\textbf{ABSTRACT}

Context. The cosmological concordance model (ΛCDM) is the current standard model in cosmology thanks to its ability to reproduce the observations. The first observational evidence for this model appeared roughly 20 years ago from the type-Ia supernovae (SNIa) Hubble diagram from two different groups. However, there has been some debate in the literature concerning the statistical treatment of SNIa, and their stature as proof of cosmic acceleration.

\textbf{Aims.} In this paper we relax the standard assumption that SNIa intrinsic luminosity is independent of redshift, and examine whether it may have an impact on our cosmological knowledge and more precisely on the accelerated nature of the expansion of the universe.

\textbf{Methods.} To maximise the scope of this study, we do not specify a given cosmological model, but we reconstruct the expansion rate of the universe through a cubic spline interpolation fitting the observations of the different cosmological probes: SNIa, baryon acoustic oscillations (BAO), and the high-redshift information from the cosmic microwave background (CMB).

\textbf{Results.} We show that when SNIa intrinsic luminosity is not allowed to vary as a function of redshift, cosmic acceleration is definitely proven in a model-independent approach. However, allowing for redshift dependence, a nonaccelerated reconstruction of the expansion rate is able to fit, at the same level of ΛCDM, the combination of SNIa and BAO data, both treating the BAO standard ruler \( r_d \) as a free parameter (not entering on the physics governing the BAO), and adding the recently published prior from CMB observations. We further extend the analysis by including the CMB data. In this case we also consider a third way to combine the different probes by explicitly computing \( r_d \) from the physics of the early universe, and we show that a nonaccelerated reconstruction is able to nicely fit this combination of low- and high-redshift data. We also check that this reconstruction is compatible with the latest measurements of the growth rate of matter perturbations. We finally show that the value of the Hubble constant (\( H_0 \)) predicted by this reconstruction is in tension with model-independent measurements.

\textbf{Conclusions.} We present a model-independent reconstruction of a nonaccelerated expansion rate of the universe that is able to fit all the main background cosmological probes nicely. However, the predicted value of \( H_0 \) is in tension with recent direct measurements. Our analysis points out that a final reliable and consensual value for \( H_0 \) is critical to definitively prove cosmic acceleration in a model-independent way.

\textbf{Key words.} cosmology: observations – cosmological parameters – supernovae: individual: SNIa luminosity evolution

1. Introduction

The cosmological concordance model (ΛCDM), mainly composed of cold dark matter and dark energy, provides an extremely precise description of the properties of our universe with very few parameters. However, recent observations (Planck Collaboration XIII 2016; Betoule et al. 2014; Beutler et al. 2011) show that these components form about 95% of the energy content of the universe, and their true nature remains unknown. The evidence for an accelerated expansion, coming from the type-Ia supernovae (SNIa) Hubble diagram from two different groups, was key to consider the ΛCDM as the concordance model. However, there has recently been a debate in the literature over whether SNIa data alone, or combined with other low-redshift cosmological probes, can prove the accelerated expansion of the universe (Nielsen et al. 2016; Shariff et al. 2016; Rubin & Hayden 2016; Riemer-Marcher & Mead 2016; Tutusaus et al. 2017; Dam et al. 2017; Lonappan et al. 2018; Haridasu et al. 2017; Lin et al. 2018; Luković et al. 2018; Colin et al. 2018). For instance, the authors in Nielsen et al. (2016) claim that, allowing for the varying shape of the light curve and extinction by dust, they find that SNIa data are still quite consistent with a constant rate of expansion, while the authors in Rubin & Hayden (2016) claim, redoing this analysis, a 11.2\( \sigma \) confidence level for acceleration with SNIa data alone in a flat universe.

In SNIa analyses it is usually assumed that two different SNIa in two different galaxies with the same color, stretch of the light curve, and host stellar mass, have on average the same intrinsic luminosity, independently of the redshift. In this work we follow the approach of our previous analysis (Tutusaus et al. 2017), and we relax this assumption by allowing these SNIa to have different intrinsic luminosities as a function of redshift. Relaxing this assumption of redshift independence has also been considered in other analyses (Wright 2002; Drell et al. 2000; Linden et al. 2009; Nordin et al. 2008; Ferramacho et al. 2009; L’Huillier et al. 2019). In Tutusaus et al. (2017) it was shown that a nonaccelerated power-law cosmology was able to fit the main low-redshift cosmological probes: SNIa, the baryon acoustic oscillations (BAO), the Hubble parameter as a function of the
redshift \((H(z))\), and measurements of the growth of structures \((f(r_s(z)))\), when some intrinsic luminosity redshift dependence is allowed. Nevertheless, this specific power-law model is excluded when considering cosmic microwave background (CMB) information (as it was shown in Tutusaus et al. 2016), and recently confirmed by the authors of Riess et al. (2018a), who showed that such a model cannot fit the latest SNIa observations at \(z > 1\), even when accounting for some luminosity evolution. In this paper we extend our previous study with a model-independent analysis, and we include the latest BAO observations as well as the complementary high-redshift CMB data. Concerning the model independence, we follow the approach of Bernal et al. (2016) and reconstruct the expansion rate at late times through a cubic spline interpolation.

In Sect. 2 we present the different cosmological probes and the specific data sets considered in the analysis. In Sect. 3 we describe the methodology used to reconstruct the expansion rate in a model-independent way. We provide the results of our study in Sect. 4, and we conclude in Sect. 5.

2. Cosmological probes

In this section we present the different cosmological probes considered in the analysis, as well as the specific data sets used.

2.1. Type-Ia supernovae

Type-Ia supernovae are considered standardizable candles and they are useful to measure cosmological distances and break some degeneracies present in other cosmological probes. The standard observable used in SNIa measurements is the so-called distance modulus,

\[
\mu(z) = 5 \log_{10} \left( \frac{H_0}{c} d_L(z) \right),
\]

where \(d_L(z) = (1 + z)r(z)\) is the luminosity distance, and \(r(z)\) the comoving distance.

