### ABSTRACT

**Aims.** We test the two-corona accretion scenario for active galactic nuclei in the case of the “bare” Seyfert 1 galaxy HE 1143-1810.

**Methods.** We perform a detailed study of the broad-band UV–X-ray spectral properties and of the short-term variability of HE 1143-1810. We present results of a joint XMM–Newton and NuSTAR monitoring of the source, consisting of  $5 \times 20$  ks observations, each separated by 2 days, performed in December 2017.

**Results.** The source is variable in flux among the different observations, and a correlation is observed between the UV and X-ray emission. Moderate spectral variability is observed in the soft band. The time-averaged X-ray spectrum exhibits a cut-off at  $\sim 100$  keV consistent with thermal Comptonization. We detect an iron  $K\alpha$  line consistent with being constant during the campaign and originating from a mildly ionized medium. The line is accompanied by a moderate, ionized reflection component. A soft excess is clearly present below 2 keV and is well described by thermal Comptonization in a “warm” corona with a temperature of  $\sim 0.5$  keV and a Thomson optical depth of  $\sim 17$ – $18$ . For the hot hard X-ray emitting corona, we obtain a temperature of  $\sim 20$  keV and an optical depth of  $\sim 4$  assuming a spherical geometry. A fit assuming a jet-emitting disc (JED) for the hot corona also provides a nice description of the broad-band spectrum. In this case, the data are consistent with an accretion rate varying between  $\sim 0.7$  and  $\sim 0.9$  in Eddington units and a transition between the outer standard disc and the inner JED at  $\sim 20$  gravitational radii.

**Conclusions.** The broad-band high-energy data agree with an accretion flow model consisting of two phases: an outer standard accretion disc with a warm upper layer, responsible for the optical–UV emission and the soft X-ray excess, and an inner slim JED playing the role of a hard X-ray emitting hot corona.

**Key words.** galaxies: active – galaxies: Seyfert – X-rays: galaxies – X-rays: individuals: HE 1143-1810

## 1. Introduction

The X-ray emission of active galactic nuclei (AGNs) is believed to originate from thermal Comptonization of optical–UV photons, emitted by the accretion disc, in a hot corona (see e.g. Haardt & Maraschi 1991; Haardt et al. 1994, 1997). This physical mechanism is able to explain the observed power-law shape of the X-ray emission. Moreover, the primary continuum often exhibits a high-energy cut-off at around 100–150 keV, which is interpreted as the roll-over of thermal Comptonization due to the finite coronal temperature. This feature has been observed in a number of sources (see e.g. Zdziarski et al. 2000; Perola et al. 2002; Dadina 2008; Baumgartner et al. 2013; Malizia et al. 2014; Lubiński et al. 2016), in particular from high-sensitivity measurements enabled by NuSTAR (Fabian et al. 2015; Tortosa et al. 2018). In addition to the primary emission, other spectral com-

ponents are often observed, such as a hump at 20–30 keV interpreted as Compton reflection from the accretion disc or more distant material (see e.g. George & Fabian 1991; Matt et al. 1991), and a soft excess below 1–2 keV with a steep rising shape (see e.g. Bianchi et al. 2009). Currently, the most debated models for the origin of the soft excess are ionized reflection (see e.g. Crummy et al. 2006; Ponti et al. 2006; Walton et al. 2013; Jiang et al. 2018; García et al. 2019) and “warm” Comptonization (see e.g. Magdziarz et al. 1998; Mehdipour et al. 2011; Done et al. 2012; Petrucci et al. 2013, 2018; Boissay et al. 2014; Matt et al. 2014; Middei et al. 2018, 2019; Porquet et al. 2018; Ursini et al. 2018). In the latter hypothesis the optical–UV emission and soft X-ray excess could originate from the upper layer of the accretion disc, consisting of a warm ( $kT_e \sim 1$  keV) optically thick ( $\tau \sim 10$ – $20$ ) slab-like corona (Rózańska et al. 2015; Petrucci et al. 2018).

In this paper we investigate the properties of the hot corona and the physical origin of the soft excess in the Seyfert 1 galaxy HE 1143-1810 ( $z = 0.0328$ , Jones et al. 2009) through a joint *XMM-Newton* and *NuSTAR* monitoring programme carried out in 2017. A previous *XMM-Newton* observation of the source in 2004 revealed the presence of a significant soft excess and of a narrow Fe K $\alpha$  emission line at 6.4 keV (Cardaci et al. 2011), with ambiguous evidence for a relativistically broadened component (Nandra et al. 2007; Bhayani & Nandra 2011).

The structure of the paper is as follows. In Sect. 2 we describe the observations and data reduction. In Sect. 3 we discuss the timing properties. In Sect. 4 we present the analysis of the *XMM-Newton* and *NuSTAR* spectra. In Sect. 5 we discuss the results and our conclusions.

## 2. Observations and data reduction

HE 1143-1810 was observed five times simultaneously by *XMM-Newton* (Jansen et al. 2001) and *NuSTAR* (Harrison et al. 2013) in December 2017. The pointings had a net exposure of  $\sim 20$  ks each, and were separated by 2 days from each other. The log of the data sets is listed in Table 1.

*XMM-Newton* observed the source with the optical monitor (OM; Mason et al. 2001), the EPIC cameras (Strüder et al. 2001; Turner et al. 2001), and the Reflection Grating Spectrometer (RGS; den Herder et al. 2001). The data were processed using the *XMM-Newton* Science Analysis System (SAS v18). The OM photometric filters were operated in the image mode; the images were taken with the U, UVW1, UVM2, and UVW2 filters, with an exposure time of 5 ks each. The OM data were processed with the SAS pipeline OMICHAIN, and converted into data suitable for the spectral analysis using the SAS task OM2PHA. The EPIC-pn instrument operated in the Small Window mode, with the thick filter applied, while the EPIC-MOS instruments operated in the Timing mode. The spectral analysis is based on pn data, because of the higher effective area compared with MOS and to avoid cross-calibration uncertainties. The data show no significant pile-up as indicated by the SAS task EPATPLOT. Source extraction radii and screening for high-background intervals were determined through an iterative process that maximizes the signal-to-noise ratio (Piconcelli et al. 2004). The background was extracted from circular regions with a radius of 50 arcsec, while the source extraction radii were allowed to be in the range 20–40 arcsec; the best extraction radius was found to be 40 arcsec for every iteration. The light curves were corrected for instrumental effects

and were background-subtracted using the SAS task EPICLCCORR. The EPIC-pn spectra were grouped such that each spectral bin contained at least 30 counts, and without oversampling the spectral resolution by a factor greater than 3. Finally, the RGS data were extracted using the standard SAS task RGSPROC. The spectra from the two detectors RGS1 and RGS2 were not combined.

The *NuSTAR* data were reduced using the standard pipeline (NUPIPELINE) in the *NuSTAR* Data Analysis Software (NUSTARDAS, v1.9.3), using calibration files from *NuSTAR* CALDB v20171002. Spectra and light curves were extracted using the standard tool NUPRODUCTS for each of the two hard X-ray detectors aboard *NuSTAR*, located inside the corresponding focal plane modules A and B (FPMA and FPMB). The source data were extracted from circular regions with a radius of 75 arcsec, and the background was extracted from a blank area close to the source. The spectra were binned to have a signal-to-noise ratio greater than 5 in each spectral channel, and without oversampling the instrumental resolution by a factor greater than 2.5. The spectra from FPMA and FPMB were analysed jointly, but were not combined.

## 3. Timing properties

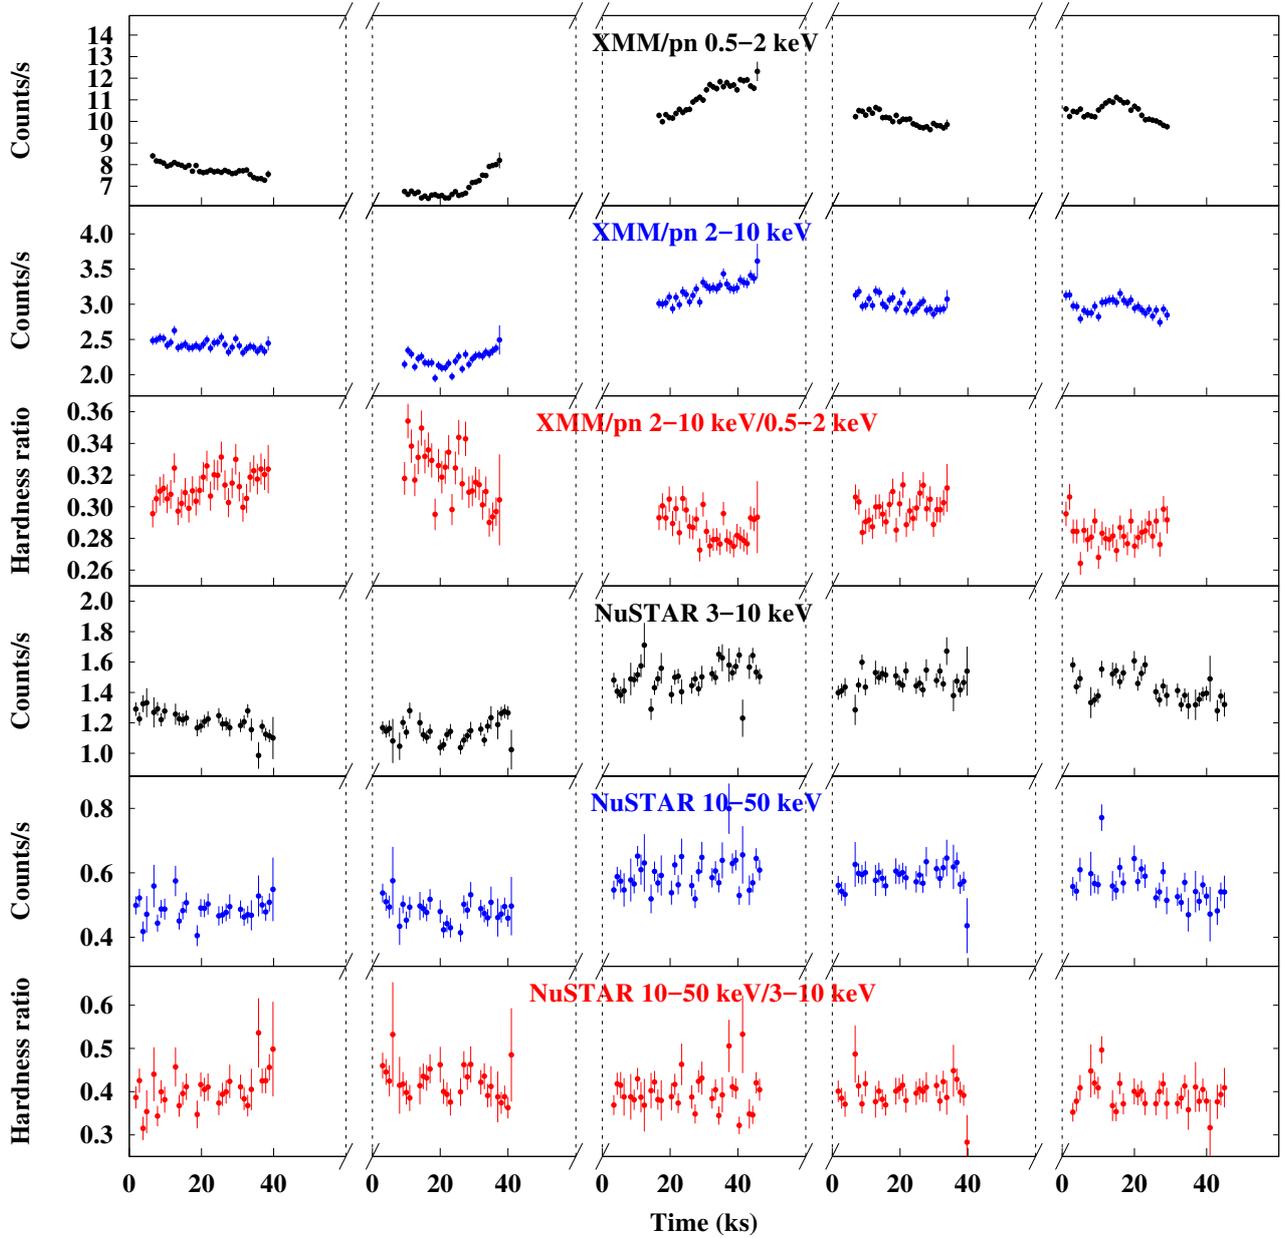

The light curves of HE 1143-1810 with *XMM-Newton*/pn and *NuSTAR*, in different energy ranges, are plotted in Fig. 1. The source exhibits a moderate flux variability between different observations, up to a factor of 1.7 in the 0.5–2 keV band. In Fig. 1 we also plot the pn (2–10 keV)/(0.5–2 keV) hardness ratios and the *NuSTAR* (10–50 keV)/(3–10 keV) hardness ratios. The soft band (0.5–10 keV) displays the most significant spectral variability between different observations; however, it is no greater than 20% in terms of the pn hardness ratio.

