ABSTRACT

The pressure of hot gas in groups and clusters of galaxies is a key physical quantity, which is directly linked to the total mass of the halo and several other thermodynamical properties. In the wake of previous observational works on the hot gas pressure distribution in massive halos, we have investigated a sample of 31 clusters detected in both the *Planck* and Atacama Cosmology Telescope (ACT), MBAC surveys. We made use of an optimised Sunyaev-Zeldovich (SZ) map reconstructed from the two data sets and tailored for the detection of the SZ effect, taking advantage of both *Planck* coverage of large scales and the ACT higher spatial resolution. Our average pressure profile covers a radial range going from $0.04 \times R_{500}$ in the central parts to $2.5 \times R_{500}$ in the outskirts. In this way, it improves upon previous pressure-profile reconstruction based on SZ measurements. It is compatible, as well as competitive, with constraints derived from joint X-ray and SZ analysis. This work demonstrates the possibilities offered by large sky surveys of the SZ effect with multiple experiments with different spatial resolutions and spectral coverages, such as ACT and *Planck*.

Key words. galaxies: clusters: intracluster medium – large-scale structure of Universe – X-rays: galaxies: clusters

1. Introduction

The thermal pressure from the hot gas in massive dark matter halos is the main force preventing the gravitational collapse of the gas towards their centre. Thermal pressure is fuelled by the infall of baryonic matter into the potential wells of groups and clusters of galaxies, inducing gravitational heating of the gas to temperatures of $\sim 10^7$ – 10^8 K, that is ~ 1 – 10 keV. The gas pressure is a key quantity for the physical characterisation of these systems and can be investigated either from the plasma X-ray emission (Sarazin 1988) or from its interaction with the cosmic microwave background (CMB), that is from the Sunyaev-Zeldovich effect (SZ effect Sunyaev & Zeldovich 1972). The former provides an indirect reconstruction of the pressure via the measurement of the gas density, n_e , and temperature, T , from the X-ray surface brightness, $S_X \propto n_e^2 \sqrt{T} \exp(-E/T)$, where E is the energy. The gas pressure is derived as $P = n_e \times T$. Conversely, the SZ effect is a direct probe of the gas pressure, since the integrated SZ flux (quantified hereafter by the integrated Comptonisation parameter, Y) over the clusters directly links to the pressure as $Y \propto \int_V P dV$.

As expected from the simplest spherical collapse scenario, the population of groups and clusters of galaxies manifest several properties of similarity (Kaiser et al. 1995; Bertschinger 1998). This behaviour is observed via their global thermodynamical properties (e.g., Giodini et al. 2013) as well as for their internal distribution (e.g., Pratt et al. 2019). The gas thermal pressure is a remarkable example of this self-similar behaviour. The integrated pressure over the volume of the cluster, that is the SZ flux, has been shown to be an excellent proxy of the total gas content, thus of the total mass of the halo. Indeed the thermal pressure is mildly affected by non-gravitational physics (AGN feedback, radiation cooling, etc.) relative to other proxies (e.g., X-ray total luminosity, see Pratt et al. 2019; Mroczkowski et al. 2019, for recent reviews).

The advances made by SZ observations in the last two decades have allowed a precise measurement of the integrated pressure over statistically significant samples (Planck Collaboration X 2011; Planck Collaboration Int. III 2013; Czakon et al. 2015; Bender et al. 2016; Dietrich et al. 2019), demonstrating the coherent view of the gas content of galaxy clusters between X-ray and millimetre measurements. Increases

in the spectral coverage, spatial resolution, and sensitivity of SZ observations have also improved constraints on the pressure distribution over the whole volume of clusters (Plagge et al. 2010; Planck Collaboration Int. V 2013; Sayers et al. 2013; Eckert et al. 2013). Both theory and numerical simulations of structure formation have provided a successful description of the gas behaviour under the influence of the key physical processes governing the intra-cluster medium (ICM, Nagai et al. 2007; Battaglia et al. 2010). One outcome of these simulations is the generalisation of the Navarro et al. (1996) profile (gNFW) for the distribution of dark matter derived from early numerical simulations, to the one for the gas pressure by Nagai et al. (2007):

$$\mathbb{P}(x) = \frac{P_0}{(c_{500} x)^\gamma [1 + (c_{500} x)^\alpha]^{(\beta-\gamma)/\alpha}} \quad (1)$$

where $x = r/r_s$ and $r_s = r_{500}/c_{500}$. The quantities r_{500} and c_{500} are the characteristic radius and the concentration corresponding to a density contrast of 500 times the critical density of the Universe at the cluster redshift. The exponents γ , β , and α are the inner, external, and transition slopes (at r_s) of the profile, respectively. The gNFW profile thus provides a simple parametric description, which can be tested against observational constraints (e.g., Arnaud et al. 2010; Planck Collaboration Int. V 2013; Eckert et al. 2013; Adam et al. 2015, 2016; Sayers et al. 2016; Romero et al. 2017; Bourdin et al. 2017; Ruppel et al. 2018). The afore-cited works have found a very good agreement between the gNFW model and the observed pressure distribution in X-ray or SZ, at least within the central part of the galaxy clusters. Beyond R_{500} , the observational constraints mainly come from SZ observations and show an average agreement with the gNFW profile, although with some scatter (e.g., Sayers et al. 2016; Ghirardini et al. 2018). These variations are potentially linked to disparate samples providing a non-homogeneous sampling of the cluster population. They might also be the imprint of intrinsic variations in the outskirts across the population of massive halos due to the complex physics governing the virialisation of the gas (e.g., shocks, turbulent and bulk motions of the gas, and complex accretion from the larger surroundings leading, for instance, to inhomogeneities and substructures Simionescu et al. 2019; Walker et al. 2019).

