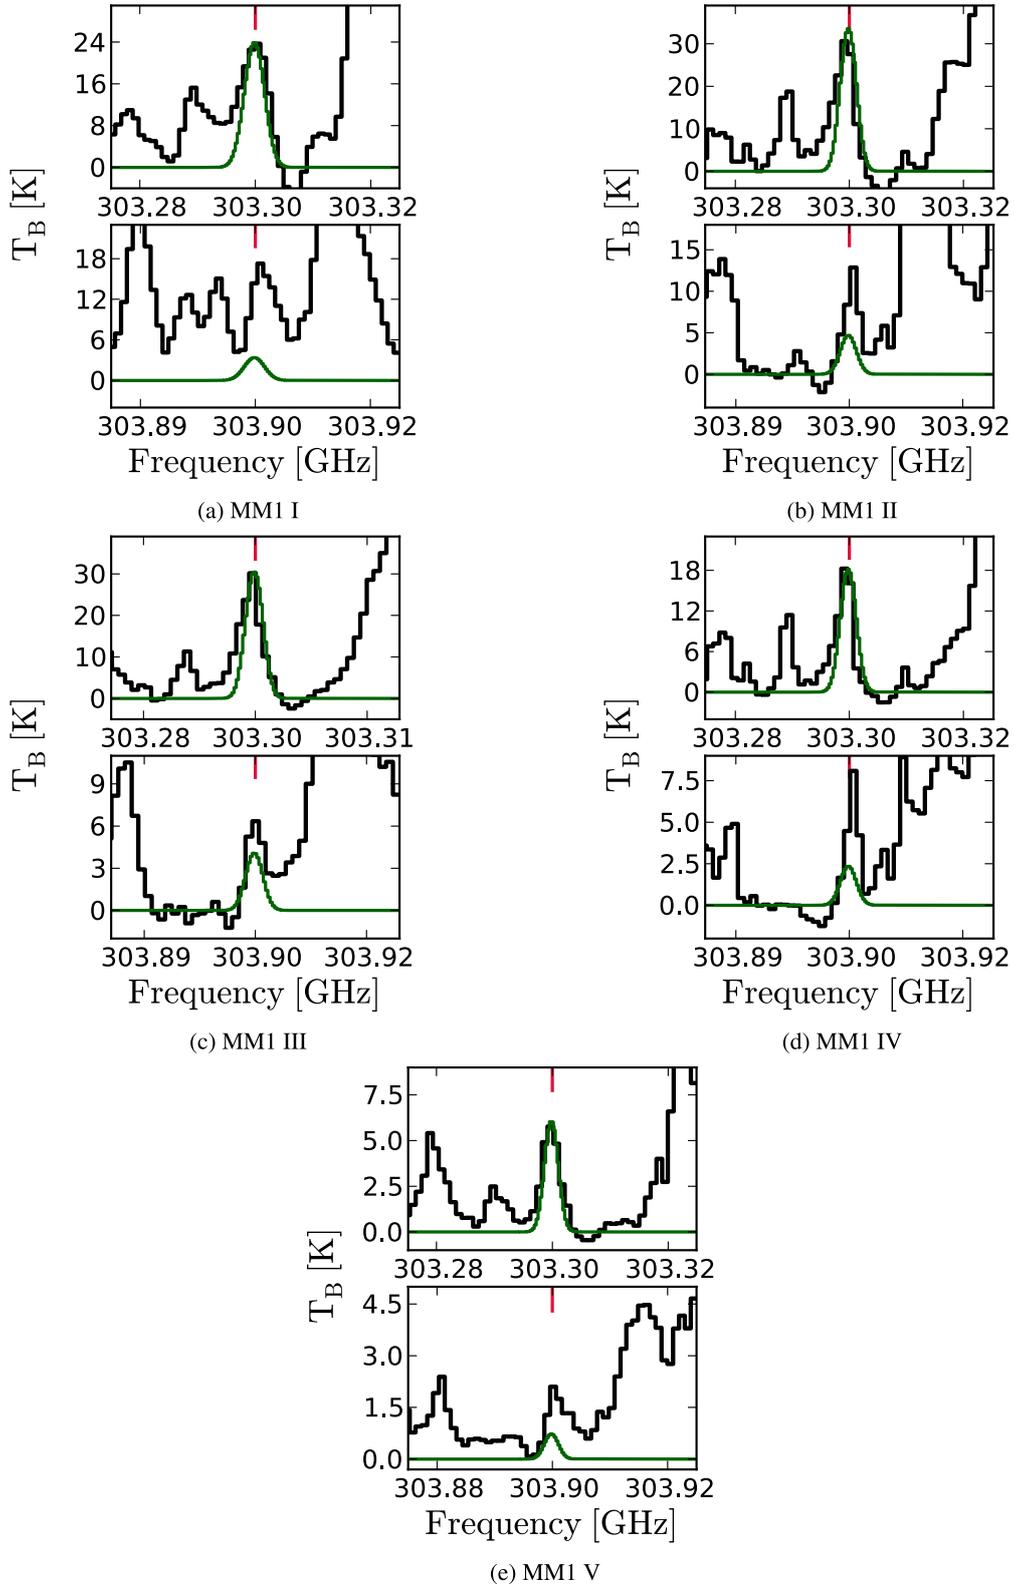

Appendix E: CH₃OD transitions

Fig. E.1. All CH₃OD lines detected towards NGC 6334I MM1 I–V. Frequencies are shifted to the rest frame of the individual regions. Green lines represent the modelled spectra of CH₃OD in each region.

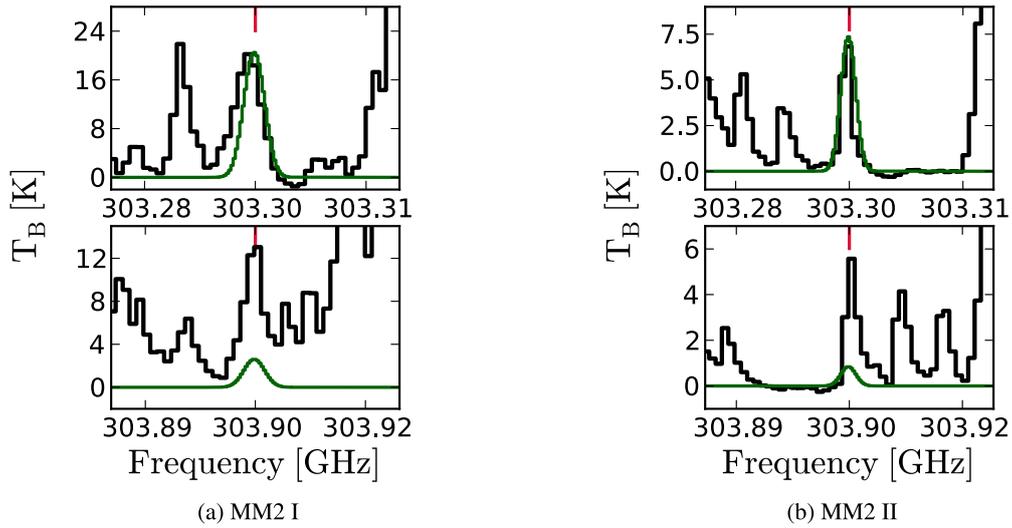

Fig. E.2. All CH_3OD lines detected towards NGC 6334I MM2 