In order to characterize the flux variability, we computed the normalized excess variance (e.g. Nandra et al. 1997; Vaughan et al. 2003; Ponti et al. 2012), defined as

$$\sigma_{\text{rms}}^2 = \frac{1}{N\mu^2} \sum_{i=1}^N [(X_i - \mu)^2 - \sigma_i^2], \quad (1)$$

where  $N$  is the number of time bins in the light curve,  $\mu$  is the unweighted mean of the count rate within that segment,  $X_i$  is the count rate, and  $\sigma_i^2$  is the associated uncertainty. Following Ponti et al. (2012), we computed the normalized excess variance in the 2–10 keV band for all the observations of our campaign; the light curves were calculated using time bins of 250 s and selecting segments of 20 ks. We also included the light curve of the 2004 *XMM-Newton* observation (Cardaci et al. 2011). We obtained  $\sigma_{\text{rms}}^2 = 7_{-6}^{+6} \times 10^{-4}$ . Then, assuming the correlation between  $\sigma_{\text{rms}}^2$  and the black hole mass  $M_{\text{BH}}$  reported by Ponti et al. (2012), we estimate  $M_{\text{BH}} = 7_{-4}^{+5} \times 10^7 M_{\odot}$ . From the properties of the H  $\beta$  emission line as reported by Winkler (1992) and Marziani et al. (2003), we derive a black hole mass of  $3\text{--}4 \times 10^7 M_{\odot}$  applying the virial mass estimators of Shen & Liu (2012) and Ho & Kim (2015). These results are consistent, and hereafter we assume a mass of  $4 \times 10^7 M_{\odot}$ .

In Fig. 2 we plot the light curves of the four *XMM-Newton*/OM filters, and the *XMM-Newton*/pn average count rate measured for each observation in the bands 0.5–2 keV and 2–10 keV. The UVW2 filter exhibits marginal variability. In Fig. 3 we plot the *XMM-Newton*/pn average count rates for each observation versus the OM/UVW2 count rate. The correlation between UVW2 and 0.5–2 keV band has a Pearson's correlation coefficient of 0.91, with a null hypothesis probability of 0.03. For the 2–10 keV band, the Pearson's coefficient is 0.86 and the

**XMM/pn and NuSTAR/FPMA+FPMB light curves and hardness ratios**

**Fig. 1.** Light curves of the five joint *XMM-Newton* and *NuSTAR* observations of HE 1143-1810. The exposures are spaced by 2 d. Time bins of 1 ks are used. *Top panel:* *XMM-Newton*/pn count rate light curve in the 0.5–2 keV band. *Second panel:* *XMM-Newton*/pn count rate light curve in the 2–10 keV band. *Third panel:* *XMM-Newton*/pn hardness ratio (2–10/0.5–2 keV) light curve. *Fourth panel:* *NuSTAR* count rate light curve in the 3–10 keV band (FPMA and FPMB data are co-added). *Fifth panel:* *NuSTAR* count rate light curve in the 10–50 keV band. *Bottom panel:* *NuSTAR* hardness ratio (10–50/3–10 keV) light curve.

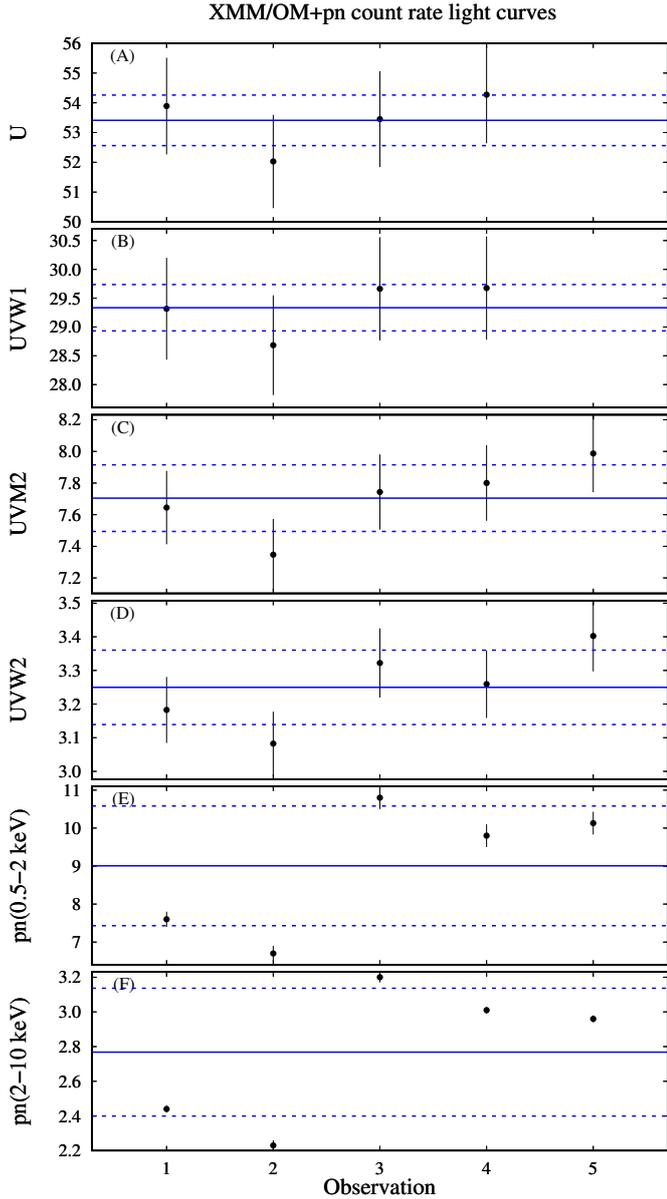

null hypothesis probability is 0.06. Such correlations, albeit not highly significant, indicate a trend of a higher X-ray flux with increasing UV flux.

#### 4. Spectral analysis

We performed the spectral analysis with the *XSPEC* v12.10 package (Arnaud 1996). The RGS spectra were not rebinned and were analysed using the *C*-statistic (Cash 1979) to exploit the high spectral resolution of the gratings in the 0.3–2 keV band. Broad-band fits (UV to X-ray, 0.3–79 keV) were performed on the rebinned pn and *NuSTAR* spectra plus the OM photometric data, using the  $\chi^2$  minimization technique. All errors are quoted

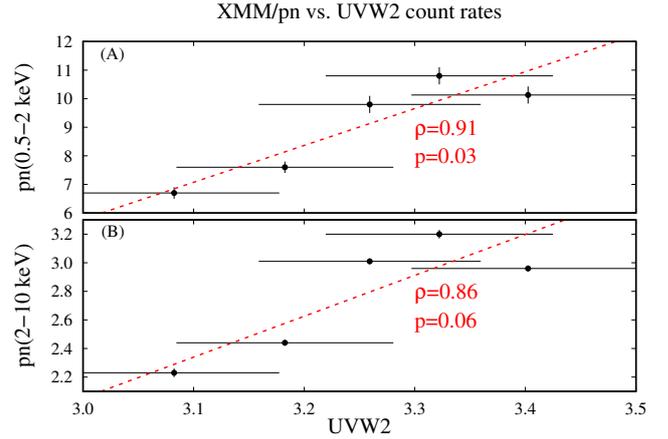

at the 90% confidence level ( $\Delta C = 2.71$  or  $\Delta\chi^2 = 2.71$ ) for one interesting parameter. In our fits we always included neutral absorption (PHABS model in *XSPEC*) from Galactic hydrogen with column density  $N_{\text{H}} = 3.47 \times 10^{20} \text{ cm}^{-2}$  (Kalberla et al. 2005). When using optical–UV data, we also included interstellar extinction (REDDEN model in *XSPEC*) with  $E(B - V) = 0.035$  (Schlafly & Finkbeiner 2011). We assumed the element abundances of Lodders (2003) and the photoelectric absorption cross sections of Verner et al. (1996).

In Fig. 4 we show the *XMM-Newton*/pn and *NuSTAR*/FPMA spectra, fitted in the 3–79 keV band with a simple power law with parameters tied between the different detectors and observations. The *NuSTAR* spectra exhibit a curvature above  $\sim 20$  keV,

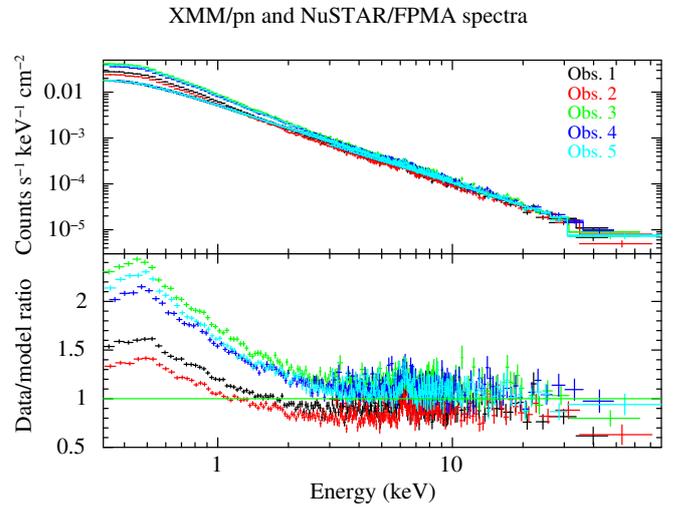

**Fig. 2.** Light curves of each of the four *XMM-Newton*/OM photometric filters: U (panel A), UVW1 (panel B), UVM2 (panel C), UVW2 (panel D); and light curves, averaged over each observation, of *XMM-Newton*/pn in the bands 0.5–2 keV (panel E) and 2–10 keV (panel F). The U and UVW1 filters were not available during Obs. 5. The blue solid lines represent the mean value of the count rate over the five observations, while the blue dashed lines represent the standard deviation (i.e. the root mean square of the deviations from the mean).

while the extrapolation of pn data below 3 keV shows a significant soft excess. The Fe  $K\alpha$  emission line is also visible in the residuals. As already reported in *XMM-Newton* and *NuSTAR* simultaneous observations of other sources, the pn spectra are flatter than the *NuSTAR* spectra in the common bandpass 3–10 keV, with a difference in photon index of  $\sim 0.1$  (e.g. Cappi et al. 2016; Fürst et al. 2016; Middei et al. 2018; Ponti et al. 2018). In some cases the largest discrepancy was found in the 3–5 keV band, where *NuSTAR* measures a higher flux (e.g. Fürst et al. 2016; Ponti et al. 2018). However, in our case the spectral discrepancy does not depend on the energy band. We discuss this issue in more detail in Appendix A. To account for this discrepancy, we included in the fits involving both *XMM-Newton* and

**Fig. 3.** *XMM-Newton*/pn count rate, averaged over each observation, in the 0.5–2 keV band (panel A) and in the 2–10 keV band (panel B) plotted against the OM/UVW2 count rate. The red dashed lines represent linear fits to the data.

**Fig. 4.** Upper panel: *XMM-Newton*/pn and *NuSTAR*/FPMA spectra of HE 1143-1810; these five spectra were fitted with a single power law in the 3–79 keV band. Lower panel: ratio of the spectra to the 3–79 keV power law. The data were binned for plotting purposes.