In this paper, we pursue this observational investigation of the pressure distribution in clusters on the basis of the combination of the *Planck* and ACT maps by Aghanim et al. (2019) (see also the work by Madhavacheril et al. 2020). The resulting reconstructed SZ map is optimised for the detection of the SZ signal with its ~ 1.5 arcmin spatial resolution and a tightly controlled noise. From the footprints of the two ACT-MBAC survey strips (Dünner et al. 2013), we have assembled a sample of massive clusters of galaxies detected by both *Planck* and ACT in order to investigate their thermal pressure distribution on the basis of the SZ observations only. This study is thus a test and pathfinder case for future work on larger survey areas, for example, the 18 000 sq. deg jointly covered by ACT and *Planck* (Aiola et al. 2020).

In the following section we briefly describe the PACT SZ map and the cluster sample defined for this work. In Sect. 3, we recall some basics on the SZ effect and the methodology adopted to reconstruct the pressure distribution in our clusters. Section 4 presents the validation procedure based on the comparison to the *Planck* data, and the related results of the various validation steps. The y - and pressure profiles are given in Sect. 5, before discussing the outcome of our work in Sect. 6

Throughout this paper, we assume a Λ CDM cosmology with $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M = 0.3$, and $\Omega_\Lambda = 0.7$.

2. The *Planck* and ACT sample and SZ data

2.1. The joint SZ map

To extract the SZ signal for each individual cluster of our sample, we employed the joint *Planck* and ACT SZ map (hereafter called the PACT map, Aghanim et al. 2019), that is a y -map reconstructed from the linear combination of the *Planck* (Planck Collaboration VIII 2016) and ACT frequency maps (Dünner et al. 2013). While *Planck* is an all-sky survey, the ACT map is constituted of two strip maps, an equatorial and a southern one. This reconstruction is performed making use of an internal linear combination (ILC) method, MILCA (Modified Internal Linear Combination Algorithm Hurier et al. 2013). Such methods perform an optimal combination of frequency maps (from a single instrument or several instruments) for the reconstruction of a targeted frequency-dependent signal, that is the SZ effect in our case. They account for the intrinsic resolution and noise (instrumental and astrophysical) of each frequency map included in the combination.

As originally shown in Remazeilles et al. (2013), this combination takes advantage of the *Planck* frequency coverage and ACT spatial resolution. Also, *Planck* has the unique ability to provide the large spatial scales, which are excluded from the ACT signal after spatial filtering needed to reduce the impact of atmospheric brightness fluctuations. Hence the final PACT y -map inherits the spatial resolution of the ACT survey, which can be well approximated by a 1.4 arcmin full width at half maximum (FWHM) Gaussian, out to the outskirts of low- z systems provided by *Planck*. We refer to the first PACT paper, Sect. 3.2 for a detailed description of the y -map reconstruction and its characterisation (Aghanim et al. 2019). The MILCA y -map and its associated noise map are provided in units of the dimensionless Comptonisation parameter. Integrated measured SZ fluxes are expressed in units of arcmin² and the SZ luminosities in Mpc². We also made use, for validation purposes (see Sect. 4), of the *Planck* all-sky y -map. We used the public MILCA y -map (Planck Collaboration XXII 2016) which has an angular resolution of 10 arcmin FWHM. We also used a second (non-public) version of the MILCA y -map reconstructed at 7 arcmin FWHM. This map has been used for the extraction of the *Planck* SZ signal by the X-COP collaboration (Tchernin et al. 2016; Eckert et al. 2017; Ghirardini et al. 2018).

2.2. The cluster samples

We have defined our samples from SZ catalogues of galaxy clusters obtained from the *Planck* (Planck Collaboration VIII 2011; Planck Collaboration XXIX 2014; Planck Collaboration XXVII 2016, ESZ, PSZ1, PSZ2, respectively) and ACT (Hasselfield et al. 2013; Hilton et al. 2018) surveys. A total of 119 clusters are detected within the ACT footprint by either instrument. Here we focus on the 34 joint detections. We exclude three sources partially covered at the edges of ACT footprint or falling into the mask of *Planck* point sources (used to construct the PACT y -map). Our final sample is thus comprised of 31 clusters of galaxies, hereafter referred as PACT31, with 18 sources distributed in the equatorial strip and 13 in the southern one. By construction our sample is neither representative nor complete. The clusters range between 0.16 and 0.70 in redshift and from 3.7×10^{14} to $1.3 \times 10^{15} M_\odot$ in M_{500} , where M_{500} is the total mass contained within R_{500} . The mean signal-to-noise ratio (S/N) of the sample is 6.0 in the *Planck* catalogues and 6.3 in ACT's. The range of angular size over the sky is $2.5 < \theta_{500} < 7.9$ arcmin, with a mean value of 4.2 ± 1.1 arcmin.