The standardization of SNIa is based on empirical observation that they form a homogeneous class of objects, whose variability can be characterized by two parameters (Tripp 1998): the time stretching of the light curve (\(H(z)\)) and the SNIa color at maximum brightness (\(C\)). If we assume that different SNIa with identical color, shape, and galactic environment have on average the same intrinsic luminosity for all redshifts, the distance modulus can be expressed as

\[
\mu_{\text{obs}} = m_B^* - (M_B - \alpha X_1 + \beta C),
\]

where \(m_B^*\) corresponds to the observed peak magnitude in the \(B\)-band rest-frame, while \(\alpha\), \(\beta\) and \(\delta\) are nuisance parameters. Although the mechanism is not fully understood, it has been shown (Sullivan et al. 2011; Johansson et al. 2013) that both \(\beta\) and \(M_B\) depend on properties of the host galaxy. In this work we use the joint light-curve (JLA) analysis from Betoule et al. (2014), where the authors approximately correct for these effects assuming that the absolute magnitude \(M_B\) is related to the stellar mass of the host galaxy, \(M_{\text{stellar}}\), by a simple step function:

\[
M_B = \begin{cases} 
M_B^1 & \text{if } M_{\text{stellar}} < 10^{10} M_\odot, \\
M_B^1 + \Delta M & \text{otherwise},
\end{cases}
\]

where \(M_B^1\) and \(\Delta M\) are two extra nuisance parameters. The authors also discard the additional dependency of \(\beta\) on the host stellar mass because it does not have a significant impact on the cosmology.

Concerning the errors and the correlations of the measurements, we use the full covariance matrix provided in Betoule et al. (2014), where the authors have considered several statistical and systematic uncertainties, such as the error propagation of the light-curve fit uncertainties, calibration, light-curve model, bias correction, mass step, dust extinction, peculiar velocities, and contamination of nontype-Ia supernovae. This covariance matrix depends on the \(\alpha\) and \(\beta\) nuisance parameters, so when we sample the parameter space we recomputate the covariance matrix at each step.

Allowing for some redshift dependence on the SNIa intrinsic luminosity, the distance modulus can be expressed as

\[
\mu_{\text{obs}} = m_B^* - (M_B - \alpha X_1 + \beta C + \Delta m_{\text{evo}}(z)),
\]

where \(\Delta m_{\text{evo}}(z)\) stands for a nuisance term that accounts for the intrinsic luminosity dependence as a function of redshift.

Although the mechanism of SNIa detonation is well understood, the difficulty of observing the system before becoming a SNIa leaves enough uncertainty to merit the consideration of whether a luminosity dependence with redshift may have an effect on the cosmological conclusions. A varying gravitational constant, or a fine structure constant variation, could generate a luminosity dependence on the redshift. Also, some studies claim that the intrinsic luminosity of SNIa may depend on the star formation rate (Rigault et al. 2013, 2017; Childress et al. 2014) — although other studies claim the contrary (see Jones et al. 2018 and references therein), the metallicity of the host galaxy (Moreno-Raya et al. 2016), or that it could be dimmed by intergalactic dust (Goobar et al. 2018). All these effects depend on the redshift. However, our approach here is just to consider a phenomenological model to explore the degeneracy of SNI distance-dependent effects and the cosmological information. Different phenomenological models have been proposed for \(\Delta m_{\text{evo}}(z)\) (see Tutusaus et al. 2017 and references therein). In this work we only consider Model B from Tutusaus et al. (2017), also illustrated in Riess et al. (2018a), where \(\Delta m_{\text{evo}}(z) = \epsilon z^\delta\). A lower \(\delta\) power contribution models a luminosity evolution dominant at low redshift, while a higher \(\delta\) power contribution leads to a luminosity evolution dominating at high redshift. It is important to note that \(\delta\) must be greater than zero in order not to be degenerate with \(M_B^1\). When sampling the parameter space we limit \(\delta\) \(\in [0.2, 2]\).

2.2. Baryon acoustic oscillations

The baryon acoustic oscillations are the characteristic patterns observed in the galaxy distribution of the large-scale structure of the universe. They are characterized by the length of a standard ruler, \(r_\text{d}\), and, in the standard cosmological model, originate from sound waves propagating in the early universe. The BAO scale \(r_\text{d}\) corresponds then to the comoving sound horizon at the redshift of the baryon drag epoch,

\[
r_\text{d} = r_s(z_{\text{drag}}) = \int_{z_{\text{drag}}}^{\infty} \frac{c_s(z)}{H(z)} \, dz,
\]

where \(z_{\text{drag}} \approx 1060\) and \(c_s(z)\) is the sound velocity as a function of the redshift,

\[
c_s(z) = \frac{c}{\sqrt{3(1 + \Omega_b(z))}}, \quad \text{with } R_b(z) = \frac{3 \rho_b}{4 \rho_\gamma}.
\]

In this latter expression \(\rho_b\) stands for the baryon density while \(\rho_\gamma\) corresponds to the photon density. Their ratio can be approximated (Eisenstein & Hu 1998) by \(R_b(z) = 3.15 \times 10^7 \Omega_b h^2 \Theta_c^{-2} \).
(1 + z)^3$, with \( \Theta_{2.7} \) = \( T_{\text{CMB}}/2.7 \) K and \( \Omega_B \) being the baryon energy density parameter. In this work we fix the temperature of the CMB to \( T_{\text{CMB}} = 2.725 \) K (Fixsen 2009).

However, it is known that models differing from the standard \( \Lambda \)CDM framework may have a value for \( r_d \) that is not compatible with \( r_s(z_{\text{rec}}) \) (Verde et al. 2017a). It has also been shown that the computed value of \( r_d \) may depend on the physics of the early universe, and that adding dark radiation at early times could alleviate the tension between the local measurement and the CMB-derived value of \( H_0 \) (Bernal et al. 2016). Moreover, there has recently been some analyses computing \( r_d \) without any dependence on late-time universe assumptions, thanks to the fact that late-time physics only affect the CMB through projection effects from real space to harmonic space, the late integrated Sachs-Wolfe effect, and re-ionization (see Verde et al. 2017b and references therein for all the details). Due to these phenomena, in this work we consider three different methods to include BAO data:

1. Compute \( r_d \) with Eq. (5).
2. Let \( r_d \) free.
3. Include the prior \( r_d = 147.4 \pm 0.7 \) Mpc from Verde et al. (2017b).

We note that the prior on \( r_d \) from Verde et al. (2017b) is less constraining than the Planck Collaboration XIII (2016), but it is more model independent, since the latter assume the concordance \( \Lambda \)CDM model to constrain \( r_d \).

It is also worth mentioning that in this work we only compute \( r_d \) (using Eq. (5)) when we consider the combination of SNIa, BAO, and CMB data, since this is the only case for which we specify the expansion rate of the universe up to very high redshift (see Sect. 3.2).

We consider here both isotropic and anisotropic measurements of the BAO. The distance scale used for isotropic measurements is given by

\[
D_N(z) = \left( \frac{r^2(z) c^2}{H(z)} \right)^{1/3},
\]

while for the radial and transverse measurements the distance scales are \( r(z) \) and \( c/H(z) \), respectively.