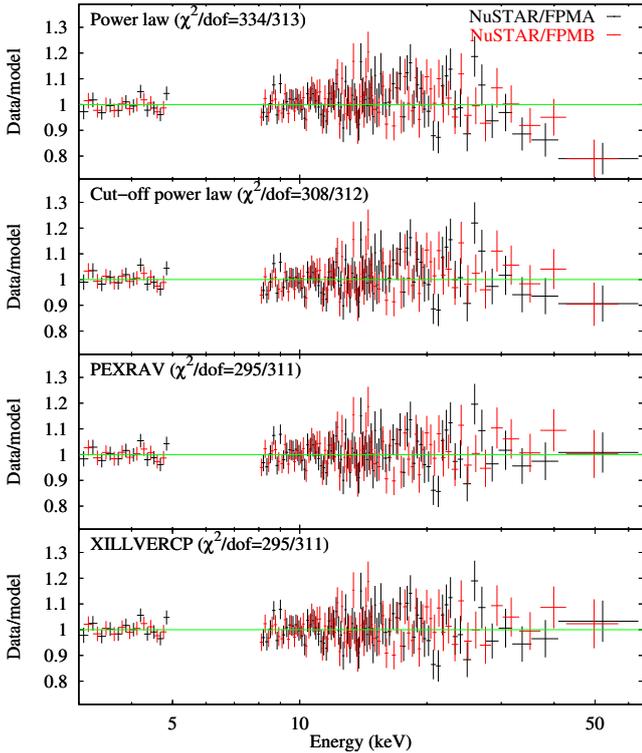

*NuSTAR* a cross-calibration function in the form  $\text{const} \times E^{\Delta\Gamma}$ , where  $\Delta\Gamma$  is the discrepancy in photon index between pn and *NuSTAR* (Ingram et al. 2017). We fixed  $\Delta\Gamma$  at zero for both *NuSTAR* modules and left it free for pn (but tied between the different observations, see Appendix A). The values of the photon index and flux reported in the following (Sects. 4.3, 4.5, and 4.6) are those measured by *NuSTAR*, unless otherwise stated. The FPMA and FPMB modules are in very good agreement with each other, with a cross-calibration factor of  $1.02 \pm 0.01$ .

The analysis of RGS data is given in Appendix B.

#### 4.1. High-energy turnover

To constrain the presence of a high-energy cut-off, we fitted the time-averaged *NuSTAR* spectra (FPMA and FPMB), co-adding the data from the five observations. We ignored the 5–8 keV band to avoid the contribution from the Fe  $K\alpha$  line at 6.4 keV.

Starting with a simple power law, we obtained a fit with  $\chi^2/\text{d.o.f.} = 334/313$  that clearly indicates a turnover at around 30 keV (Fig. 5, upper panel). Then we included an exponential high-energy cut-off, finding an improved fit with

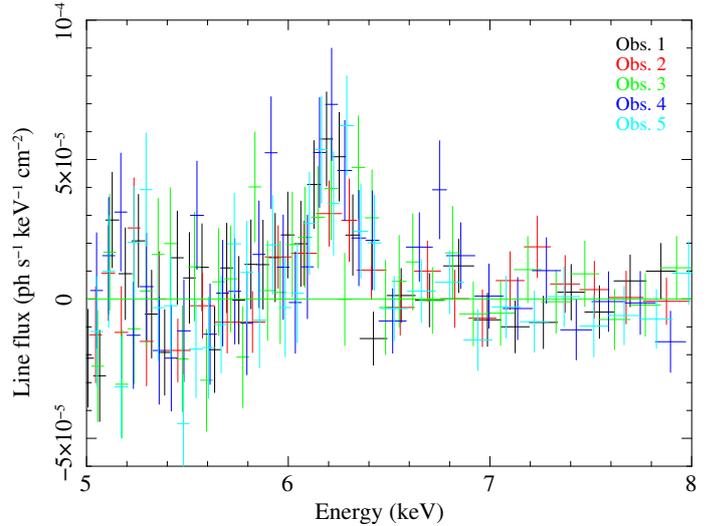

**Fig. 5.** Residuals of the fits of the time-averaged *NuSTAR* spectra with different models. *Upper panel:* simple power law. *Second panel:* power law with exponential cut-off. *Third panel:* power law plus reflection (PEXRAV). *Lower panel:* thermal Comptonization model plus reflection (XILLVERCP). The data were binned for plotting purposes.

$\chi^2/\text{d.o.f.} = 308/312$  ( $\Delta\chi^2/\Delta\text{d.o.f.} = -26/-1$ ). The cut-off energy is found to be  $150^{+10}_{-50}$  keV. However, despite the improvement, the fit with a power law with exponential cut-off still leaves significant residuals in the high-energy band (Fig. 5, second panel).

We then included Compton reflection, replacing the cut-off power law with PEXRAV (Magdziarz & Zdziarski 1995). This model includes Compton reflection off a neutral slab of infinite column density. We fixed the inclination angle at 30 deg, since the fit was not sensitive to this parameter. We assumed solar abundances. We left free the reflection fraction  $\mathcal{R} = \Omega/2\pi$ , where  $\Omega$  is the solid angle subtended by the reflector. We obtained a good fit with  $\chi^2/\text{d.o.f.} = 295/311$  ( $\Delta\chi^2/\Delta\text{d.o.f.} = -13/-1$ ) and without prominent residuals (Fig. 5, third panel). In this case we obtained  $E_c = 100^{+50}_{-20}$  keV and  $\mathcal{R} = 0.17^{+0.09}_{-0.08}$ .

Finally, we tested a thermal Comptonization model. We fitted the spectra with the model XILLVERCP, that includes the Comptonization model NTHCOMP (Zdziarski et al. 1996; Życki et al. 1999) plus ionized reflection with the code XILLVER (García & Kallman 2010; García et al. 2011, 2013). We left free the photon index  $\Gamma$  of the asymptotic power law, the electron temperature  $kT_e$ , and the reflection fraction. We fixed the inclination angle at 30 deg, the ionization parameter at  $\log \xi = 0$ , and the iron abundance at the solar value. We obtained a good fit (i.e. equivalent to the PEXRAV fit) with  $\chi^2/\text{d.o.f.} = 295/311$  (Fig. 5, last panel). The electron temperature was found to be  $20^{+5}_{-3}$  keV, while we only had an upper limit of 0.13 to the reflection fraction.

We conclude that the spectral turnover is nicely described by either a power law with exponential cut-off plus modest reflection or by a thermal Comptonization model. In the following we analyse the Fe  $K\alpha$  line (Sect. 4.2) and investigate the presence of a reflection component including pn data as well (Sect. 4.3).

**Fig. 6.** Fe  $K\alpha$  line profile from *XMM-Newton*/pn data (observer's frame). The plot shows the residuals of a simple power law fit performed in the 3–10 keV band.

#### 4.2. The Fe $K\alpha$ line

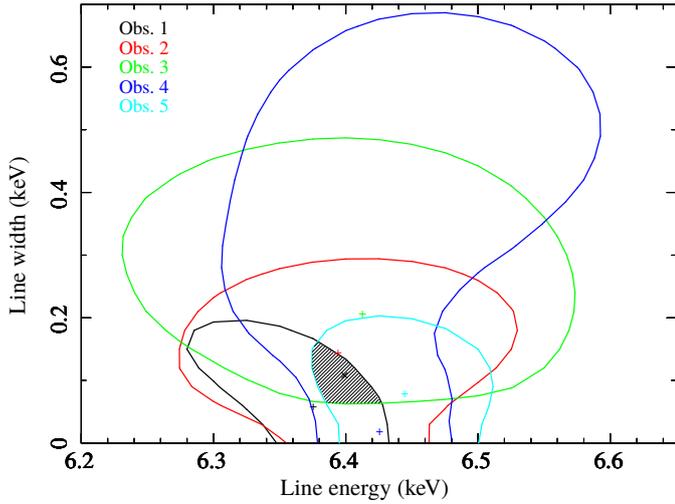

To investigate the shape and variability of the Fe  $K\alpha$  line at 6.4 keV, we focused on *XMM-Newton*/pn data between 3 and 10 keV because of the better energy resolution and throughput compared with *NuSTAR* in that energy band. In Fig. 6 we plot the profile of the Fe  $K\alpha$  line from pn data. We simultaneously fitted the five pn spectra with a model consisting of a variable power law plus a Gaussian line. We first assumed an intrinsically narrow single emission line (i.e. the intrinsic width  $\sigma$  was fixed at zero) with a constant flux among the different observations. We found  $\chi^2/\text{d.o.f.} = 505/511$ , with positive residuals around 6.7 keV (observer's frame). We thus included a second, narrow Gaussian line, keeping its flux tied among the different observations, obtaining  $\chi^2/\text{d.o.f.} = 496/509$  ( $\Delta\chi^2/\Delta\text{d.o.f.} = -9/-2$ ). The rest-frame energy of the second line was found to be  $7.00 \pm 0.07$  keV, consistent with both the Fe XXVI  $K\alpha$  line at 6.966 keV and the neutral Fe  $K\beta$  line at 7.056 keV. This line is weak in any case; it has a flux of  $(3.4 \pm 1.8) \times 10^{-6}$  photons  $\text{cm}^{-2} \text{s}^{-1}$  and an equivalent width (EW) in the range 5–30 eV.

Next we tested for the variability of the neutral Fe  $K\alpha$  line as follows. We first left the line flux free to vary among the observations, and found no strong improvement ( $\chi^2/\text{d.o.f.} = 490/505$ , i.e.  $\Delta\chi^2/\Delta\text{d.o.f.} = -6/-4$ ). Then, we left the energy free to vary, and obtained an equivalent fit ( $\chi^2/\text{d.o.f.} = 486/501$ , i.e.  $\Delta\chi^2/\Delta\text{d.o.f.} = -4/-4$ ). Then we left the intrinsic width free, but tied between the observations, and found a minor improvement ( $\chi^2/\text{d.o.f.} = 481/500$ , i.e.  $\Delta\chi^2/\Delta\text{d.o.f.} = -5/-1$ ). Finally, we left the line width free to vary among the different observations, but found no strong improvement ( $\chi^2/\text{d.o.f.} = 475/496$ , i.e.  $\Delta\chi^2/\Delta\text{d.o.f.} = -6/-4$ ). The contours of the line intrinsic width versus rest-frame energy for the different observations are plotted in Fig. 7; all the parameters are summarized in Table 2. We also reanalysed the archival 2004 *XMM-Newton*/pn observation, as above, to investigate the Fe  $K\alpha$  line variability on longer timescales. The parameters, which are listed in Table 2, are consistent with those found by Cardaci et al. (2011) and agree within the errors with those of the 2017 campaign. We conclude that the line is consistent with being constant in flux during the 2017 monitoring, with no significant variations since 2004 (see Fig. 8).

**Table 2.** Properties of the Fe  $K\alpha$  emission line.

	2004	Obs. 1	Obs. 2	Obs. 3	Obs. 4	Obs. 5
$E$	$6.40 \pm 0.05$	$6.38^{+0.05}_{-0.07}$	$6.40 \pm 0.10$	$6.41^{+0.12}_{-0.13}$	$6.43^{+0.04}_{-0.05}$	$6.45 \pm 0.05$
$\sigma$	$<0.12$	$<0.16$	$<0.25$	$0.2^{+0.2}_{-0.1}$	$<0.7$	$<0.2$
Flux	$1.4 \pm 0.5$	$1.6^{+0.7}_{-0.5}$	$1.4^{+0.7}_{-0.6}$	$1.9^{+1.0}_{-0.8}$	$1.6^{+1.8}_{-0.5}$	$1.8^{+0.7}_{-0.6}$
EW	$44 \pm 17$	$70 \pm 25$	$55^{+50}_{-20}$	$50^{+50}_{-20}$	$50^{+30}_{-10}$	$70^{+20}_{-30}$

**Notes.**  $E$  is the energy of the line (rest-frame) in keV,  $\sigma$  is the intrinsic line width in keV, the flux is in units of  $10^{-5}$  photons  $\text{cm}^{-2} \text{s}^{-1}$ , and EW is the equivalent width in eV. The second column is relative to the 2004 *XMM-Newton* observation.