Fig. 1. Distribution of the PACT31 (red dots) and PLCK62 (blue dots) in the $M_{500} - z$ (left), $M_{500} - \theta_{500}$ (middle) and $\theta_{500} - z$ (right). Crosses picture the median value and associated maximum absolute deviation over each sample. Values for the redshift, masses and angular radii are taken from the PSZ2 catalogue (Planck Collaboration XXVII 2016).

We also consider the sample of 62 massive local clusters used in Planck Collaboration Int. V (2013, P13 hereafter) to derive the pressure profile of the hot intra-cluster gas from the first *Planck* all-sky survey. Here the *Planck* maps used to derive the y -map (see above) are those from the all-sky survey (i.e., 2015 data release Planck Collaboration VIII 2016). We therefore use this sample, hereafter PLCK62, in order to compare to the profiles derived from our PACT map (see Sect. 4). From

the second *Planck* catalogue, PSZ2, the redshift of the PLCK62 sample ranges between 0.04 to 0.44 and the S/N from 7 to 49. The covered mass interval is $2.4 \times 10^{14} < M_{500} < 2.0 \times 10^{15} M_{\odot}$, for an angular size one of $3.7 < \theta_{500} < 22.8$ arcmin with a mean value of 9.8 ± 5.4 arcmin.

Masses for the PLCK62 sample are M_{500} hydrostatic masses from P13, derived from the *XMM-Newton* observations. For the PACT31 sample, we make use of the M_{500} values provided in

the PSZ2 catalogue. The latest are derived from an $Y_{500} - M_{500}$ relation calibrated with *Planck* SZ integrated fluxes and *XMM-Newton* hydrostatic masses (Planck Collaboration XX 2014; Planck Collaboration XXIV 2016). We checked the consistency between the P13 hydrostatic mass and the PSZ2 masses for the PLCK62 sample, finding a mean ratio of 0.98 ± 0.11 . We provide, in Fig. 1, the distribution of the two samples in the $M_{500} - z$, $M_{500} - \theta_{500}$ and $\theta_{500} - z$ plans.

3. Computation of the y and pressure profile

To recover the pressure profiles from the SZ y-map, we strictly followed the method described and used by P13. The SZ flux is the product of the SZ spectrum integrated over a frequency band and the integrated Compton parameter, Y , within a given solid angle, Ω . The latter is proportional to the thermal pressure of the ICM gas integrated over the line of sight:

$$Y(\Omega) = \frac{\sigma_T}{m_e c^2} \int_{\Omega} d\Omega \int_{\text{los}} P(l) dl. \quad (2)$$

The effect of the weakly relativistic velocities of the electrons as a function of the gas temperature on the SZ spectrum shape (e.g., Pointecouteau et al. 1998) are neglected in the y-map reconstruction as accounting for these effects would require a priori knowledge on the gas temperature distribution across the cluster.

From the y-map and error map, we extracted patches from the $20 \times \theta_{500}$ side centred on the ACT cluster position. We chose a pixel size defined in constant units of θ_{500} , which is thus common to all clusters in our sample (i.e., all 31 patches have different angular pixel sizes). The pixel size also implies a sampling of the PACT PSF and therefore a possible oversampling of the y-map pixel (Sect. 4). We take into account and propagate the correlations induced by this oversampling factor.

We compute an azimuthal y-profile from the map. The value in each radial bin is obtained from the mean of the pixel values it encompasses. A background offset is estimated from radii greater than $5 \times R_{500}$ and is subtracted. We masked point sources in a two step process: (i) obvious positive or negative¹ sources are masked manually, and (ii) a pixel clipping is applied on the map with a 2.5σ criterium with respect to the mean map flux outside a radius of $5 \times R_{500}$. To account for the correlation introduced by the aforementioned sampling and intrinsic correlated noise of the PACT y-map, we computed the covariance matrix associated to the y-profile. To do so, we estimated the power spectrum of the noise (astrophysics, instrument, systematics) in the region surrounding the cluster ($\theta > 5 \times R_{500}$). We drew a thousand realisations of the noise patch, applied the same profile extraction as for the y-patches, and derived the covariance matrix as $C = N_{n,m}^T N_{n,m}$ (where $N_{n,m}$ is a matrix of n points per profiles $\times m$ simulated noise profiles).

The 2D y-profiles are binned to maximise S/N out to the largest possible radius. To derive the 3D pressure profiles, we assumed spherical symmetry of our clusters and applied a regularised PSF deconvolution and geometrical deprojection algorithm, adapting the method described in Croston et al. (2006) for X-ray surface brightness profiles. Errors encoded in the 2D y-profile covariance matrix were propagated to the 3D pressure profile on the basis of the matrix's Choleski decomposition (assuming correlated Gaussian noise), from which 10 000 random realisations of the y-profile are drawn. Each of

these realisations is deconvolved from the PSF and deprojected individually. In the process, the dispersion in flux in each radial bin, derived from y-map, is used as a weight for each point of the y-profile. The covariance matrix of the pressure profile, C_P , is derived from the combination of $l = 10\,000$ realisations of the pressure profile, $C_P = N_{n,l}^T N_{n,l}$ (where $N_{n,l}$ is a matrix of n points per profiles $\times m$ simulated noise profiles). Both profile and covariance matrix are then scaled in physical units.