We use the isotropic measurements provided by 6dFGS at \( z = 0.106 \) (Beutler et al. 2011) and by SDSS–MGS at \( z = 0.15 \) (Ross et al. 2015). We also consider the anisotropic final results of BOSS DR12 at \( z = 0.38, 0.51, 0.61 \) (Alam et al. 2017), and the new anisotropic measurements from the eBOSS DR14 quasar sample (Gil-Marín et al. 2018) at \( z = 1.19, 1.50, 1.83 \). These results were obtained by measuring the redshift space distortions using the power spectrum monopole, quadrupole, and hexadecapole. Gil-Marín et al. (2018) have shown that their results are entirely consistent with those obtained using different methods to analyze the same data (Hou et al. 2018; Zarrouk et al. 2018). We finally consider the latest results from the combination of the Ly-\( \alpha \) forest auto-correlation function (Bautista et al. 2017) and the Ly-\( \alpha \)-quasar cross-correlation function (du Mas des Bourboux et al. 2017) from the complete BOSS survey at \( z = 2.4 \). We take into account the covariance matrix provided for the measurements of BOSS DR12 and eBOSS DR14, we consider a correlation coefficient of \(-0.38\) for the Ly-\( \alpha \) forest measurements, and we assume measurements of different surveys to be uncorrelated. In order to take into account the nonGaussianity of the BAO observable likelihoods far from the peak, we follow Bassett & Afshordi (2010) by replacing the usual \( \Delta \chi^2 = -2\ln L_G \) for a Gaussian likelihood observable by

\[
\Delta \chi^2 = \frac{\Delta \chi^2_G}{\sqrt{1 + \Delta \chi^4_G (\frac{\sigma}{\chi})^{-4}}},
\]

where the ratio S/N stands for the detection significance, in units of \( \sigma \), of the BAO feature. We consider a detection significance of 2.4\( \sigma \) for 6dFGS, 2\( \sigma \) for SDSS–MGS, 9\( \sigma \) for BOSS DR12, 4\( \sigma \) for eBOSS DR14, and 5\( \sigma \) for the Ly-\( \alpha \) forest. Some of these values are slightly lower than those quoted by the different collaborations in order to follow a conservative approach, and in case the likelihood becomes nonGaussian at these high confidence levels.

### 2.3. Cosmic microwave background

The CMB is an extremely powerful source of information due to the high precision of modern data. Furthermore it represents high-redshift data, complementing low-redshift probes. As was shown in Wang & Mukherjee (2007), a significant part of the information coming from the CMB can be compacted into a few numbers, the so-called reduced parameters: the scaled distance to recombination \( R \), the angular scale of the sound horizon at recombination \( \ell_s \), and the reduced density parameter of baryons \( \omega_b \). For a flat universe their expressions are given by

\[
R \equiv \sqrt{\Omega_m H_0^2} \int_0^{z_{\text{CMB}}} \frac{dz}{H(z)},
\]

\[
\ell_s \equiv \frac{\pi c}{r_s(z_{\text{CMB}})} \int_0^{z_{\text{CMB}}} \frac{dz}{H(z)},
\]

\[
\omega_b \equiv \Omega_b h^2.
\]

where \( z_{\text{CMB}} \) stands for the redshift of the last scattering epoch. In this work we consider the data obtained from the Planck 2015 data release (Planck Collaboration XIV 2016), where the compressed likelihood parameters are obtained from the Planck temperature-temperature plus the low-\( \ell \) Planck temperature-polarization likelihoods. We specifically consider the reduced parameters obtained when marginalizing over the amplitude of the lensing power spectrum for the lower values, since it leads to a more conservative approach, together with their covariance matrix.

It is important to recall that the reduced parameters can only be used for models close to \( \Lambda \)CDM, since this is the model assumed to derive the values of the reduced parameters from Planck data. In this work, although we allow for a general expansion rate at low redshift, we consider a concordance matter-radiation-dominated early universe (see Sect. 3.2); therefore, we only expect major differences with respect to the concordance model at low redshift, which should have a small impact on the integrals of the reduced parameters. Although not being perfectly model independent, we consider here the reduced parameters of the CMB. A fully model-independent analysis merging the model-independent reconstruction of the expansion rate together with the Boltzmann code is left for future work.

### 3. Methodology

In this section we first reiterate the details of the standard \( \Lambda \)CDM model and we then present the reconstruction method used to obtain the expansion rate as a function of redshift. We give a detailed explanation of how we introduce each cosmological probe in the analysis, and we finally describe the method used to sample the parameter space.
3.1. The $Λ$CDM model

The flat $Λ$CDM model assumes a flat Robertson-Walker metric together with Friedmann-Lemaître dynamics, leading to the comoving distance,

$$r(z) = c \int_0^z \frac{dz'}{H(z')}$$

and the Friedmann-Lemaître equation,

$$E(z)^2 \equiv \frac{H(z)^2}{H_0^2} = \Omega_r (1 + z)^4 + \Omega_m (1 + z)^3 + (1 - \Omega_r - \Omega_m),$$

where $\Omega_m$ ($\Omega_r$) stands for the matter (radiation) energy density parameter. We follow Planck Collaboration XIII (2016) in computing the radiation contribution as

$$E_r = \Omega_r \left[ 1 + N_{\text{eff}} \frac{7}{8} \left( \frac{4}{11} \right)^{1/3} \right],$$

where $E_r$ corresponds to the photon contribution

$$E_\gamma = 4 \times 5.6704 \times 10^{-6} \frac{T_{\text{CMB}}^4}{c^3} \frac{8\sigma G}{3H_0^2}$$

In this work we fix the effective number of neutrino-like relativistic degrees of freedom to $N_{\text{eff}} = 3.04$. When we consider only SNIa data, or SNIa combined with BAO data letting $r_d$ free, we fix the value of $H_0$ for the radiation contribution on $\Lambda$CDM (see Eqs. (12), (13)) to $H_0 = 68$ km s$^{-1}$ Mpc$^{-1}$, since there is no sensitivity to $H_0$ in these cases. However, $H_0$ is left free for all the other cases and reconstructions in the rest of the work. The remaining parameters when fitting $\Lambda$CDM to the data are $\Omega_m$ and the corresponding nuisance parameters of the cosmological probes considered (see Table 1).