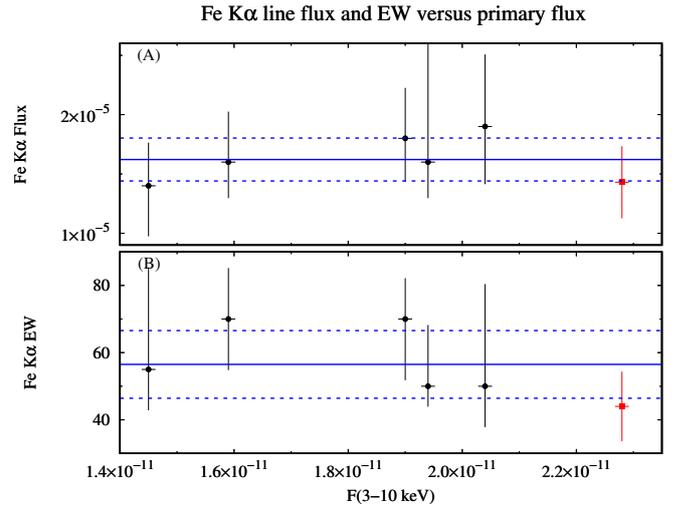

**Fig. 7.** Contour plots of the Fe  $K\alpha$  line intrinsic width vs. rest-frame energy at the 90% confidence level. The shaded area represents the intersection of the contours, while the black cross corresponds to the average values ( $E = 6.40$  keV,  $\sigma = 0.11$  keV).

The line has an intrinsic width of  $\sim 0.11$  keV and a rest-frame energy of  $\sim 6.40$  keV. We then tested a model in which the Gaussian line is broadened by relativistic effects in the inner region of the accretion disc. We used a narrow Gaussian line ( $\sigma = 0$ ) convolved with *KDBLUR* in *XSPEC*. We left the inner disc radius  $R_{\text{in}}$  free to vary among the different observations, and fixed the outer disc radius to  $400 R_G$  (the fit being insensitive to this parameter). The disc inclination was fixed at  $30$  deg, with no improvement by leaving it free to vary. We obtained a fit with  $\chi^2/\text{d.o.f.} = 505/496$ , worse than the fit with a free  $\sigma$  ( $\Delta\chi^2 = +30$ ), and lower limits on the inner disc radius of about  $100 R_G$ . The moderate broadening and the possible presence of a  $7$  keV feature could indicate that the line is produced in a mildly ionized medium, possibly being a blend of the  $K\alpha$  emission from intermediate ions of iron (e.g. Fe XVII–Fe XX; García et al. 2011, 2013). We discuss this point in the following analysis.

#### 4.3. Reflection component

We tested the presence of a Compton reflection hump fitting simultaneously the pn and *NuSTAR* data in the  $3\text{--}79$  keV band. First, we fitted the five observations with a simple model consisting of a power law with an exponential cut-off plus two Gaussian lines. The photon index, cut-off energy, and normalization of the power law were free to vary among the different observations. Since the neutral Fe  $K\alpha$  line is consistent with being constant (Sect. 4.2), we kept the energy, width, and flux of the Gaussian lines tied among the observations. We fixed

**Fig. 8.** Parameters of the Fe  $K\alpha$  line plotted against the primary flux in the  $3\text{--}10$  keV band. The red square corresponds to the 2004 *XMM-Newton* observation. *Panel A*: line flux in units of photons  $\text{cm}^{-2} \text{s}^{-1}$ . *Panel B*: line equivalent width in units of eV. Error bars denote the  $1\sigma$  uncertainty. The blue solid lines represent the mean value for each parameter during the campaign, while the blue dashed lines represent the standard deviation.

the width of the  $7$  keV line at zero. We found a good fit with  $\chi^2/\text{d.o.f.} = 1584/1646$ . We then replaced the cut-off power law with *PEXRAV*. We fixed the inclination angle at  $30$  deg since the fit was not sensitive to this parameter. We assumed a constant reflection fraction  $\mathcal{R}$ . We found  $\chi^2/\text{d.o.f.} = 1577/1645$  ( $\Delta\chi^2/\Delta\text{d.o.f.} = -7/-1$ ) and  $\mathcal{R} = 0.11^{+0.08}_{-0.07}$ , and no improvement by leaving  $\mathcal{R}$  free to vary among the observations.

Then we replaced *PEXRAV* and the Gaussian line with *XILLVER* (which self-consistently incorporates fluorescence lines and the Compton hump) assuming illumination from a cut-off power law spectrum. We fixed the inclination angle at  $30$  deg, leaving the iron abundance  $A_{\text{Fe}}$  and the ionization parameter  $\log \xi$  as free parameters, but constant among the different observations. We found a good fit with  $\chi^2/\text{d.o.f.} = 1584/1648$  and  $\mathcal{R} = 0.18^{+0.06}_{-0.05}$ ,  $A_{\text{Fe}} = 3^{+4}_{-2}$ , and  $\log \xi < 2.1$  erg  $\text{s}^{-1} \text{cm}$ . Next we replaced *XILLVER* with *RELXILL*, which describes relativistically blurred reflection off an ionized accretion disc (García et al. 2014; Dauser et al. 2016). The iron abundance and the ionization parameter were free and tied, as in the *XILLVER* fit, while we left the inner disc radius free to vary among the different observations. Furthermore, we left the inclination  $i$  free. We found no improvement ( $\chi^2/\text{d.o.f.} = 1582/1642$ , i.e.  $\Delta\chi^2/\Delta\text{d.o.f.} = -2/-6$ ), with lower limits to the inner disc radius of  $20\text{--}30 R_G$  and  $i < 17$  deg; the other parameters are consistent within the errors with the *XILLVER* fit.

#### 4.4. The broad-band fit I. Testing relativistic reflection

After obtaining constraints on the reflection component, we proceeded to fit the pn and *NuSTAR* data in the whole X-ray energy band (0.3–79 keV). Extrapolating the best-fitting model (cut-off power law plus XILLVER) above 3 keV to lower energies, we found a significant soft excess (Fig. 9). In addition, refitting the data in the 0.3–79 keV band and including a 0.5 keV Gaussian emission line (see Appendix B), we found that the fit using XILLVER or RELXILL only is very poor ( $\chi^2/\text{d.o.f.} > 2.5$ ), with significant residuals below 1 keV.

We then tested a broad-band model including the primary continuum plus two reflection components. We used RELXILL to model the continuum plus the ionized reflection from the inner disc, which produces a soft excess. For the constant reflection component we tested two different models, namely XILLVER and BORUS, as we describe below. We note that when using these models an additional 0.5 keV Gaussian line is not required.

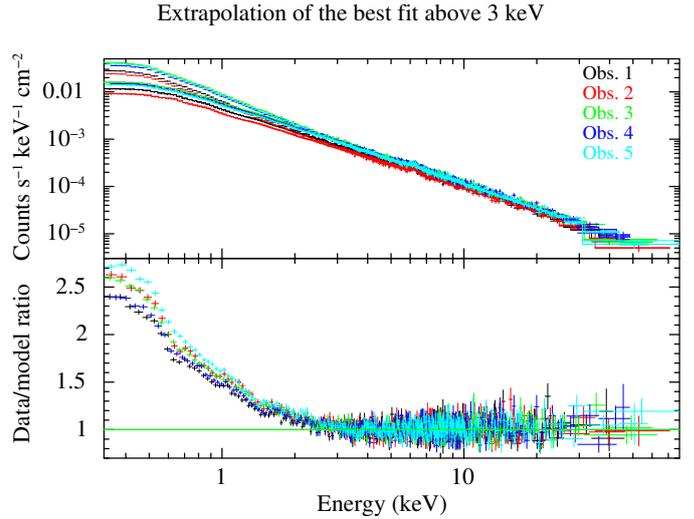

**Model A: RELXILL+XILLVER.** In RELXILL, the emissivity index  $q$ , the inner disc radius, and the ionization were left free, but were tied among the observations, with no significant improvement by leaving them free to change. The photon index of the continuum, the cut-off energy, the reflection fraction, and the normalization were all free to vary among the observations. The outer disc radius was fixed at  $400 R_G$ . In XILLVER, the ionization and the normalization were free and tied among the observations; the photon index and the cut-off energy were instead fixed at the average values of the continuum in RELXILL. We also left free (but tied among the observations) the iron abundance and the inclination, assuming the same values for RELXILL and XILLVER.

**Model B: RELXILLD+XILLVERD.** We tested the flavour of RELXILL and XILLVER that provides the density of the reflecting material as a free parameter (García et al. 2016). We left the disc density in both RELXILLD and XILLVERD free but tied among the observations, without imposing a link between the two components. The other parameters were set as in model A, with the difference that in the current version of RELXILLD and XILLVERD the cut-off energy is fixed at 300 keV.

**Model C: RELXILL+BORUS.** We replaced XILLVER with BORUS (Baloković et al. 2018), which describes neutral reflection from a gas torus. This model includes Compton scattering plus self-consistent fluorescent line emission. In BORUS, the half-opening angle of the torus  $\theta_{\text{tor}}$  and the normalization were free and tied among the observations, while the photon index and cut-off energy were fixed at the RELXILL average values. The iron abundance and the inclination were linked between RELXILL and BORUS, and tied among the observations. We note that the inclination angle is defined in the same way in RELXILL and BORUS, being measured from the symmetry axis in both cases. The other parameters of RELXILL were set as in model A.

We list the best-fitting parameters for each model in Table 3. In Fig. 10 we show the residuals for the three fits.

Model A provides the best fit in a statistical sense, having  $\chi^2/\text{d.o.f.} = 2171/1977$  (1.098). However, the model leaves significant positive residuals in the high-energy band above 20 keV. The best-fitting photon indices of the continuum are relatively steep, being 2.0–2.1. Related to this, the cut-off energy is mostly found to have lower limits  $>500$  keV. Very similar results are obtained replacing RELXILL and XILLVER with the corresponding Comptonization flavours, RELXILLCP and XILLVERCP, thus fitting for the electron temperature instead of the exponential

**Fig. 9.** Upper panel: pn and *NuSTAR* spectra fitted with a cut-off power law plus XILLVER in the 3–79 keV band (see Sect. 4.3). Lower panel: ratio of the broad-band spectra, down to 0.3 keV, to the model. The data were binned for plotting purposes.

cut-off. RELXILLCP+XILLVERCP actually yield a worse fit with  $\Delta\chi^2 = +50$  for the same number of d.o.f., and mostly lower limits to the temperature. Model B yields  $\chi^2/\text{d.o.f.} = 2209/1980$  (1.116) with significant, positive residuals above 20 keV. The fixed cut-off energy at 300 keV likely explains the worse fit compared with model A, as well as the tight constraints on the photon index (which is  $\sim 2.0$ , as in model A) and on the reflection fraction. The pn–*NuSTAR* discrepancy in photon index is essentially zero, which is unexpected (see Appendix A).

Finally, model C yields  $\chi^2/\text{d.o.f.} = 2222/1976$  (1.124), with positive residuals above 20 keV and at 0.8–0.9 keV. The latter are possibly due to the lack of soft emission lines in the neutral reflection component BORUS (while they are included in XILLVER). This model also requires some extreme parameters. In RELXILL, the inner radius is pegged at the minimum value of  $1.235 R_G$  with an upper limit of  $1.3 R_G$ , and the emissivity index is pegged at 10 with a lower limit of 9. In BORUS, the half-opening angle has a lower limit of 76 deg and the column density is pegged at the maximum value  $\log N_H = 25.5$ . Also, the iron abundance is  $<0.52$  and the inclination is tightly constrained at 67–68 deg.

We conclude that model A (RELXILL+XILLVER) provides the most satisfactory fit to the data, even if only assuming that the inclination is very low (pegged at the minimum value of 3 deg, with an upper limit of only 5 deg; fixing the inclination at 30 deg, we obtained a worse fit with  $\Delta\chi^2 = +25$  for 1 additional d.o.f.), and the spin very high (given the small inner disc radius,  $1.64^{+0.06}_{-0.04} R_G$ ).

#### 4.5. The broad-band fit II. Testing the two-corona scenario

In the next step we tested a two-corona scenario, in which warm Comptonization accounts for the soft excess. We fitted the pn and *NuSTAR* data in the 0.3–79 keV band, also including the optical–UV data from the OM. The different components of the model are described below.

**The primary continuum and soft excess.** The hard X-ray spectrum is modelled with the thermal Comptonization model NTHCOMP. We left the electron temperature  $kT_e$  and the photon index  $\Gamma$  of the asymptotic power law free to vary among the different observations. For the seed photons, we assumed a

**Notes.** In the second column we list the fit parameters that were tied among all observations. In the subsequent columns, we give the fit parameters that were free to vary for each observation.  $^{(\dagger)}$ Constraint estimated from the 1D contour plot (STEPPAR command in XSPEC).