I–II. Frequencies are shifted to the rest frame of the individual regions. Green lines represent the modelled spectra of CH_3OD in each region.

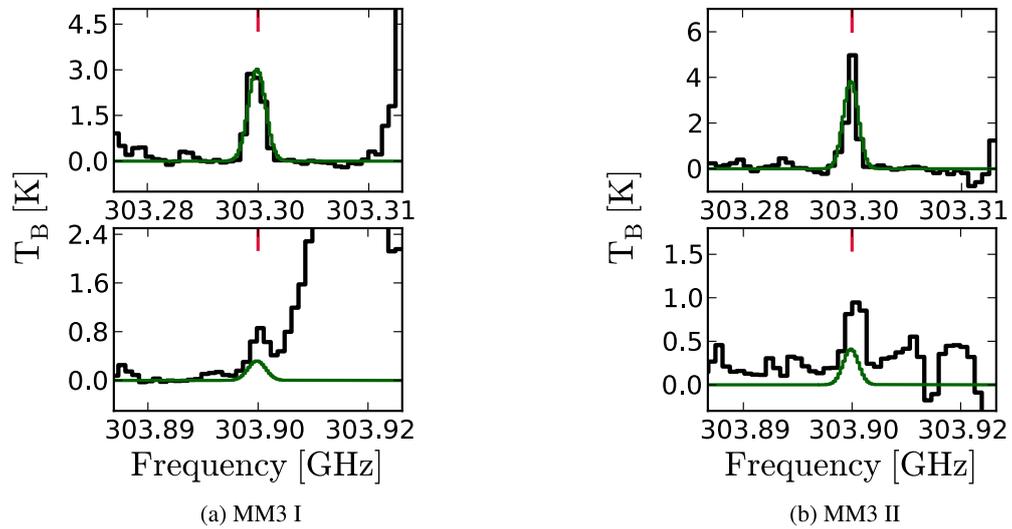

Fig. E.3. All CH_3OD lines detected towards NGC 6334I MM3 I–II. Frequencies are shifted to the rest frame of the individual regions. Green lines represent the modelled spectra of CH_3OD in each region.