3.2. Expansion rate reconstruction method

We want our reconstruction to be as model-independent as possible, and we impose a smooth and continuous expansion rate together with a flat, homogeneous, and isotropic universe. Several model-independent reconstruction methods have been used in the literature (since a decade ago Seikel & Schwarz 2008, 2009) to reconstruct the dark energy equation of state parameter, or even the Hubble parameter. Among them let us mention the principal component analysis (Huterer & Starkman 2003; Crittenden et al. 2009; Liu et al. 2016; Said et al. 2013; Qiu et al. 2015), the Gaussian processes (Clarkson & Zunckel 2010; Holscw & Zunckel 2010; Seikel et al. 2012; Yu et al. 2018; Busti et al. 2014; Wang & Meng 2017; Haridasu et al. 2018a), the iterative model-independent smoothing method (Starobsinsky et al. 2006; Shafieloo 2007; L’Huillier et al. 2018; L’Huillier & Shafieloo 2017), or, very recently, the weighted polynomial regression method (Gómez-Valent & Amendola 2018; Gómez-Valent 2018). See Viteni & Penna-Lima (2015) for a detailed review on different model-independent reconstruction methods.

In this work we follow the approach from Bernal et al. (2016), reconstructing the late-time expansion history by expressing $E(z)$ as $H(z)/H_0$ in piece-wise natural cubic splines (see also Penna-Lima et al. 2019 for a recent analysis using a cubic spline-based reconstruction methodology). When we consider SNIa data alone, $E(z)$ is specified by its values at five different “knots” in redshift: $z = 0, 0.1, 0.25, 0.5, 0.7, 0.8, 1.3$. Therefore, our reconstruction when analyzing SNIa data considers the following set of parameters $[h, \alpha, \beta, M, \Delta_M, \epsilon, \delta]$ with $h_i$ for $i \in [1, 5]$ being the five knots in redshift, $\alpha, \beta, M, \Delta_M$ the standard SNIa nuisance parameters, and $\epsilon, \delta$ the SNIa intrinsic luminosity evolution parameters.

When BAO data are added into the analysis we consider an extra knot in our reconstruction at $z = 2$. We follow two different approaches to include the BAO measurements: first we consider the product $H_0r_d$ as a free parameter, and secondly we add information coming from the early universe through the prior on $r_d$ from Verde et al. (2017b), $r_d = 147.4 \pm 0.7$ Mpc. In the first case, the set of parameters considered in our reconstruction of $E(z)$ is $[h, \alpha, \beta, M, \Delta_M, H_0, r_d, \epsilon, \delta]$ with $h_i$ for $i \in [1, 6]$ being the six knots in redshift, while in the second case we consider $H_0$ and $r_d$ separately $[h, \alpha, \beta, M, \Delta_M, H_0, r_d, \epsilon, \delta]$. It is important to mention here that our statistical approach in this work is frequentist; therefore, by prior we mean here that we add a Gaussian likelihood centered at the corresponding value (of $r_d$ in this case) with the corresponding 1σ error to our full likelihood before minimizing the $\chi^2$ function. Rigorously, we are modifying the likelihood from a frequentist approach.

When we finally add the reduced parameters for the CMB we need to specify $E(z)$ up to early times. In order to do this we add the seventh knot at $z = 2.7$ computed according to a matter-dominated model (with flat Robertson-Walker metric and Friedmann-Lemaître dynamics) with free $H_0$ and $\Omega_m$ parameters (see Eq. (11)), and we extend the model up to very high redshift. The main idea in this reconstruction is to start at early times following a matter-dominated model (plus radiation and a negligible contribution of dark energy through a cosmological constant) and, when we start to have low-redshift data and a cosmological constant is still negligible with respect to the quantity of matter present in the universe, we reconstruct $E(z)$ through a cubic spline interpolation; in this way we give our reconstruction the freedom to choose the preferred expansion without specifying a particular model for dark energy. When analyzing the data we consider three different cases, depending on the way that the BAO measurements are introduced. First, we consider $r_d$ as a free parameter, while, in a second place, we add the prior on $r_d$ from Verde et al. (2017b). In both cases, the set of parameters that enters into the reconstruction is given by $[h, \alpha, \beta, M, \Delta_M, H_0, r_d, \Omega_m, \Omega_\gamma, \Omega_b, \epsilon, \delta]$, and we add the prior on $\Omega_\gamma = 1089.90 \pm 0.23$ (Planck Collaboration XIII 2016). As a last case we compute the value of $r_d$ using Eq. (5). In this case the set of parameters is given by $[h, \alpha, \beta, M, \Delta_M, H_0, \Omega_m, \Omega_\gamma, \Omega_b, \epsilon, \delta, z_{dug}]$, and we add the prior on $z_{dug} = 1059.68 \pm 0.29$ (Planck Collaboration XIII 2016).

In order to test the degeneracy between a SNIa intrinsic luminosity evolution and cosmic acceleration, we consider different cases with and without luminosity redshift dependence, so $\alpha$ and $\delta$ can be removed from the analysis. Finally, we also consider the so-called coasting reconstructions, in which the universe has a late-time constant expansion rate. More specifically, we fix the first four knots3 (since it is roughly the region where the expansion is accelerated in the concordance model) such that

\footnote{These values have been chosen such that the expansion rate has a significant amount of freedom at low redshift, and because this is the interval for which SNIa data are available.}

\footnote{This corresponds to the redshift of the Ly-$\alpha$ forest measurements.}

\footnote{When using SNIa data alone we only fix the first three knots because there is not a lot of data beyond $z \sim 0.8$, but we have checked that fixing the first four knots leads to equivalent conclusions.}
it is likely to obtain higher \( \chi^2 \) goodness of fit statistic. A probability close to 1 indicates that correlations between the different measurements within probes. Nevertheless, we have checked using Monte Carlo simulations that the impact of these correlations is negligible when we consider Eq. (15), and therefore we use this equation in the following.

4. Results

In this section we present the results of the reconstruction of the expansion rate of the universe as a function of redshift for different sets of cosmological probes: SNIa, SNIa combined with BAO, and SNIa combined with both BAO and CMB data. We also comment on the linear growth of structure measurements, and the importance of the value of the Hubble constant, \( H_0 \), to draw conclusions on the accelerated expansion of the universe.