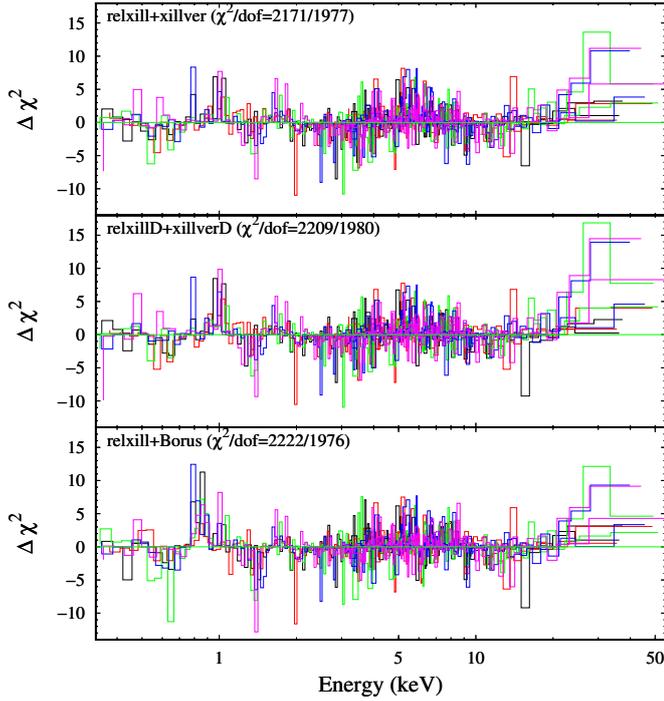

multicolour disc black-body distribution (Mitsuda et al. 1984; Makishima et al. 1986) and left the seed temperature  $kT_{\text{BB}}$  free, but tied among the observations. We used NTHCOMP also to model the soft excess, fitting for the electron temperature and the photon index. The model thus included a hot NTHCOMP component with electron temperature  $kT_{\text{e,h}}$  and photon index  $\Gamma_{\text{h}}$ , and a warm NTHCOMP component with temperature  $kT_{\text{e,w}}$  and photon index  $\Gamma_{\text{w}}$  (see Table 4). The seed temperature  $kT_{\text{BB}}$  was the same for both components.

**Reflection.** Following Sect. 4.3, to model the reflection component we used XILLVERCP namely the flavour of XILLVER in which the illumination spectrum is modelled with NTHCOMP instead of a cut-off power law. The free parameters of XILLVERCP were the iron abundance, the ionization parameter, and

the normalization. These parameters were kept tied to a common value as they were consistent with being constant. We fixed the photon index and electron temperature of the incident spectrum to the average values found in each observation for the primary continuum (see also Sect. 4.3).

**Soft emission lines.** We included a narrow Gaussian line to account for positive residuals around 0.5 keV that can be associated with the O VII complex detected in the RGS spectra (Appendix B).

**Small blue bump.** This broad feature is generally observed in the optical–UV spectrum of AGNs, in the 2000–4000 Å band, and is due to a blend of strong Fe II lines and the Balmer continuum emission (Grandi 1982; Wills et al. 1985). To account

**Fig. 10.** Contributions to  $\chi^2$  for the relativistic reflection fits (rebinned for plotting purposes) discussed in Sect. 4.4.

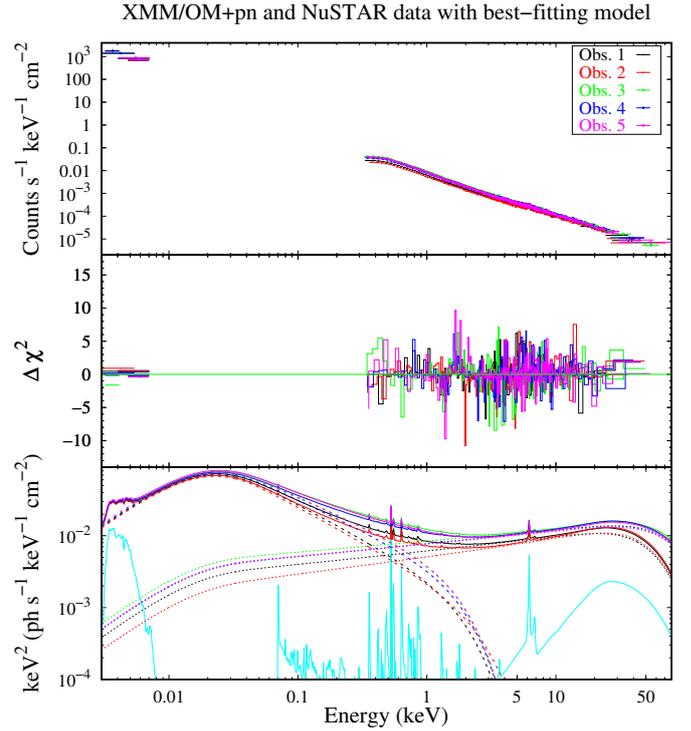

for this component, we produced a table model for XSPEC (SMALLBB) using the calculations of Wills et al. (1985) and Grandi (1982) for the Fe II lines and for the Balmer continuum, respectively. The model flux of this component was found to be  $(8.3 \pm 0.7) \times 10^{-12} \text{ erg s}^{-1} \text{ cm}^{-2}$ , and is consistent with being constant among the different observations.

We show the data, residuals, and best-fitting model in Fig. 11, while all the best-fitting parameters are listed in Table 4. We obtain  $\chi^2/\text{d.o.f.} = 2048/1986$ . Considering the X-ray data only, this corresponds to  $\chi^2/\text{d.o.f.} = 2042/1968$  ( $\Delta\chi^2/\Delta\text{d.o.f.} = -129/-9$  compared with the RELXILL+XILLVER fit). The pn–NuSTAR discrepancy in photon index is  $\Delta\Gamma = 0.07$ .

For the warm NTHCOMP component, we find a variable photon index in the range 2.7–3.0 and a temperature in the range 0.4–0.8 keV (see Fig. 12). The corresponding optical depth, as derived from the NTHCOMP model<sup>1</sup>, is roughly consistent with 17.5 with some hints of variability between observations 2 and 3. The hot NTHCOMP component is nearly constant in spectral shape, with the exception of observation 2, which has a flatter photon index (see Fig. 13). Given the uncertainties, the temperature is roughly consistent with being always  $\sim 20$  keV, while the optical depth is consistent with  $\sim 4$ . However, the flatter photon index in observation 2 suggests a slightly greater optical depth (and possibly a smaller temperature).

The warm NTHCOMP photon index is significantly anticorrelated with the flux (see Fig. 14, panel A): the Pearson’s correlation coefficient is  $-0.98$  with a  $p$ -value of 0.003. Also, the flux of the hot NTHCOMP component in the 3–10 keV band is correlated with the flux of the warm NTHCOMP component in the 0.3–2 keV band (see Fig. 14, panel B), with a Pearson’s correlation coefficient of 0.92 and a  $p$ -value of 0.03. This indicates a correlation

<sup>1</sup> The optical depth  $\tau$  in NTHCOMP is related to the photon index  $\Gamma$  of the asymptotic power law and to the temperature  $\Theta \equiv kT_e/m_e c^2$  via the formula  $\tau = \{2.25 + 3/[\Theta \times (\Gamma + 0.5)^2 - 2.25]\}^{0.5} - 1.5$ .

**Fig. 11.** Broad-band UV–X-ray data and best-fitting model discussed in Sect. 4.5 (see Table 4). *Upper panel:* XMM–Newton/OM, pn, and NuSTAR data (rebinned for plotting purposes) with folded model. *Middle panel:* contribution to  $\chi^2$ . *Bottom panel:* best-fitting model  $E^2 f(E)$ , without absorption, with the plot of the warm and hot NTHCOMP components (dashed and dotted lines, respectively), the small blue bump, the Gaussian line at 0.54 keV, and the reflection component (cyan solid lines).

between the primary X-ray emission from the hot corona and the soft excess.

The absorption-corrected model luminosities in the 0.001–1000 keV band are in the range  $0.8\text{--}1.0 \times 10^{45} \text{ erg s}^{-1}$ . Assuming a black hole mass of  $4 \times 10^7 M_\odot$ , we obtain an Eddington ratio  $L/L_{\text{Edd}} \approx 0.16\text{--}0.20$ . The seed photon temperature of both NTHCOMP components is found to be around 7 eV. This temperature is expected at a radius of  $\sim 10 R_G$  in a standard Shakura & Sunyaev (1973) accretion disc, for the black hole mass and accretion rate above.

To further investigate the nature of the accretion flow, we tested a physically motivated model for the hot corona: the jet-emitting disc (JED; Ferreira et al. 2006; Marcel et al. 2018a,b), originally proposed for X-ray binaries. Assuming scale invariance for accreting black hole systems, the JED can be used to model the high-energy emission of AGNs by simply changing the black hole mass.

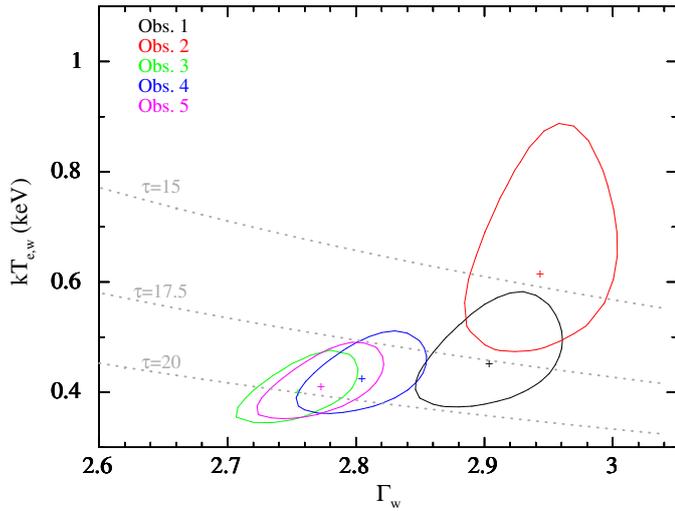

#### 4.6. Testing the jet-emitting disc

The JED model has been developed to explain the different spectral states observed in X-ray binaries (Ferreira et al. 2006). In particular, the model is able to explain the X-ray spectral properties and the presence of radio jets observed during hard states (Petrucci et al. 2010). Although HE 1143-1810 is classified as a radio-quiet Seyfert, it shows an unresolved radio emission with a flux density of  $9.5 \pm 0.6 \text{ mJy}$  at 1.4 GHz (from Very Large Array data: Condon et al. 1998) which is consistent with the prediction of the so-called fundamental

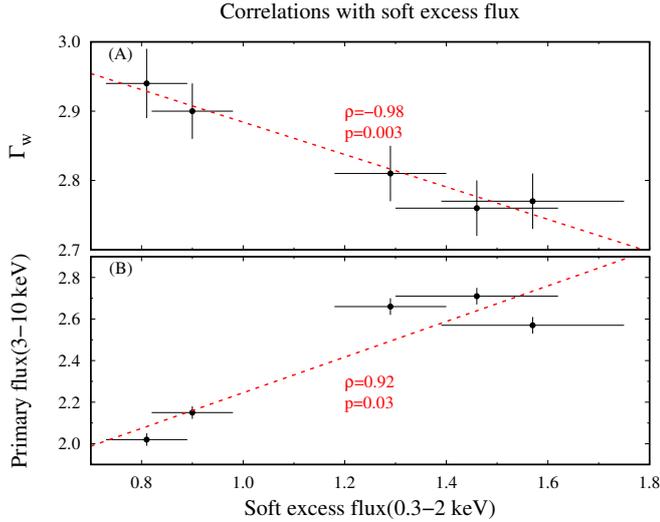

**Fig. 13.** Contour plots of the electron temperature vs. photon index of the hot corona at the 90% confidence level. Grey dotted lines correspond to contours of constant optical depth.

plane of black hole activity ([Merloni et al. 2003](#)), given the observed X-ray luminosity and black hole mass of the source.