We followed the stacking procedure described in Sect. 4.3.2, Eq. (14) of P13 to stack the y-profiles. We recall here that the output stacked profile and associated covariance matrix are:

$$\tilde{y} = \frac{1}{n} \sum_i^n \frac{y_i}{\Phi_i} \quad \text{and} \quad \tilde{C} = \frac{1}{n^2} \sum_i^n \frac{C_i}{\Phi_i^2}, \quad (3)$$

with $\Phi_i = Y_{500,i}/R_{500,i}^2$ for the i th cluster, n the number of clusters in the sample and y_i and C_i the y-profile and associated covariance matrix for the i th cluster. The stacked pressure profile and its covariance matrix are derived in a similar way, with $\Phi_i = P_{500,i} \times f(M_i)$ for the i th cluster. P_{500} is the pressure integrated within R_{500} and $f(M) = (M_{500}/3 \times 10^{14} h_{70}^{-1} M_{\odot})^{0.12}$.

4. Validation of the PACT profiles

To fully assess our y and pressure profiles derived from the PACT maps, we proceeded through the following validation procedure which relies on two quantities: the SZ y-profiles and the SZ flux Y_{500} (integrated within the radius R_{500} as projected on the sky). Radial profiles, $y(\theta)$, are derived from the y-map together with their correlation matrix as described in the previous section. Each integrated SZ flux is derived from the corresponding y-profile, assuming a universal pressure profile (Arnaud et al. 2010, A10 hereafter), which is projected and convolved by the PACT PSF into a y-profile model, M . Folding in the covariance matrix, C , of the y-profile, the SZ flux, Y_{500} , is obtained from the optimal solution minimising the chi-square: $Y_{500} = \sigma_{Y_{500}}^2 M^T C^{-1} y(\theta)$, with $\sigma_{Y_{500}}^2 = (M^T C^{-1} M)^{-1}$.

4.1. Working method and setup

We computed $y(\theta)$ and Y_{500} over the public and non-public *Planck* MILCA y-maps, with 10 and 7 arcmin FWHM, respectively, for the PLCK62 sample (i.e., named configurations D10 and D7, respectively), and over the latter only for the PACT31 sample (i.e., configuration P7₁₂₀).

We first used the same setup adopted by P13 for the radial sampling, with $\delta_r = \Delta\theta/\theta_{500} = \Delta r/R_{500} = 0.25$. We also later on used a value of $\delta_r = 0.08$, a higher resolution sampling more appropriate for the PACT PSF. This value is derived in order to properly sample the PACT PSF accounting for the angular extension of our clusters (see Table 1). The PSF sampling imposed the need for $\delta_r < \text{PSF}/2 = 0.7$ arcmin. As we extracted our profiles over a regular grid in units of R_{500} out to a value of 10, the number of radial bins is fixed by the cluster in our sample with the largest angular extension, that is C20 with $\theta_{500} = 7.9$ arcmin. This led to a minimum of 112 bins with $10 \times \theta_{500}$, which we rounded up to 120 points. The PSF sampling thus complies with the Nyquist-Shannon criteria for all our objects, with the PSF oversampling rate increasing for clusters with smaller angular extent, and ranging from 2.1 to 6.6 pixel per PSF, with an average value of 4.2. The ensuing correlation between the successive radial bins in a given profile is encoded in the correlation matrix. The 120 points sampling applies to the setups D7₁₂₀,

¹ Negative sources are due to negative coefficients in the linear combination of frequency maps.

P7₁₂₀, and P7. (All the configurations defined above are summarised in Table 2.)

We have compared the individual integrated SZ fluxes one-to-one and the stacked y profiles over the two samples for the various setups summarised in Table 2. We chose as reference fluxes the estimation of Y_{500} as derived from the matched multi-filter (MMF) procedure described and used in our first PACT paper (Aghanim et al. 2019). These fluxes were extracted with the MMF positioned at the ACT cluster coordinates and with a filter size fixed to θ_{500} for each source. For the profile comparison, we have cross-checked the stacked profile over the whole two samples, adopting as reference the y stacked profiles (and its dispersion envelop) derived for the PLCK62 sample by P13.

4.2. Validation on the Planck y -map

We first compared the integrated SZ fluxes and profiles derived from the first single all-sky *Planck* survey (P13) on PLCK62 (PIPV) with those derived for the second *Planck* public release. The latter accounts for more than five co-added all sky surveys (hereafter DR2015). Profiles and fluxes were derived for both all sky y -map reconstructed with a 10 arcmin (D10) and 7 arcmin (D7) resolution FWHM, respectively. The comparisons of fluxes and profiles are shown in Fig. 2, left-column. All three flux estimations are consistent with each other and with the PACT MMF one. The average ratios to the PACT MMF fluxes over the sample are 1.09 ± 0.13 , 1.10 ± 0.07 and 1.07 ± 0.07 for PIPV, D10 and D7, respectively. The profiles for the three cases are also fully consistent in shape (the D7 profiles being more peaked is a simple consequence of the smaller PSF which convolves the actual y profile). This agreement demonstrates that, for profiles computed with a radial sampling of $\Delta r/R_{500} = 0.25$, there is no bias between the first all-sky survey and the full DR2015 *Planck* survey, and nor between the flux estimations from the 10 arcmin to 7 arcmin FWHM reconstructed MILCA y -map. We thereby adopted the D7 setup for further comparisons.