4.1. Case 1: SNIa

We first start considering only SNIa data. We present this case as an illustration of the reconstruction method used. The best-fit values for the cosmological and nuisance parameters are presented in Table 2 together with the 1\( \sigma \) error bars, and the reconstructions are shown in Fig. 1. We show three different models in this case: the reconstruction through cubic splines (red), the reconstruction for a coasting universe (labeled CS) at low-redshift (fixing the first three knots – green), and \( \Lambda \mathrm{CDM} \) as a reference (black). We do not consider any SNIa luminosity evolution for the moment. In Table 2 we also provide the ratio of the \( \chi^2 \) to the number of degrees of freedom, and the probability \( \mathcal{P}(\chi^2, v) \) from Eq. (15). In order to obtain the bands for the reconstructions we generate 500 splines from an \( N \)-dimensional Gaussian centered at the best-fit values and with the covariance matrix obtained from the fit to the data. We further require each spline to have a \( \Delta \chi^2 \) value smaller than or equal to 1 with respect to the best-fit reconstruction. We recall that the derivative of \( E(z)/(1+z) \) is proportional to \( \dot{a} \); therefore a decreasing \( E(z)/(1+z) \) as a function of the redshift implies acceleration, while an increasing one implies deceleration.

In Table 2 we can clearly see that all the SNIa nuisance-parameter values \((\alpha, \beta, M, \Delta M)\) are compatible for the three models, and that a coasting universe shows a lower expansion rate when we increase the redshift with respect to the standard spline reconstruction. This is confirmed from Fig. 1 where we see that the expansion rate drops above \( z = 0.8 \). We can also observe in this figure that the bands increase when we increase the redshift; this is expected since there are less data points in this region. Comparing the three models, we observe that the spline function for BAO and CMB data. In other words, we consider the correlations between the different measurements within probes. Nevertheless, we have checked using Monte Carlo simulations that

\[ E(z) \text{ is equal to } (1 + z) \text{ at these points. Let us reiterate that } E(z) = H(z) \equiv \dot{a}/a; \text{ therefore, } E(z) = (1 + z) \text{ implies that } \dot{a}/a \propto 1/a; \text{ thus } \dot{a} \text{ is constant, giving a coasting universe. See Table 1 for a summary of the different cases considered and the cosmological and nuisance parameters present in them.} \]

\[ 3.3. \text{Fitting the data} \]

In order to reconstruct the expansion rate as a function of redshift, we fit the data minimizing the common \( \chi^2 \) function,

\[ \chi^2 = (u - u_{\text{data}})^T C^{-1} (u - u_{\text{data}}), \]

where \( u \) stands for the model prediction, while \( u_{\text{data}} \) and \( C \) hold for the observables and their covariance matrix, respectively. We sample the parameter space to minimize this function using the MIGRAD application from the \texttt{minuit} Python package\(^4\), a Python implementation of the former MINUIT Fortran code (James & Roos 1975), conceived to find the minimum value of a multi-parameter function and analyze the shape of the function around the minimum. We use it to extract the best-fit values for the parameters, as well as their errors and the covariance matrix of the parameters.

We also compute the probability that a higher value for the \( \chi^2 \) occurs for a fit with \( v = N - k \) degrees of freedom, where \( N \) is the number of data points and \( k \) is the number of parameters,

\[ P(\chi^2, v) = \frac{\Gamma\left(\frac{v}{2}\right)\Gamma\left(\frac{v}{2}\right)}{\Gamma\left(\frac{v}{2}\right)^2}, \]

where \( \Gamma(t, x) \) is the upper incomplete gamma function and \( \Gamma(t) = \Gamma(t, 0) \) the complete gamma function. This value provides us with a goodness of fit statistic. A probability close to 1 indicates that it is likely to obtain higher \( \chi^2 \) values than the minimum found, pointing to a good fit by the model. When we combine different probes, we minimize the sum of the individual \( \chi^2 \) functions for each probe, that is, we assume the probes to be uncorrelated.

It is worth mentioning that Eq. (15) can, in principle, only be used when our \( N \) data points come from \( N \) independent random variables with Gaussian distributions. However, SNIa data come from correlated Gaussian random variables, as is the case for BAO and CMB data. In other words, we consider the correlations between the different measurements within probes.

reconstruction provides a slightly smaller $\chi^2$ value (681.38) than LCDM (682.89), but the former has many more parameters in the model, and so the ability of these models to fit the data is roughly the same, being slightly better for LCDM ($P(\chi^2, \nu) = 0.915$) than the spline reconstruction ($P(\chi^2, \nu) = 0.905$). However, the $\chi^2$ value obtained for the coasting reconstruction (717.60) is much larger than the previous values, which also implies that this model is less able to perfectly fit the data ($P(\chi^2, \nu) = 0.661$). A detailed model comparison is beyond the scope of this work, since we do not aim to propose a new cosmological model to confront LCDM but are interested in studying the accelerated expansion of the universe and the relation it may have with SNIa luminosity. However, the coasting reconstruction has a relative probability of $\exp(-\Delta \chi^2/2) \approx 1.4 \times 10^{-6}$%, showing that a coasting universe at low redshift is highly disfavored ($>5\sigma$), even using SNIa data alone, when SNIa intrinsic luminosity is assumed to be redshift independent. We also note that, even if we ask the reconstruction to be nonaccelerated at low redshift, it prefers to add some acceleration at earlier times (above $z \approx 0.8$) rather than simply having a constant velocity expansion.

4.2. Case 2: SNIa+BAO

After having shown how the reconstruction method works, and having applied it to SNIa data alone, we focus on the combination of SNIa and BAO data. As is shown in Table 1 we consider two different ways to combine these data sets: we either let the product $H_{0r3}$ free, or we add a prior on $r_3$. Since we consider the models with and without SNIa intrinsic luminosity evolution, and we always add LCDM as a reference, we finally have four different sub-cases with the corresponding three models per

$^5$ We note that we do find more than a $5\sigma$ preference for cosmic acceleration (when SNIa luminosity does not evolve with the redshift), contrary to the results of Nielsen et al. (2016), because we consider the standard SNIa systematics instead of the extra systematics proposed by these authors. However, we are still far from the $11.2\sigma$ detection from Rubin & Hayden (2016), because we use a model-independent reconstruction with many more degrees of freedom than a fixed nonaccelerated model.

4.3. Case 3: SNIa+BAO+CMB

Let us recall that the addition of CMB data is a key ingredient when studying cosmological models thanks to its complementarity to low-redshift cosmological probes (see e.g., Tutusaus et al. 2016 where cosmological models are ruled out thanks to the introduction of CMB scale information). Therefore, as a final case we consider the combination of the three main background expansion cosmological probes: SNIa, BAO, and CMB. We have already presented two different ways to combine SNIa and BAO data, so when we add CMB data we keep this approach and, since we now include the physics of the early universe, we add a third way consisting in computing the explicit value of $r_3$. The best-fit values of the parameters for these three sub-cases are presented in Table 4 with the $1\sigma$ errors, and the corresponding reconstruction is shown in Fig. 3. Let us mention that even if $z_{\text{CMB}}$ and $z_{\text{avg}}$ in Table 4 seem to be fixed, both of them have been fitted each time adding the Planck priors; however, the
best-fit values are very stable and are identical in the table given the number of decimals presented.