The JED paradigm assumes the existence of a large-scale vertical magnetic field  $B_z$  that can become dominant in the innermost region of the disc, allowing the production of self-confined jets. The capability of generating jets strongly depends on the disc magnetization, defined as the ratio  $B_z^2/\mu_0 P_{\text{tot}}$ , where  $P_{\text{tot}}$  is the gas plus radiation pressure. Stationary jets are only produced at high disc magnetization, of order unity ([Ferreira & Pelletier 1995](#); [Petrucci et al. 2008](#)). A much lower magnetization would thus correspond to a standard accretion disc (SAD). Within this paradigm, the accretion flow has two constituents: an outer SAD, extending down to a transition radius  $r_j$  where the magnetization becomes of order unity, and an inner JED down to the inner-

most stable circular orbit (ISCO). When the transition radius is close to the ISCO, the thermal emission from the SAD dominates and the source is in a soft state; for large transition radii, the X-ray emission from the JED dominates and the source is in a hard state (for details, see [Marcel et al. 2018b](#)). In addition to the transition radius, the other crucial parameter is the accretion rate, which determines the total luminosity and influences the aspect ratio of the disc height to radius ([Marcel et al. 2018a](#)). The evolution of transition radius and accretion rate can explain the spectral properties of X-ray binaries like GX 339-4 during outbursting cycles ([Marcel et al. 2018b, 2019](#)).

We tested the SAD-JED model, for the first time on an AGN, following [Marcel et al. \(2018a,b\)](#), who developed a

**Fig. 14.** *Panel A:* photon index  $\Gamma_w$  vs. flux (0.3–2 keV) of the warm NTHCOMP component, for the different observations. *Panel B:* primary X-ray flux (3–10 keV) of the hot NTHCOMP component vs. flux of the warm NTHCOMP component. The fluxes are in units of  $10^{-11}$  erg  $s^{-1}$   $cm^{-2}$ . Red dashed lines represent linear fits to the data.

two-temperature plasma code which includes advection and radiation losses via Bremsstrahlung, synchrotron, and Comptonization. These radiative processes are taken into account through the BELM code (Belmont et al. 2008; Belmont 2009). The effect of the illumination on the inner JED by cold photons from the outer SAD is also taken into account (Marcel et al. 2018b). We fitted the *XMM-Newton* and *NuSTAR* data as in Sect. 4.5. We produced two XSPEC tables, one for the JED and one for the SAD, which both have the same two parameters  $r_j$  and  $\dot{m}$ . Having two separate tables allows us to model the soft excess as a Comptonized tail of the SAD alone. The different components of the model are described below.

*The primary continuum.* In the SAD–JED scenario translated to AGNs, the SAD produces the optical–UV bump while the JED produces the bulk of the X-ray emission. The free parameters of these models are the SAD–JED transition radius  $r_j$  and the accretion rate  $\dot{m}$  at the ISCO in Eddington units ( $\dot{M}_{\text{Edd}} \equiv L_{\text{Edd}}/c^2$ , thus  $\dot{m} \equiv \dot{M}/\dot{M}_{\text{Edd}} = L/\eta L_{\text{Edd}}$ , where  $\eta$  is the efficiency of mass-energy conversion.)<sup>2</sup> No link is imposed a priori between  $r_j$  and  $\dot{m}$  in the SAD–JED model. We left  $r_j$  and  $\dot{m}$ , which determine the broad-band spectral shape, free to change among the different observations. The observed flux is not a free parameter per se, because it depends only on the total luminosity (which is mostly set by the accretion rate and the black hole mass) and on the distance of the object. We assumed a distance of 144 Mpc, as obtained from the redshift and assuming a standard cosmology with  $H_0 = 70$  km  $s^{-1}$ ,  $\Omega_M = 0.3$ , and  $\Omega_\Lambda = 0.7$ . To allow for flux normalization, we left also the black hole mass  $M_{\text{BH}}$  free to vary (but tied among the different observations). The SAD–JED model also has several dynamical parameters related to the production of jets, and thus not relevant for the present work. We thus used the same parameters that were chosen by Marcel et al. (2019) to reproduce an outburst from the X-ray binary GX 339-4: the disc magnetization, set to 0.5, which does not strongly influence the X-ray emission (Marcel et al. 2018a); the local JED ejection efficiency, set

<sup>2</sup> The JED accretion rate is linked to the SAD accretion rate via  $\dot{m}(r)/\dot{m}_{\text{SAD}} = (r/r_j)^\xi$ , where  $\xi$  is the ejection efficiency (fixed at 0.01).

to 0.01; the sonic Mach number, set to 1.5; the fraction of the accretion power channelled into the jet, set to 0.3. The definition of these parameters and a study of their effects can be found in Marcel et al. (2018a,b).

*The soft excess.* Motivated by the results of the broad-band spectral analysis given in Sect. 4.5, we modelled the soft excess as a Comptonized tail of the SAD emission. We thus convolved the SAD component with the model SIMPL in XSPEC (Steiner et al. 2009), in which a fraction of the input photons is scattered into a power law component. We left the photon index of SIMPL free to vary among the observations, in close analogy to the NTHCOMP fit discussed above. In SIMPL, we assumed a scattered fraction of 1, with no improvement found when leaving this parameter free. Since the model SIMPL currently available in XSPEC does not take into account the roll-over due to the finite temperature of the scattering medium, we also included an exponential cut-off. This is an acceptable approximation, since our main goal was to get insights into the nature of the hot corona.

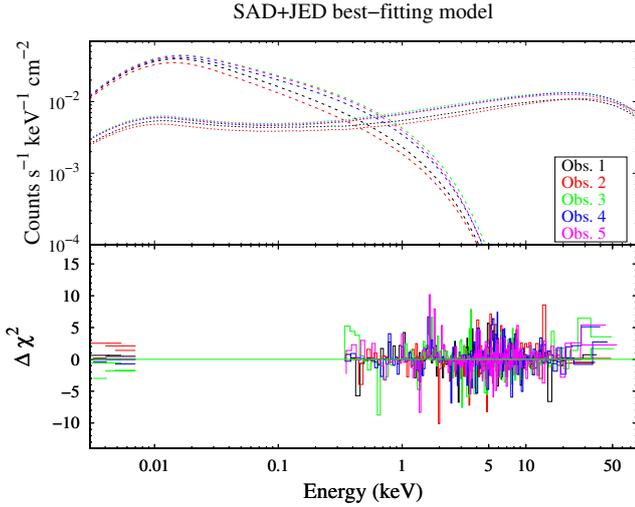

*Reflection.* Again motivated by the results of Sect. 4.5, we included a reflection component modelled with XILLVERCP. We fixed the parameters at the best-fitting values found in Sect. 4.5, with no significant improvement by leaving them free to vary.

*Soft emission line and small blue bump.* We included these components, as in Sect. 4.5. We note that the small blue bump is related to the broad-line region and is not reproduced by the SAD component.

We found a good fit with  $\chi^2/\text{d.o.f.} = 2052/1999$  (i.e.  $\Delta\chi^2/\Delta\text{d.o.f.} = +4/+13$  compared with the two-corona fit). The electron temperature and Thomson optical depth of the JED are computed as a function of radius assuming thermal equilibrium (Marcel et al. 2018b). We obtained a temperature of roughly  $\sim 10^8$  K and an optical depth of 3–4, i.e. of the same order of magnitude as the values found in Sect. 4.5. The physical properties of the SAD–JED solution are discussed in detail in Appendix C. In Fig. 15 we plot the best-fitting SAD and JED components. We note that this SAD–JED model has only five free parameters. One, the black hole mass, is constant among the observations, while four are variable:  $r_j$ ,  $\dot{m}$ , the soft excess photon index  $\Gamma_s$ , and its cut-off energy  $E_s$  (we use the subscript  $s$  to distinguish these parameters from those of the warm NTHCOMP used in Sect. 4.5). In the SAD–JED model there is no need for a free normalization because the model luminosity is a function of the black hole mass and the other free parameters. Assuming a luminosity distance of 144 Mpc, the observed flux is correctly reproduced with a best-fitting black hole mass of  $(3.69 \pm 0.07) \times 10^7 M_\odot$ . This value of the mass is consistent with that estimated from the X-ray variability and from the H $\beta$  line (Sect. 3). The SAD–JED transition radius is between 18 and 20 gravitational radii, while the accretion rate varies between 0.7 and 0.9 in units of  $L_{\text{Edd}}/c^2$ . No significant correlation is found between these two parameters, although there is a hint of a lower accretion rates for smaller transition radii (see Fig. 16). A correlation between the accretion rate and the transition radius has been found during the intermediate state of GX 339-4; this is briefly discussed by Marcel et al. (2019; see their Fig. 7). However, in our case the error bars are of the same order of magnitude as the variations, thus preventing us from drawing any strong conclusions.

## 5. Discussion and conclusions

The joint *XMM-Newton* and *NuSTAR* campaign on HE 1143-1810 discussed in this paper allowed us to study the high-energy spectral properties of this unabsorbed Seyfert 1 galaxy in detail,

**Fig. 15.** Upper panel: best-fitting Comptonized SAD and JED model components (dashed and dotted lines, respectively). Lower panel: residuals of the SAD–JED model.

constraining the physics and geometry of its accretion flow. Below we summarize the main results, then we discuss in more detail their physical interpretation.

The source is clearly variable in flux during the campaign; a significant variation is seen between the “low-flux period”, corresponding to observations 1 and 2, and the “high-flux period”, corresponding to observations 3, 4, and 5. The spectral shape also shows some variability in the soft band (below 10 keV), while little spectral variability is found in the hard band. The data indicate the presence of a correlation between the UV and soft X-ray emission, consistent with a Comptonization origin for the latter, as we discuss below.

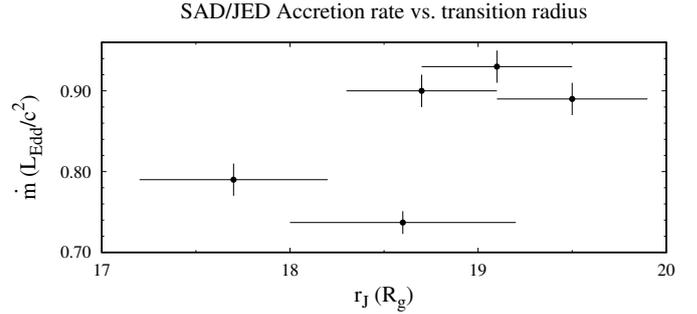

The time-averaged spectrum shows a clear indication of a turnover at high energies above 30 keV. This turnover can be phenomenologically reproduced by a power law with exponential cut-off plus a moderate reflection bump; in this case, the cut-off energy is  $100_{-20}^{+50}$  keV. Alternatively, the spectral turnover is nicely described by thermal Comptonization, with an electron temperature of  $\sim 20$  keV.

We find the presence of a Fe  $K\alpha$  emission line at 6.40 keV (rest-frame), with an intrinsic width of 0.11 keV, and consistent with being constant in flux during our campaign. The line is consistent with originating from a mildly ionized medium and is accompanied by a moderate reflection component, also consistent with being constant. The X-ray spectral properties are consistent with an ionized reflector with  $\log \xi \approx 1.7 \text{ erg s}^{-1} \text{ cm}$  and an iron overabundance of  $\sim 3$ . These values explain the moderate broadening of the line. The reflecting material can be identified with the outer part of the accretion disc since we find no strong evidence of relativistic effects due to the proximity of the black hole.

We confirm the presence of a significant soft X-ray excess below 2 keV in addition to the primary power law. Relativistic reflection can reproduce this excess, but only assuming a very low inclination and with a fit of the X-ray spectrum, which is not completely satisfactory, especially in the high-energy band. On the other hand, the broad-band (optical–UV to X-rays) data are consistent with a two-corona scenario.

### 5.1. Two-corona scenario

According to our results, the warm corona is consistent with having a constant temperature of  $\sim 0.5$  keV. However, the observed

**Fig. 16.** Accretion rate vs. transition radius of the SAD–JED model for the different observations (see Table 5).

variability of the photon index of the asymptotic power law implies some physical and/or geometrical variations. We can distinguish between the low-flux period, namely observations 1 and 2 (with  $\Gamma_w \approx 2.9$ ) and the high-flux period ( $\Gamma_w \approx 2.75$ ). The optical depth is consistent with being in the range 16–17 during the low-flux period and in the range 18–20 during the high-flux period. To constrain the geometry of the warm corona, we can estimate the Compton amplification factor  $A_w$  (i.e. the ratio between the total power emitted by the corona and power of the seed soft photons from the disc). Following the procedure of [Petrucci et al. \(2018\)](#), later corrected in [Petrucci et al. \(2020\)](#), we estimate  $A_w \approx 1.1$ . Given the values of the photon index, this amplification indicates that the disc is consistent with having an intrinsic emission of around 10% of the total, rather than being completely passive (see the Appendix in [Petrucci et al. 2020](#)).