We recomputed over the 7 arcmin FWHM y -map, the profiles with a sampling of $\Delta r/R_{500} = 0.08$ and calculated the subsequently associated fluxes (i.e., D7₁₂₀ setup). They are compared in Fig. 2, middle-column. The profiles are perfectly consistent and so are the fluxes with average ratios to the MMF fluxes of 1.06 ± 0.07 D7₁₂₀, showing that no bias is introduced by further oversampling the PSF with the corresponding increased bin-to-bin correlation being properly encoded in the correlation matrix.

4.3. Validation on the PACT y -map

We switched to PACT31 and computed profiles and fluxes over the *Planck* 7 arcmin FWHM DR2015 map with a sampling factor of $\Delta r/R_{500} = 0.08$, that is P7₁₂₀ setup, and over the PACT maps with the same sampling factor, that is the P7 setup. The latest is the nominal setup for the results on the PACT map and sample presented in this paper. The comparison of fluxes and profiles (see Fig 2, right-column) allows us to assess that no bias is introduced due to the difference in sample. The differences between the D7₁₂₀ and P7₁₂₀ stacked profiles reflects the intrinsic difference between the PACT31 and PLCK62 samples. As shown in Fig. 1, they are populating different regions of the mass and redshift plane. The two samples fully overlap in terms of the mass range (with PLCK62 covering a slightly broader range). The main difference lies in their respective redshift coverage. As a consequence the angular sizes of the PACT31 clusters are smaller, hence the increase dilution in the *Planck* beam explaining the flatter y profile for the P7₁₂₀ setup. As a further conse-

Table 2. Definition of setups for the validation procedure.

Name	Sample	y -map	$FWHM$	$\Delta r/R_{500}$
PIPV	PLCK62	PC-internal	10 arcmin	0.25
D10	PLCK62	DR2015	10 arcmin	0.25
D7	PLCK62	DR2015	7 arcmin	0.25
D7 ₁₂₀	PLCK62	DR2015	7 arcmin	0.08
P7 ₁₂₀	PACT31	DR2015	7 arcmin	0.08
P7	PACT31	PACT	1.4 arcmin	0.08

quence, the profile convolution by the beam redistributes power towards larger scales, and explains the slightly shallower shape at larger radii. Unsurprisingly, when switching to the P7 setup, the stacked y -profiles for the PACT31 sample as measured from the PACT map is more peaked at $r < R_{500}$ than the one obtained from the *Planck* data only. This is the direct illustration of the differences in smoothing by a PSF of 1.4 arcmin with respect to 10 arcmin (public releases) for PACT and *Planck*, respectively. However the match in fluxes demonstrates that no bias is introduced in the integrated SZ flux, Y_{500} , when switching to the PACT maps. The average ratios to the reference MMF values are 1.24 ± 0.27 and 0.95 ± 0.12 for P7₁₂₀ and P7 respectively. The results on the PACT map and PACT31 sample are further discussed in the next section.

5. PACT profiles

Following the validation procedure presented in the previous section, we consider hereafter the PACT results only, thus we adopted the P7 configuration as defined in Table 2 for the rest of our study.

5.1. y profiles

We present in the left panel of Fig. 3, the individual y -profiles for the whole PACT31 sample, together with the stacked average and median profiles. The two stacked profiles present no significant differences, hence following (P13) we adopted the average over the median. The right panel shows the colour coded individual and associated stacked profiles for both equatorial and southern strip sub-samples, composed by 18 and 13 clusters, respectively. Within the limits of our sub-sample sizes, we did not find any significant differences between the two, and thereafter consider the PACT31 sample as a whole.

To give further support to our result, we followed the procedure described by P13, and we stacked the individual y maps across the sample. Each individual map, m_i , was rescaled by the factor Φ_i (see Sect. 3) and randomly rotated by 0, 90, 180 or 270° before averaging. The stacked map was finally converted in units of Comptonisation parameter by $\langle \Phi_i \rangle$. A null test map is built from $\sum (-1)^i m_i$. The rms values of this null test map and of the stacked SZ map, outside $5 \times R_{500}$, are 8.9×10^{-6} and 4.7×10^{-6} , respectively. These two rms values are of the same order of magnitude. They are also compatible with the average value of the stacked error y map, 8.8×10^{-6} . The stacked y -map is shown in Fig. 4. It displays a clear SZ signal out to $\sim 2 \times R_{500}$. From our stacked average y -profile in Fig. 3, we detect the SZ signal out to a radius of $\sim 2.5 \times R_{500}$. This is slightly less extended than for the *Planck* sample of P13. This is due to the difference in sample construction, where ours is made of more distant and compact clusters, as illustrated by their respective distribution in the $\theta_{500} - z$ in Fig. 1.

Fig. 2. *Top-row:* one-to-one comparison of the integrated SZ flux, Y_{500} , using as reference x -axis values fluxes computed from the PACT maps as presented in Aghanim et al. (2019). *Bottom-row:* average stacked y profiles in units of R_{500} and Y_{500}/R_{500}^2 . Columns present the various steps of validation: *left-column:* check of *Planck* dataset version and y map resolution. *Middle-column:* check of the impact of the radial sampling factor δ_r . *Right-column:* comparison of profiles derived from *Planck* and PACT maps and samples. Labels in the legends are for the various test configurations as defined in Table 2 and discussed Sect. 4. For the three profile plots, the red shaded envelop is the same and corresponds to the 1 σ dispersion across this same sample as published by P13 (left panel of their Fig. 3). We also adopted their radial range. The error bars correspond to the square root of the diagonal of the covariance matrix and therefore bear a certain degree of correlation between points.