Let us start with the combination considering $r_3$ a free parameter. Either assuming the SNIa intrinsic luminosity to be redshift independent or allowing it to vary, the three models provide compatible values for all the parameters except $H_0$, which is significantly smaller for the coasting reconstruction, as was already shown in the combination of SNIa and BAO data, and which is compensated by a larger $\Omega_m$. We note that the CMB is sensitive to the physical matter energy density $\Omega_m h^2$, which is roughly equal to 0.14 for all models. Therefore, even if the value of $H_0$ is smaller than in the concordance model, if the value of $\Omega_m$ is large enough, the coasting reconstruction can also perfectly fit the CMB. When SNIa luminosity is allowed to vary, a coasting reconstruction provides roughly the same $\chi^2$ (698.30) as $\Lambda$CDM (698.09) with a slightly smaller probability (0.898 against 0.908), showing that a nonaccelerated expanding universe can fit the three main background probes when SNIa intrinsic luminosity is allowed to vary.

In a second place we add a prior on $r_3$ (Verde et al. 2017b) obtained without assumptions on the late-time universe. All the best-fit values are compatible between the different models as before, except for $H_0$ and $\Omega_m$, which are smaller and larger for a coasting reconstruction, respectively, accounting for SNIa luminosity evolution or not. The obtained $\chi^2$ values are very similar, leading to very similar probabilities to correctly fit the data, $P(\chi^2, \nu)$, and they show that a coasting reconstruction can correctly fit the data when SNIa luminosity evolution is accounted for. In the last place we compute $r_3$ using Eq. (5). All the best-fit values are compatible with the previous results, and compatible between the different models, except for $H_0$ and $\Omega_m$. It is also the case for the $\chi^2$ values and the corresponding probabilities.

We conclude that, if we account for a redshift dependence in the intrinsic luminosity of SNIa, the main cosmological probes cannot firmly prove the accelerated nature of the expansion of the universe in a model-independent way, since a nonaccelerated reconstruction of the expansion rate can correctly fit the observations.

For completeness, we present in Fig. 4 the residuals to SNIa and BAO observations for three different models: $\Lambda$CDM (black), the reconstruction through cubic splines (red), and the nonaccelerated model using a coasting reconstruction (green) taking into account SNIa intrinsic luminosity evolution. We also provide the predictions for the CMB quantities $R$, $f_s$, and $\omega_B$ in Table 5. All these predictions have been computed using the best-fit values of the parameters obtained from the global fit to the combination of SNIa, BAO, and CMB data, explicitly computing the value of $r_3$ using Eq. (5). From these results we can see graphically that all three models are perfectly able to fit the data; including the coasting reconstruction with SNIa luminosity evolution. As can be seen in Table 4, a different approach when combining SNIa, BAO, and CMB data (free $r_3$ or prior on $r_3$) gives nearly the same values for the parameters of the reconstruction, which leads to almost the same predictions for the observables.

4.4. Pantheon SNIa sample

Although our main cosmological data set for SNIa measurements in this analysis is the JLA compilation from Betoule et al. (2014), there is a newer compilation available in the community called Pantheon (Scolnic et al. 2018). It contains SNIa measurements coming from the Pan-STARRS1 Medium Deep Survey, SDSS, SNLS, various low-redshift surveys, and HST samples. Pantheon is the largest combined sample of SNIa with a total amount of 1048 SNIa from $z \approx 0.01$ up to $z = 2.3$. Besides the increased number of SNIa compared to JLA (740), and the extended redshift range ($z \approx 1$ for JLA), the Pantheon compilation considers a different treatment of SNIa systematic errors. For instance, the mass step $\Delta M$, $\alpha$, and $\beta$ nuisance parameters appearing in the JLA compilation are here pre-solved in a cosmology independent manner (see Scolnic et al. 2018 for the details), so the Pantheon compilation provides only the redshifts, distance moduli, and distance moduli uncertainties, together with the covariance matrix for the distances moduli. A detailed comparison between the different treatment of systematic errors between these two compilations is beyond the scope of this work.

Our interest here is to test the stability of our results from the previous section when using the Pantheon sample instead of the JLA compilation. In order to do this, we reconstruct

![Fig. 2. Reconstruction of the expansion rate, $E(z)/(1+z)$ (left) and $H(z)/(1+z)$ (right), as a function of the redshift using the combination of SNIa and BAO data.](image-url)
Fig. 3. Reconstruction of the expansion rate, $H(z)/(1+z)$, as a function of the redshift using the combination of SNIa, BAO, and CMB data. In the top panel the data sets have been combined considering $r_d$ a free parameter, while in the central panel a prior on $r_d$ has been used, and it has been explicitly computed in the bottom panel. In all panels the black and gray lines represent the $\Lambda$CDM model (without and with SNIa luminosity evolution, respectively), while the red band shows the reconstruction with $\Lambda$CDM model (without and with SNIa luminosity evolution, respectively), while the red band shows the reconstruction, when SNIa intrinsic luminosity is allowed to vary as a function of the redshift, is able to provide a very good fit to the main background cosmological probes. It is important to mention however that the $\Delta \chi^2$ between the coasting reconstruction in Fig. 3 (JLA) and the concordance model is equal to $-0.3$ (smaller for the coasting reconstruction), while the $\Delta \chi^2$ when considering the Pantheon compilation is equal to $4.3$ (smaller for the concordance model). Although this difference is not large enough to rule out the coasting reconstruction, it already shows some tension; therefore, it might point towards the fact that with future SNIa compilations, with even higher sample sizes, we might be able to discard this kind of reconstruction. It is also interesting to note that the reduced $\chi^2$/d.o.f. are always smaller than 1 when considering the Pantheon compilation, but they are slightly larger than the ones obtained with the JLA compilation. This is probably due to the different treatment of systematic errors in the different compilations; however, all models provide a very good fit to the data and a detailed comparison on the treatment of systematic errors is beyond the scope of this work.