The observed anticorrelation between the photon index and the flux of the warm Comptonization component, previously reported in NGC 4593 ([Middei et al. 2019](#)), indicates that the spectrum of the soft excess hardens as the source brightens. This behaviour could be an effect of the X-ray illumination of the warm corona by the hot one. As the hot corona brightens, the warm corona is more illuminated and thus heated, producing a harder spectrum.

The parameters of the hot corona do not exhibit a strong variability: the temperature is consistent with 15–20 keV, while the optical depth is around 4 (assuming a spherical geometry). We also estimate an amplification factor  $A_h \approx 13$ –17 for the hot corona, with no clear trend between the low-flux and high-flux periods. In any case, the estimate of  $A_h$  allows us to estimate the geometrical parameter  $g$  that describes the compactness or patchiness of the corona, since  $g \approx 2/A_h$  ([Petrucci et al. 2018](#)). We find  $g \approx 0.12$ –0.15, indicating that the hot corona intercepts around 12–15% of the seed soft photons. The observed correlation between the primary flux and the flux of the soft excess suggests an interplay between the hot and warm coronae, and can be explained if the photons Comptonized in the hot corona are emitted by the warm corona. In the spectral model used in this work, the two components are independent. Exploring the consequences of their coupling will be a future extension of the two-corona scenario. We note, however, that the warm corona emits most of the photons in the optical–UV band, similarly to a standard disc. Therefore, our assumption of a hot corona illuminated by a multicolour disc black body can be considered as a fair approximation.

Finally, we note that the warm Comptonization model for the soft excess has been critically examined by [García et al. \(2019\)](#). These authors argued that in a warm corona the photoelectric opacity is expected to dominate over the Thomson opacity, yielding

**Table 5.** Best-fitting parameters of the SAD–JED model described in Sect. 4.6: SMALLBB+ZGAUSS+HIGHECUT\*SIMPL\*SAD+JED+XILLVERCP in XSPEC notation.

	All obs.	Obs. 1	Obs. 2	Obs.3	Obs. 4	Obs. 5
$F_{\text{SMALLBB}}$ ( $10^{-12}$ erg s $^{-1}$ cm $^{-2}$ )	$7.2 \pm 0.6$					
$E_{\text{ZGAUSS}}$ (keV)	$0.533^{+0.009}_{-0.004}$					
$N_{\text{ZGAUSS}}$ ( $10^{-4}$ )	$2.3 \pm 0.4$					
$\Gamma_s$		$2.55 \pm 0.02$	$2.58 \pm 0.02$	$2.40 \pm 0.0$	$2.44 \pm 0.02$	$2.41 \pm 0.02$
$E_s$ (keV)		$1.37^{+0.16}_{-0.13}$	$1.5 \pm 0.2$	$1.20^{+0.08}_{-0.04}$	$1.20^{+0.10}_{-0.09}$	$1.13 \pm 0.07$
$M_{\text{BH}}$ ( $10^7 M_{\odot}$ )	$3.69 \pm 0.07$					
$r_J$ ( $R_G$ )		$17.7 \pm 0.5$	$18.6 \pm 0.6$	$19.1 \pm 0.4$	$19.5 \pm 0.4$	$18.7 \pm 0.4$
$\dot{m}$ ( $L_{\text{Edd}}/c^2$ )		$0.79 \pm 0.02$	$0.737 \pm 0.014$	$0.93 \pm 0.02$	$0.89 \pm 0.02$	$0.90 \pm 0.02$
$\Gamma_{\text{XILLVERCP}}$	1.82(f)					
$kT_{\text{XILLVERCP}}$ (keV)	18.5(f)					
$A_{\text{Fe,XILLVERCP}}$	2.8(f)					
$\log \xi_{\text{XILLVERCP}}$ (erg s $^{-1}$ cm)	1.71(f)					
$N_{\text{XILLVERCP}}$ ( $10^{-5}$ )	2.9(f)					
$\Delta\Gamma$	$0.039 \pm 0.013$					
$\chi^2/\text{d.o.f.}$	2052/1999					

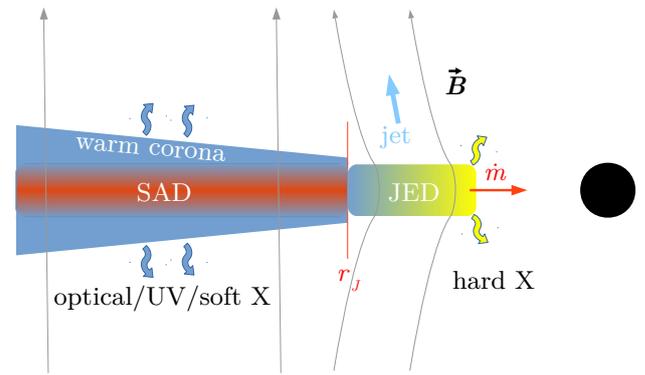

**Notes.** The parameters of XILLVERCP were frozen at the values found in Sect. 4.5 (see Table 4).

significant absorption features in the soft X-ray band that are not actually observed. Petrucci et al. (2020) addressed this problem by performing new simulations of spectra emitted by warm and optically thick coronae. Petrucci et al. used the radiative transfer code TITAN (Dumont et al. 2003) coupled with the Monte Carlo code NOAR (Dumont et al. 2000), the latter fully accounting for Compton scattering of continuum and lines. These simulations show, in a large part of the parameter space, that the warm corona is dominated by Compton cooling and the emitted spectrum presents no strong absorption or emission lines. Furthermore, the spectrum is consistent with the generally observed properties of the soft excess. The results rely on the crucial assumption that the warm corona has a source of internal heating power. In other words, the upper layer of the disc must be heated via dissipation of accretion power, which is possible for example by means of magnetic fields (e.g. Gronkiewicz & Różańska 2020)<sup>3</sup>. This is consistent with the concept of an energetically dominant warm corona covering a quasi-passive disc. The results of these simulations validate warm Comptonization as a scenario to explain the soft excess.

## 5.2. A jet-emitting disc?

The SAD–JED model also provides a nice description of the data. Perhaps the most striking feature of this model is the relatively small number of free parameters needed to fit the data. There are essentially two parameters, namely the accretion rate and the SAD–JED transition radius. The accretion rate (in Eddington units) is found to vary between  $\sim 0.7$ – $0.8$  in the low-flux period and  $\sim 0.9$  in the high-flux period. The data also indicate small ( $\sim 10\%$ ) fluctuations of the transition radius around  $19 R_G$ . Moreover, the SAD model nicely describes the optical–UV emission, both in terms of flux and temperature. The black hole mass is tightly constrained by the total luminosity and by the observed spectral shape in the optical–UV band. In the SAD–

<sup>3</sup> This assumption is especially realistic in the SAD–JED configuration, as the SAD portion is threaded by a large-scale vertical magnetic field. Moreover, the existence of a large-scale magnetic field does not preclude the existence of small-scale fields, such as those invoked in earlier works to explain the X-ray emission from accretion disc coronae (e.g. Galeev et al. 1979).

**Fig. 17.** Sketch of the two-corona scenario in which the JED plays the role of the hot corona. The best-fitting parameters for HE 1143-1810 are  $r_J \sim 19R_G$  and  $\dot{m} \sim 0.7$ – $0.9 L_{\text{Edd}}/c^2$ .

JED model, the precise value of the black hole mass depends on the distance and, potentially, on the other fixed parameters. However, there is good agreement between the best-fitting mass and the independent estimates based on the X-ray variability and the H  $\beta$  line. We note that the Comptonized tail of the SAD is, in this context, essentially a phenomenological component to account for the soft excess. Future extensions of the model will be needed to treat the emission from the warm corona in a more physical and self-consistent way.

The relation between the radio power of the disc-driven jet and the SAD–JED physical properties is (Eq. (3) in Marcel et al. 2019)

$$\frac{\nu L_{\nu}}{L_{\text{Edd}}} = \tilde{f}_R \dot{m}^{17/12} r_{\text{in}} (r_J - r_{\text{in}})^{5/6}, \quad (2)$$

where  $\nu L_{\nu}$  is the radio power and  $\tilde{f}_R$  is a dimensionless factor. In general, the radio emission of radio-quiet sources can have different origins (Panessa et al. 2019, and references therein); in any case, assuming that the observed 1.4 GHz flux of HE 1143-1810 is due to a jet, and taking  $\dot{m} = 0.8$  and  $r_J = 19 R_G$ , we derive  $\tilde{f}_R = 1.3 \times 10^{-9}$ . Interestingly, this factor is not too far from that derived by Marcel et al. (2019) for the X-ray binary GX 339-4

( $\tilde{r}_R = 4.5 \times 10^{-10}$ ). High-resolution radio interferometric observations of HE 1143-1810 will be needed to probe the presence of a radio jet in this source and, potentially, to study its relation with the high-energy emission.

All in all, our results suggest the following tentative scenario (see also the sketch in Fig. 17). The outer part of the accretion flow can be described by a thin standard disc, with a warm upper layer in which most of the gravitational power is released (Różańska et al. 2015; Petrucci et al. 2018). This warm corona is responsible for the optical–UV emission and the soft X-ray excess via thermal Comptonization. Below  $\sim 20$  gravitational radii, the accretion flow inflates and switches to an inner slim disc corresponding to the hot corona and illuminated by the outer thin disc. The flux variability, which is significant on a timescale of a few days, is driven by the variability of the accretion rate. The hot corona in turn illuminates the warm corona, possibly producing more heating (i.e. a harder warm corona spectrum) as the flux increases.

## Appendix A: Spectral discrepancy between pn and *NuSTAR*

To systematically check the spectral discrepancy between *XMM-Newton*/pn and *NuSTAR*, we studied the shape of the spectra from the different observations in the common band-pass 3–10 keV. For this analysis, we also included *XMM-Newton*/MOS2 data. We did not use the MOS1 data because they are affected by a known hot column issue, which is particularly severe in Timing mode<sup>4</sup>. We extracted the MOS2 spectra from rectangular regions having a width of 40 pixels for the source (coordinate RAWX in the range 284–324) and 26 pixels for the background (RAWX in the range 256–284). The MOS2 spectra were grouped to have at least 30 counts per bin and without oversampling the spectral resolution by a factor greater than 3.

We fitted the *NuSTAR*, pn, and MOS2 spectra with a simple power law in the 3–10 keV band, excluding the 6–7 keV range to avoid the contribution of the Fe  $K\alpha$  line. The photon index was left free to vary for each instrument, being tied only between *NuSTAR*/FPMA and FPMB. We list in Table A.1 the best-fitting photon indices. In general, pn yields lower values than *NuSTAR*. The discrepancy is significant in three observations out of five (observations 2, 4, and 5), whereas it is marginally consistent with zero in the other two (observations 1 and 3). The largest discrepancy is found in observation 2 (see Fig. A.1) However, the difference in photon index is always consistent with the average value of  $\Delta\Gamma \approx 0.07$ , with an uncertainty of 0.02 from simple error propagation. Concerning the fluxes, pn yields values smaller by  $\sim 10\%$  compared with *NuSTAR*. For MOS2, given the poorer signal-to-noise ratio, the photon index has a relatively large uncertainty and is roughly consistent with both *NuSTAR* and pn in the first four observations, while in observation 5 it is consistent only with *NuSTAR*. Therefore, even though we cannot derive strong conclusions, the MOS2 spectral shape seems to be in slightly better agreement with *NuSTAR* than with pn. On the other hand, the MOS2 fluxes are always smaller than the pn and *NuSTAR* values. This is possibly due to instrumental calibration issues of MOS in Timing mode.