Fig. 3. y profiles for the PACT31 sample. *Left panel:* stacked average (red) and median (blue) profiles. *Right panel:* average stacked profiles for the clusters in the equatorial (green) and southern (yellow) strips. The reported errors are correlated and correspond to the square root of the diagonal values of the covariance matrix for the y profile. Individual profiles are shown as solid lines.

Fig. 4. Stacked scaled y map over the PACT31 sample (size is $8 \times R_{500}$ on a side, displayed in units of $10^{-5} \times y$). Individual maps are rescaled by Φ_i (see Sect. 3) before averaging, and then multiplied by $\langle \Phi_i \rangle$.

Table 3. Best fit parameter for the gNFW pressure profile.

	P_0	c_{500}	α	β	γ
A10	8.40	1.18	1.05	5.49	0.31
P13	6.41	1.81	1.33	4.13	0.31
P13 _{NCC}	4.72	2.19	1.82	3.62	0.31
S13	6.41	1.81	1.33	3.67	0.67
S16	9.13	1.81	1.33	6.13	0.31
P7	3.36 +0.90 -0.71	1.18	1.08 +0.13 -0.11	4.30 +0.12 -0.12	0.31

Notes. A10, P13, S13 and S16 are the parameterisations provided by A10, P13, Sayers et al. (2013, 2016), respectively, and tested against our average stacked profile. P7 corresponds to the best fit parametrisation for this work. Best fit values for free parameters are printed in boldface. Errors accompanying P7 give the 68% confidence interval of the marginalised distribution for each parameter.

5.2. Pressure profile

From the individual y profiles, we followed the methodology presented in P13 to reconstruct the 3D pressure profiles of each of our clusters. We then stacked them into a normalised average profile and also computed the associated stacked covariance matrix (details of the formalism are provided in Sect. 3, see Eq. (3)).

The derived stacked pressure profile for our sample is shown in Fig. 5 (right panel) and compared to previous results from different samples (left panel). Altogether, it is in perfect agreement with the profile derived from the PLCK62 sample by P13 within the dispersion of both samples. We recall that the PACT31 and PLCK62 samples contain 31 and 62 clusters, respectively. The outer slopes for both samples are in good agreement, whereas the inner part (i.e., $r < R_{500}$) differs slightly, our PACT profile more shallower than the PLCK62 non-cool core sub-sample.

We fitted our stacked mean pressure profile to a gNFW model (Nagai et al. 2007) with a Monte Carlo Markov chain, making use of an implementation based on the Metropolis-Hastings algorithm (Hurt & Armstrong 1996; Braswell et al. 2005; Zobitz et al. 2011). We accounted in the fit for the corre-

lation between our points through the covariance matrix of the pressure profile, and of the dispersion on the mean across our sample. The latter is quadratically added to the diagonal elements of the profile covariance matrix. Following P13 and from the previous consideration we performed two fits with four and three free parameters, respectively. In both cases, since we lack the spatial resolution to resolve the inner profile, we fixed the slope to $\gamma = 0.31$, the best fit value from A10. We note that the joint MUSTANG-1 and Bolocam study by Romero et al. (2017) also converge towards this value. The four parameter fit let P_0 , c_{500} , α , and β be free with uniform prior intervals of $[0.5, 20]$, Adam et al. (2016), Aghanim et al. (2019), $[0.1, 4]$, and Bender et al. (2016), respectively. The three parameter fit uses the same configuration, but the concentration parameter is fixed to the best fit value of A10, that is $c_{500} = 1.18$. Each MCMC fit was run with a 100 chains ending up with a number of iterations of ~ 30000 each in the converged final chain. The fit processed is assessed on the basis of the likelihood logarithm, that is $-\chi^2/2$ and $\chi^2 = (P - M)^T C^{-1} (P - M)$, where P , M and C are the observed profile, the model profile and the profile covariance matrix, respectively. The fit with four free parameters leads to a solution where c_{500} hits the lower boundary of its prior interval. Letting this parameter run towards smaller value leads to a catastrophic degeneracy with the outer slope β . The scale radius $r_s = R_{500}/c_{500}$ becomes very large, inducing a similarly large value for the external slope β , hence to a quite unphysical solution. We have thus preferred the fit with three free parameters, where the scale parameter is fixed. The results of the three-parameter fit are gathered in Table 3 together with the same from previous works, and displayed in Fig. 5. The heat map for each pair of free parameters and the associated posterior probabilities for P_0 , α , and β are shown on Fig. 6. The 68% confidence-level errors associated with the parameters are derived from the posterior probabilities and reported in Table 3. For our best fit with three free parameters, we find a $\chi^2 = 2.19$. We attribute the relatively low value of the χ^2 to the fact of considering for the uncertainties of the stacked profile both the statistical uncertainties (propagated from the individual profiles) and the dispersion across the sample as discussed above. This might overestimate the actual uncertainties and as so artificially reduce the χ^2 . Conversely, the purely statistical error conveyed by the covariance matrix lead to a χ^2 of 43.5 for our 18 data points profile. In this case the error is likely underestimated possibly due to some non-Gaussian correlated noise component in the y -map. In order to further assess the quality of our derived best parametrisation, we computed the associated F-test to our best fit against our pressure profile data points, and derived a significance of 0.49 denoting the goodness of our fit.