4.5. Growth rate

The measurements of the growth rate of matter perturbations offer an additional constraint on cosmological models. Their values depend on the theory of gravity used and it is well known that there are identical background evolutions with different growth rates (Piazza et al. 2014). Defining the linear growth factor of matter perturbations as the ratio between the linear density perturbation and the energy density, $D \equiv \delta \rho_m/\rho_m$, we can derive the standard second-order differential equation for $D$ (Peebles 1993)

$$D + 2HD - 4\pi G \rho_m D = 0,$$

(16)

where the dot stands for differentiation over cosmic time. Neglecting second-order corrections, this differential equation can be rewritten with derivatives over the scale factor (Dodelson 2003)

$$D'(a) + \left[\frac{3}{a} - \frac{H'(a)}{H(a)}\right]D'(a) - \frac{3}{2} \Omega_m H_0^2 D(a) - \frac{D(a)}{a^2} = 0,$$

(17)

which is valid under the assumption that dark energy cannot be perturbed and does not interact with dark matter. We can now define the growth rate as

$$f(a) \equiv \frac{d \ln D}{d \ln a},$$

(18)

and then compute the observable weighted growth rate $f \sigma_8$ as

$$f \sigma_8(z) = f(z) \cdot \left(\sigma_{\text{Planck}} \frac{D(z)}{D_{\text{Planck}}(0)}\right),$$

(19)

where $\sigma_{\text{Planck}}$ stands for the $\Lambda$CDM observed value (with Planck) of the root mean square mass fluctuation amplitude on scales of $8h^{-1}$ Mpc at redshift $z = 0$ (fixed to 0.8159 in this work Planck Collaboration XIII 2016), and $D_{\text{Planck}}$ represents the $\Lambda$CDM Planck growth factor (Planck Collaboration XIII 2016). In this work we consider the measurements of the weighted growth rate from the 6dFGS survey (Beutler et al. 2012), the WiggleZ survey (Blake et al. 2012), and the VIPERS survey (de la Torre et al. 2013), as well as the different SDSS projects: SDSS-II MGS DR7...
4.6. The Hubble constant

The Hubble constant, $H_0$, is one of the most important parameters in modern cosmology, since it is used to construct time and distance cosmological scales. It was first measured by Hubble to be roughly $500\,\text{km}\,\text{s}^{-1}\,\text{Mpc}^{-1}$ (Hubble 1929). Current data supports a value for $H_0$ close to $70\,\text{km}\,\text{s}^{-1}\,\text{Mpc}^{-1}$. However, nearly 100 years later there is still no consensus on its value. Local measurements already show some tension on the results depending on the calibration of SNIa distances and the methodology used. Using median statistics, the authors from Gott et al. (2001), Chen et al. (2003), and Chen & Ratra (2011) finally found a local value of $H_0$ equal to $68 \pm 5.5\,\text{km}\,\text{s}^{-1}\,\text{Mpc}^{-1}$ (95\% statistical and systematic errors). Following these studies, there were different analyses claiming values close to $68\,\text{km}\,\text{s}^{-1}\,\text{Mpc}^{-1}$ using different methods and assumptions (see e.g., Chen et al. 2017; Yu et al. 2018; Rigault et al. 2015; Zhang et al. 2017; Dhawan et al. 2018; Fernández Arenas et al. 2018; Lin & Ishak 2017, and Haridasu et al. 2018b). However, there are other studies claiming significantly higher values (Riess et al. 2018b,c, 2019) and some others finding slightly smaller values (Tammann & Reindl 2013). Moreover, there is also some tension between some direct measurements of $H_0$ and the value inferred from the CMB assuming a $\Lambda$CDM model (Planck Collaboration XIII 2016). There have been many attempts in the literature to solve this discrepancy both from an observational and a theoretical perspective (see Bernal et al. 2016; Gómez-Valent & Amendola 2018; Mörtsell & Dhawan 2018; Dhawan et al. 2018; Ben-Dayan et al. 2014; D’Arcy Kenworthy et al. 2019; Shanks et al. 2019; Riess et al. 2018d, and references therein for a detailed discussion on the trouble with $H_0$). In this work we consider two recent cosmological model-independent measurements of $H_0$ in order to check its effect on the conclusions we can draw concerning cosmic acceleration. We first consider the value obtained from the Hubble Space Telescope observations (Riess et al. 2018b; R18 in the following), $H_0 = 73.45 \pm 1.66\,\text{km}\,\text{s}^{-1}\,\text{Mpc}^{-1}$. We then consider the value obtained with Gaussian processes using SNIa data, and constraints on $H(z)$ from cosmic chronometers (Gómez-Valent & Amendola 2018; GVA18 in the following), $H_0 = 67.06 \pm 1.68\,\text{km}\,\text{s}^{-1}\,\text{Mpc}^{-1}$. This last value is closer to the one derived with an “inverse distance ladder” approach in Aubourg et al. (2015), $H_0 = 67.3 \pm 1.1$, where the measurement assumes standard pre-recombination physics but is insensitive to dark energy or space curvature assumptions. It is also closer to the value derived from the CMB observations using a flat $\Lambda$CDM model, $H_0 = 67.51 \pm 0.64$ (Planck Collaboration XIII 2016).

Let us mention that in this work we also provide constraints on $H_0$ obtained using a cubic spline reconstruction on SNIa, BAO, and CMB data without SNIa intrinsic luminosity evolution (as in GVA18). They are given by $H_0 = 68.5 \pm 1.7$ (free $r_d$), $H_0 = 68.3 \pm 1.2$ (prior $r_d$), and $H_0 = 68.2 \pm 1.2$ (compute $r_d$). See Table 4 for the constraints including SNIa luminosity evolution. All our constraints are compatible (within 1$\sigma$) with GVA18.

### Table 5. Prediction of the different models for the CMB quantities $R$, $\ell_c$, $\omega_m$, for the combination of SNIa, BAO, and CMB data computing $r_d$ explicitly, and accounting for SNIa intrinsic luminosity evolution as a function of the redshift when dealing with a coasting reconstruction.

Notes. The measured values are added as a reference.

(Howlett et al. 2015; with the main galaxy sample of the seventh data release), SDSS-III BOSS DR12 (Alam et al. 2017; with the LRGs from the twelfth BOSS data release), and SDSS-IV DR14Q (Gil-Marín et al. 2018; with the latest quasar sample of eBOSS). We have not included this data set in our fitting analysis for simplicity, but we show in Fig. 6 when using the best-fit values of the parameters from the SNIa+BAO+CMB fit the prediction for the three models considered (LCDM, spline reconstruction, and coasting reconstruction with SNIa luminosity evolution) is in very good agreement with the observations. We note that the values for the parameters used in Fig. 6 have been obtained computing the value of $r_d$, but the results are equivalent using the other approaches for the combination of our three main data sets.
and Planck but they are in tension with R18. However, we keep R18 and GVA18 in the following to use $H_0$ constraints, without assumptions on the cosmological model, which are independent from this work.