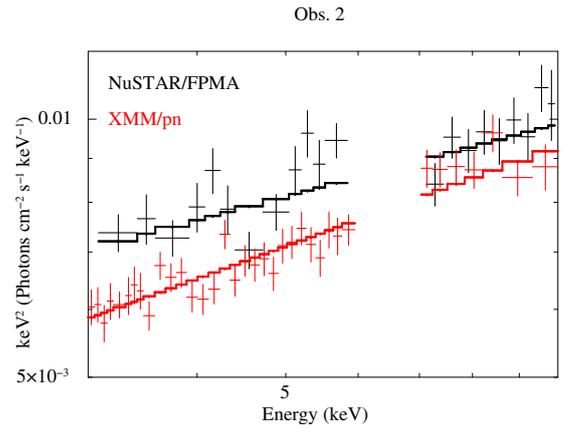

Finally, we checked whether variable absorption could help to explain the discrepancy between pn and *NuSTAR*. We first fitted the pn and *NuSTAR* data set (not including MOS2 in this case) in the 3–10 keV range leaving the photon index of the power law free to vary between different observations, but keeping it tied between pn and *NuSTAR*. We included a free flux cross-calibration constant. Only Galactic column density was included at this stage. We obtained a fit with  $\chi^2/\text{d.o.f.} = 793/780$ . Then we included an absorption component (PHABS) free to vary among the different observations. We obtained only a marginal improvement, namely  $\chi^2/\text{d.o.f.} = 786/775$  ( $\Delta\chi^2/\Delta\text{d.o.f.} = -7/-5$  and p-value of 0.22 from an F-test). Finally, we left the photon index free to vary between pn and *NuSTAR*. We found a significant improvement, with  $\chi^2/\text{d.o.f.} = 767/770$  ( $\Delta\chi^2/\Delta\text{d.o.f.} = -19/-5$ ; p-value of 0.002 from an F-test) and a column density in addition to the Galactic value always consistent with zero.

We conclude that the pn-*NuSTAR* spectral discrepancy is likely due to cross-calibration issues between the two instruments. The magnitude of the discrepancy is consistent with being constant among the observations of our campaign. However, since different values have been reported in the literature, there is currently no indication of a systematic discrepancy for

**Table A.1.** 3–10 keV photon indices ( $\Gamma$ ) and fluxes ( $F$ ) for each observation, as measured by the different instruments.

	Obs. 1	Obs. 2	Obs. 3	Obs. 4	Obs. 5
$\Gamma_{\text{NuS}}$	$1.75 \pm 0.04$	$1.72 \pm 0.04$	$1.77 \pm 0.04$	$1.78 \pm 0.04$	$1.77 \pm 0.04$
$\Gamma_{\text{pn}}$	$1.70 \pm 0.03$	$1.61 \pm 0.04$	$1.73 \pm 0.03$	$1.72 \pm 0.03$	$1.70 \pm 0.03$
$\Gamma_{\text{MOS2}}$	$1.73 \pm 0.09$	$1.56 \pm 0.19$	$1.77 \pm 0.09$	$1.81 \pm 0.09$	$1.87 \pm 0.09$
$F_{\text{NuS}}$	$1.71 \pm 0.02$	$1.62 \pm 0.02$	$2.14 \pm 0.02$	$2.09 \pm 0.03$	$2.03 \pm 0.03$
$F_{\text{pn}}$	$1.58 \pm 0.02$	$1.43 \pm 0.02$	$2.03 \pm 0.02$	$1.92 \pm 0.03$	$1.89 \pm 0.02$
$F_{\text{MOS2}}$	$1.42 \pm 0.05$	$1.3 \pm 0.1$	$1.89 \pm 0.06$	$1.72 \pm 0.06$	$1.70 \pm 0.05$

**Notes.** The fluxes are in units of  $10^{-11} \text{ erg s}^{-1} \text{ cm}^{-2}$ .

**Fig. A.1.** Unfolded *NuSTAR*/FPMA (black) and *XMM-Newton*/pn (red) spectra with best-fitting power law for observation 2.

which an aprioristic correction is possible. Nevertheless, it is possible to obtain acceptable fits using a multiplicative correction factor, as we did in this work following Ingram et al. (2017).

## Appendix B: The RGS spectrum

**Table B.1.** Emission lines detected in the RGS spectra.  $\lambda_T$  and  $E_T$  are the theoretical wavelength and energy of the lines (rest-frame), as reported in the ATOMDB data base (Foster et al. 2012).

Line Id.	$\lambda_T$ (Å)	$E_T$ (keV)	$E_{\text{obs}}$ (keV)	Flux
O VII (r)	21.602	0.574	$0.5730^{+0.0003}_{-0.0010}$	$2.1^{+1.7}_{-0.9}$
O VII (f)	22.101	0.561	$0.5605^{+0.0007}_{-0.0005}$	$2.5^{+1.3}_{-1.2}$
O VII (i)	22.807	0.569	$0.5687 \pm 0.0007$	$2.5^{+1.5}_{-1.2}$

**Notes.** The flux is in units of  $10^{-5} \text{ photons cm}^{-2} \text{ s}^{-1}$ .

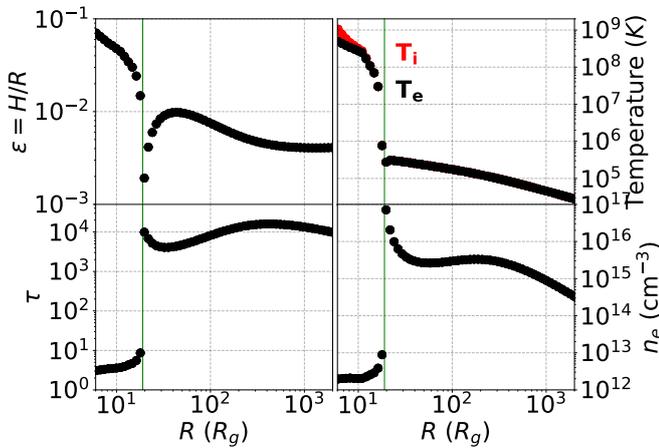

From the 2004 *XMM-Newton*/RGS and pn data, Cardaci et al. (2011) detected one O VII emission line in the soft X-ray band, and found no evidence of warm absorption. We used the RGS data obtained during our campaign to search for putative emission lines. The RGS spectra from different epochs show significant flux variability, but with a modest spectral variability in the continuum. Therefore, to obtain a better signal-to-noise ratio, we co-added the different spectra (separately for the two detectors RGS1 and RGS2). We fitted the co-added spectra in the 0.3–2 keV band.

First, we fitted the spectra with a simple power law, finding  $C/\text{d.o.f.} = 5786/5371$ . The fit left significant, positive

<sup>4</sup> <https://www.cosmos.esa.int/web/xmm-newton/sas-watchout-mos1-timing>

residuals around 22 Å (i.e. at the energies corresponding to the  $K\alpha$  triplet of O VII). We then performed a local fit at 22 Å, on an interval  $\sim 100$  channels wide. Because of the limited bandwidth, we fixed the photon index of the underlying continuum at 2. We detected three significant emission lines (at the 90% confidence level), that can be identified as the resonance ( $1s^2\ ^1S_0-1s2p\ ^1P_1$ ), intercombination ( $1s^2\ ^1S_0-1s2p\ ^1P_{2,1}$ ), and forbidden ( $1s^2\ ^1S_0-1s2s\ ^3S_1$ ) components of the O VII triplet. Including these lines in the fit over the 0.3–2 keV band, we found  $C/d.o.f. = 5750/5365$  ( $\Delta C/\Delta d.o.f. = -36/-6$ ) without significant residuals attributable to strong atomic transitions. The properties of the triplet are summarized in Table B.1.

### Appendix C: Physical properties of the SAD–JED solution

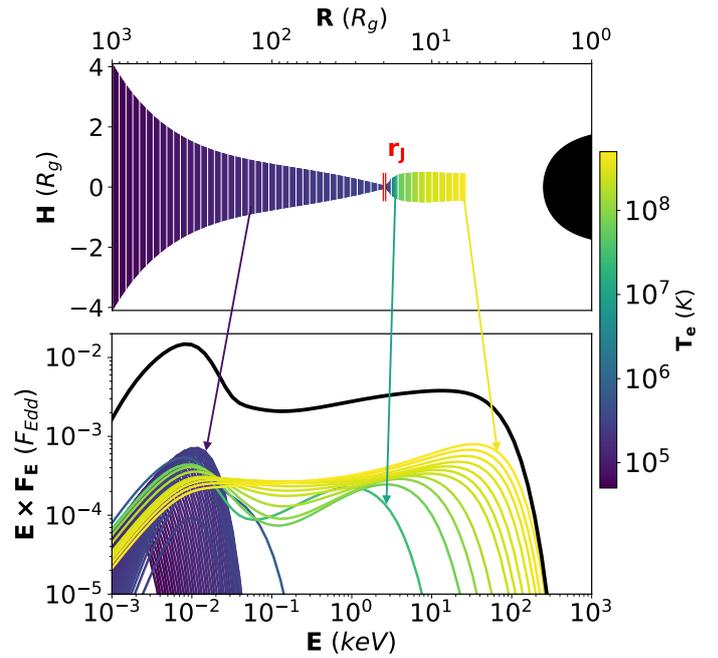

**Fig. C.1.** SAD–JED physical structure as a function of the radius. A green vertical line marks the SAD–JED transition at  $r_J = 19$ . *Top left:* aspect ratio  $\varepsilon = h/r$ . *Top right:* electron temperature  $T_e$  (black) and ion temperature  $T_i$  (red) in K. *Bottom left:* Thomson optical depth  $\tau_T$ . *Bottom right:* electron–ion density  $n_e = n_i$  in  $\text{cm}^{-3}$ .

The combination of an outer standard accretion disc (SAD, Shakura & Sunyaev 1973) and an inner jet-emitting disc (JED, Ferreira 1997) allows us to reproduce all the typical high-energy spectra of stellar-mass black hole X-ray binaries (Marcel et al. 2018a). However, the equations involved are self-similar, implying that this model can be extended to AGNs.

Using the code developed in Marcel et al. (2018a,b), we solved for the thermal structure and self-consistently computed the resulting spectra for different values of black hole masses, accretion rates, and transition radii between the two different flows. The other parameters of the accretion flow are frozen to those that best reproduce high-luminosity hard states. We also assume here that the black hole is not spinning ( $a = 0$ , i.e.  $r_{\text{in}} = 6 R_G$ ; Misner et al. 1973). The table is calculated in the following ranges of free parameters:

- Black hole mass:  $m \in [10^6, 10^9]$  in solar masses;

**Fig. C.2.** *Top panel:* computed geometrical shape of the SAD–JED, divided in annuli, colour-coded according to the electron temperature. *Bottom panel:* total emitted spectrum (in black) with the contribution from each annulus, using the same colour-coding as above. The arrows associate three annuli at different radii with their spectrum.

- Inner disc accretion rate:  $\dot{m} \in [10^{-2}, 10^2]$  in Eddington units ( $\dot{M}_{\text{Edd}} \equiv L_{\text{Edd}}/c^2$ );
- Transition radius:  $r_J \in [r_{\text{in}} = 6, 10^2]$  in gravitational radii.

Here we show the physical properties of the SAD–JED solution assuming  $r_J = 19$  and  $\dot{m}_{\text{in}} = 0.8$  (i.e. average values from the fits; see Sect. 4.6). In Fig. C.1, we show some local properties of the flow: aspect ratio, Thomson optical depth, temperature, and density. For a radius greater than  $r_J$ , the disc is assumed to be a typical  $\alpha$ -disc (SAD) with  $\alpha = 0.1$ . For the given accretion rate, the SAD is dense, geometrically thin ( $\varepsilon < 0.01$ ) and optically thick ( $\tau_T \sim 10^4$ ); ions and electrons are thermalized and cold ( $T_e \sim 10^5$  K). Below  $r_J$ , the flow is magnetized and jets are produced (JED). The presence of jets produces a magnetic torque within the disc that accelerates accretion up to supersonic speeds, with Mach number  $m_s > 1$ . Since the disc density is linked to the Mach number  $n_s \propto m_s^{-1}$  (Petrucci et al. 2010), the JED solution has a relatively low density and is geometrically slim or thick ( $\varepsilon \sim 0.01-0.1$ ). The Thomson optical depth is  $\sim 3$  and ions and electrons are not thermalized ( $T_i \gtrsim T_e$ ), with  $T_e \sim 10^8-10^9$  K.

In Fig. C.2, we show the computed geometrical shape of the SAD–JED and its emitted spectrum. The SAD produces multicolour disc black-body spectra, with typical temperatures of  $\sim 10$  eV, while the inner JED, below  $\sim 10 R_G$ , strongly radiates in the hard X-rays. The sum of the different contributions yields a smooth power-law spectrum (see also Marcel et al. 2018b).