6. Discussion and conclusion

From our Fig. 5, it is clear that the derived average stacked pressure profile for our PACT31 sample is consistent at large scales in external slope and normalisation with previous published works from distinct samples (i.e., A10; P13; Sayers et al. 2013, 2016). Within $\sim 0.5 \times R_{500}$ our profile is slightly flatter, although the differences remain within the dispersions of these respective samples.

As emphasised by Mroczkowski et al. (2019), the point of a universal pressure profile is in its shape more than in the intrinsic values of its parameters. In our case, we note the very consistent shape of the outer parts of our profile with that derived from v . We are more marginally compatible with the S13 and S16, which are bracketing our dispersion. Within this

Fig. 5. Stacked average pressure profiles over the PACT31 sample (red points). The reported errors bars on the data points are correlated and correspond to the square root of the diagonal value of the covariance matrix for the pressure profile. *Left:* comparison to published profiles over different samples by (A10; P13; Sayers et al. 2013, 2016) are overlaid as green, purple, yellow and blue lines and labelled as A10, P13, S13 and S16, respectively. The brown dotted-dashed line, labelled N07, shows the original parametrisation from Nagai et al. (2007). For the P13 profiles, the solid and dashed lines correspond to the best fit to the whole PLCK62 sample and the non cool-core sub-sample, respectively. The purple shaded area picture the dispersion of the stacked *Planck* profiles for the PLCK62 sample (as published by P13, their Fig. 4). *Right:* best fit of our data to a gNFW pressure distribution (solid black line – see Table 3 and Sect. 5.2). The red shaded area shows the dispersion of the stacked profiles for the PACT31 sample. The dashed purple solid line is identical to the left panel.

dispersion, we are also compatible at large radii with the A10 profile, hence with the theoretical predictions from numerical simulations by Borgani et al. (2004), Nagai et al. (2007), Piffaretti & Valdarnini (2008), against which it is constrained beyond R_{500} . The outer profile is also consistent (similar to P13) with the predictions from (Battaglia et al. 2012; Gupta et al. 2017). This result denotes that for both P13 and our profile, the large scales are constrained by the *Planck* measurements, with no obvious signature due to the differences in sample composition. The radial range $[0.1, 1] R_{500}$ presents the most differences with previously published profiles. As the P13 profile is derived from a joint *Planck* and *XMM-Newton* analysis, the inner parts are strongly constrained by the X-ray data (see their Fig 4, left panel). A fit performed on the *Planck* profile only, may have lead to a shallower profile. At the same time we are mainly consistent within this radial range and the respective dispersions with the S16 profile. Conversely, as shown on the left panel of Fig. 5, the comparison to the original parametrisation $[P_0 h_0^{2/3}, c_{500}, \alpha, \beta, \gamma] = [3.3, 1.8, 1.3, 4.3, 0.7]$ published by (Nagai et al. 2007) normalised against *Chandra* observations of relaxed clusters (Vikhlinin et al. 2006) is mostly consistent with our profile within this inner radial range. The same stands for an update of this parametrisation, $[\alpha, \beta, \gamma] = [0.9, 5.0, 0.4]$ presented in Mroczkowski et al. (2009). The shallower shape of our profile in the central parts is likely due to the fainter and more compact nature of our clusters relative to those of P13 and S16.

Sayers et al. (2016) noted that the differences found in pressure profile analyses originate from various possible factors: the sample definition and selection, the biases intrinsic to instruments, and methods for data analysis. The comparison to the PLCK62 sample minimises the possible sources of these differences as we adopted the same data analysis methodology. While the instrumental setups differ, the approach for the reconstruction of the PACT y -map is similar to that of the *Planck* survey. We refer here to Aghanim et al. (2019) for the extensive validation of this dataset with respect to both ACT and *Planck*. For these two

samples we attribute the differences in the mean pressure profile to the difference in composition of the PACT31 and PLCK62 samples. As shown in Fig. 1, the PACT31 and PLCK62 selections do sample two different regions of the $M-z$ plane (and subsequently the $M-\theta$ and $\theta-z$ planes). Their direct comparison is not straightforward. Their respective selection function is different, and in both cases, neither quantified nor easy to apprehend. The PLCK62 sample is composed of 62 clusters with $S/N > 6$ from the first *Planck* all-sky survey. Our PACT31 sample, though of reasonable statistically size, is two times smaller with 31 clusters based on the union of the full *Planck* survey (i.e., more than 5 all-sky passes) and the ACT-MBAC survey with S/N going down to 4 in the *Planck* PSZ2 catalogue (see Table 1). As a simple verification, if we only consider clusters in the common box interval of $0.15 < z < 0.45$ and $5 \times 10^{14} < M_{500} < 1 \times 10^{15} M_\odot$ between the PLCK62 and PACT31 samples, we obtained averaged values for the SZ flux (i.e., PSZ2 integrated Comptonisation parameter Y_{500}), of 2.4×10^{-3} and 1.3×10^{-3} arcmin², from 25 and 20 clusters, respectively. The latter is on average fainter by a factor of ~ 2 . This discrepancy is increased to a factor of ~ 8 when Y_{500} are compared in units of Mpc². This renders the detection of the SZ signal more difficult in the case of our PACT31 sample. As they are also more compact on average, the reconstruction of their 3D pressure profile is more prone to effects such as smoothing at large scales by the *Planck* beam, and thus potential biases from the regularised deconvolution and deprojection process.