In Fig. 7 we represent the profile likelihood (assuming Gaussian likelihoods) for both the observed values of $H_0$, R18 (black) and GVA18 (blue), and the values derived from the nonaccelerated reconstruction for the combination SNIa+BAO+CMB taking into account the SNIa intrinsic luminosity evolution. We present the three values obtained for the three approaches followed when combining the data sets: considering $r_d$ a free parameter (green), adding a prior on it (yellow), or computing it explicitly (purple). From the figure alone it is clear that the $H_0$ value for the nonaccelerated reconstruction is in tension with R18 at more than $5\sigma$, independently of the approach used when combining the data sets. More precisely, a nonaccelerated reconstruction is ruled out if we consider the R18 measurement at 5.60$\sigma$ (free $r_d$, $H_0 = 62.2 \pm 1.1$), 6.47$\sigma$ (prior $r_d$, $H_0 = 62.13 \pm 0.55$), or 6.55$\sigma$ (compute $r_d$, $H_0 = 62.08 \pm 0.51$), showing that, with the R18 measurement, cosmic acceleration is proven even if some astrophysical systematic errors evolving with the redshift modify the intrinsic luminosity of SNIa. However, we can also see from the figure that if we consider the measured value from the Gaussian processes, a nonaccelerated reconstruction shows slightly less than a 3$\sigma$ tension. More precisely, there is a tension of 2.39$\sigma$ (free $r_d$), 2.79$\sigma$ (prior $r_d$), or 2.84$\sigma$ (compute $r_d$). In this case, the measured value of $H_0$ points towards ruling out these reconstructions, but the tension is still far from the usually recognized 5$\sigma$ threshold.

Before moving on to our conclusions, let us mention that there have been several analyses in the literature where the authors constrain the expansion rate of the universe, $H(z)$, using measurements of it. Different cosmological models or reconstruction methods have been used (see e.g., Farooq & Ratra 2013; Farooq et al. 2017, 2013; Moresco et al. 2016, and Yu et al. 2018). Using local measurements of $H_0$, these analyses also show current acceleration and earlier deceleration, which enables us to obtain the redshift of transition between deceleration and acceleration. In order to compare our results to theirs, we compute this transition redshift for the different (noncoasting) spline reconstructions. For SNIa alone, the redshift of transition is $z_t = 0.9 \pm 1.2$, given the lack of constraining power from SNIa data alone. However, when we include BAO data this transition becomes $z_t = 0.55 \pm 0.32$ (free $H_0$), and $z_t = 0.54 \pm 0.25$ (prior $r_d$).  If we also add CMB data into the analysis, the transition redshift is then given by $z_t = 0.53 \pm 0.33$ (free $r_d$), $z_t = 0.53 \pm 0.24$ (prior $r_d$), and $z_t = 0.53 \pm 0.24$ (compute $r_d$). These results are compatible with the transition redshift derived in a model-independent way in Moresco et al. (2016): $z_t = 0.4 \pm 0.1$, as well as the value derived using median statistics in Farooq et al. (2017): $z_t = 0.74 \pm 0.05$. Therefore, our cubic spline reconstructions (without SNIa intrinsic luminosity evolution) provide information on the transition from deceleration to acceleration compatible to that obtained with $H(z)$ and $H_0$ data.

5. Conclusions

Here we address the question of whether or not relaxing the standard assumption that SNIa intrinsic luminosity does not depend on the redshift can have an impact on the conclusions that can be drawn on the accelerated nature of the expansion of the universe. Although there is no theoretically fully motivated model for this luminosity evolution yet, it has not been proven that two SNIa in two galaxies with the same light curve, color, and host stellar mass have the same intrinsic luminosity independently of redshift. Moreover, there are different studies claiming a detection of SNIa luminosity dependence on the star formation rate or metallicity of the host galaxy, which depend on the redshift (Rigault et al. 2013, 2017; Childress et al. 2014; Moreno-Raya et al. 2016). Also, with this kind of analysis we can distinguish between the effect of unknown astrophysical systematics varying with the redshift and the cosmological information.

The impact of SNIa luminosity evolution on our cosmological knowledge has already been addressed (Wright 2002;
either we considered verse down to to follow a matter–radiation-dominated model from the early uni-
forced to specify the model up to very high redshifts. We decided reduced parameters. In order to deal with this information we were 
vary as a function of the redshift.

we checked that when using the best-fit values from the global 
CMB share the same physics. For simplicity we did not add the 
add a prior on it, or compute it assuming that the BAO and the 
ifying any dark energy model. When adding the CMB data we 
consider the main background cosmological probes: SNIa, BAO, and 

We then coupled the model to our spline reconstruction. In other 

We showed that if we consider the R18 value, cosmic accelera-
tion is at a 
value, a nonaccelerated reconstruction for the expansion rate is at a 

After this conclusion, we focus on the impact that the Hub-
ble constant may have on this question. We considered two differ-
ent recent model-independent measurements of $H_0$: 73.45 ± 1.66 
km s$^{-1}$ Mpc$^{-1}$ (R18) from Riess et al. (2018b), and 67.06 ± 1.68 
km s$^{-1}$ Mpc$^{-1}$ (GVA18) from Gómez-Valent & Amendola (2018).
We showed that if we consider the R18 value, cosmic acceleration is proven at more than 5.60σ for a general expansion rate reconstruction (for which we get $H_0 = 62.2 ± 1.1$ (free $r_d$), $H_0 = 62.13 ± 0.55$ (prior $r_d$), and $H_0 = 62.08 ± 0.51$ (compute $r_d$)), even if SNIa intrinsic luminosity varies as a function of the redshift due to some astrophysical unknown systematic error. It is important to mention, however, that if we consider the GVA18 value, a nonaccelerated reconstruction for the expansion rate is at a 3σ tension with the measurement, but still below the 5σ detection.

In conclusion, if SNIa intrinsic luminosity varies as a function of the redshift, a nonaccelerated universe is able to correctly fit all the main background probes. However, the value of $H_0$ turns out to be a key ingredient in the conclusions we can draw concerning cosmic acceleration. If we take $H_0$ into account we are close to claim an accelerated expansion of the universe using an approach that is very independent of the cosmological model assumed, and even if SNIa intrinsic luminosity varies as a function of the redshift. A final consensus on a direct measurement of $H_0$ and its precision will be decisive in finally proving the cosmic acceleration independently of the cosmological model and any redshift dependent astrophysical systematic error that may remain in the SNIa analysis.