Our PACT31 sample, as with all the samples used in previous published works on pressure profiles from SZ observations, has been assembled on a best-effort basis given specific observational constraints and working contexts. For instance, the PLCK62 sample is SZ selected, but is constrained by the *XMM-Newton* available archive data at the time of P13's publication. Our PACT31 sample is fully SZ selected but constrained on the basis of the PACT construction and coverage. The Bolocam sample used in S13 and S16 was assembled on the basis of X-ray

Fig. 6. Posterior probability distributions and heat maps corresponding to our MCMC fit to a gGNFW pressure profile (see Sect. 5.2). The blue crosses in the 2D heat maps show the optimal solution reported in Table 3. The colour filled area show the locus of the 68, 95 and 99.7% confidence levels, respectively.

coverage by *Chandra* from the CLASH (Postman et al. 2012) and MACS samples (Ebeling et al. 2007). Thought, not actually SZ selected the SPT sample, followed-up through a very large *Chandra* programme, has led to several key results (e.g., McDonald et al. 2013, 2016). None of these is representative of the cluster population in its sampling of the mass and redshift space. The only representative sample to which we compare to is the REXCESS sample (Böhringer et al. 2007) from which the A10 universal pressure profile is parametrised. However this is an X-ray selected sample. Quantifying their differences and trying to promote one as a reference versus the others is therefore a complex and risky task. This limitation makes any extensive discussion on the physical meaning of the differences in the central parts of our mean pressure profile to others quite speculative at this stage. For instance, if we consider the evolution with redshift of the intrinsic SZ flux, Y_{500} , at a given mass, the self-similar evolution is expected to be proportional to $E(z)^{2/3} = [(1+z)^3 \times \Omega_m + \Omega_\Lambda]^{1/3}$. At the average redshift value of the PACT31 and PLCK62 samples, that is 0.33 ± 0.11 versus 0.17 ± 0.11 , respectively, we expect an average evolution of $\sim 6\%$. Accounting for the dispersion in redshift over the two samples, this expectation is uncertain by $\sim 12\%$. The likely differences in population sampling for the two samples, the associated dispersion of each sample in the $M - z$ plane, and their proximity in

redshift convolved by their underlying selection function prevent us from drawing any serious constraints on the evolution of the pressure profile.

The advantage provided by the combination of the *Planck* and ACT data lies on the combination of the ACT higher spatial resolution and the *Planck* large-scale coverage. It provides a more accurate description of the SZ signal from the central parts to the outskirts of individual clusters. Towards the cluster centre our constraints stretch down to $r = 0.04 \times R_{500}$ (see Fig. 5). This can be compared to the SZ-only reach of the P13 pressure profiles for the PLCK62 sample, which is $0.125 \times R_{500}$ (see the red envelop in Fig. 5). With our adopted parametrisation (see Table 2) this is only illustrated by an extra central point in the reconstructed 3D pressure profile with respect to P13. This is however an improvement by more than a factor 3 in the central radial reach (obtained with a sample two times smaller). Our radial coverage towards the centre falls short of the P13 joint *XMM-Newton* X-ray and *Planck* SZ profile, which goes down in radius by an extra factor of 2, to $0.02 \times R_{500}$. Such a resolution is achievable in SZ alone, making use of high resolution facilities such as *MUSTANG-2* and *NIKA-2* (e.g., Ruppen et al. 2018; Romero et al. 2020), though assembling data for a sample as large or larger than our PACT31 sample with these two facilities would require a very large amount of time (e.g.,

the *NIKA-2* SZ guaranteed-time programme of 300 hours for 45 clusters, [Mayet et al. 2020](#)).

In conclusion, we have demonstrated the self consistency of two sets of SZ data by combining *Planck* and ACT data to reconstruct the ICM gas pressure distribution. We note that, as for previous works, the non-representative nature of our sample limits its broader applicability, beyond the basic comparisons given here. An unbiased sample at low-to-intermediate redshifts is needed to serve as a reference for the community. Such a sample will have to be a carefully selected sample, based on large SZ catalogues of clusters (e.g., [Planck Collaboration XXIX 2014](#); [Planck Collaboration XXVII 2016](#); [Bleem et al. 2020](#); [Hilton et al. 2021](#)). The CHEX-MATE sample from the *XMM-Newton* heritage class programme ‘Witnessing the culmination of structure formation in the Universe’ fulfils this requirement by construction. ([CHEX-MATE Collaboration et al. 2021](#)). SZ selected from the *Planck* survey, it gathers 118 clusters with $S/N_{\text{PSZ2}} > 6$ and shall be fully covered by deep *XMM-Newton* observations. The combination of the *XMM-Newton* and *Planck* data following the work from [P13](#) will provide a precise joint X-ray and SZ view of the ICM properties over this sample. This will provide a solid base to investigate changes in the pressure distribution with mass and redshift. Indeed, such variations impact the detection of clusters and the modelling of the SZ spectrum, as both rely on knowing the spatial distribution for the thermal pressure. Furthermore, as demonstrated in the present work, the combination with higher resolution SZ data constitutes a key improvement for its physical characterisation. Pointed observations with facilities such as *MUSTANG-2* and *NIKA-2* will be an asset, though the largest coverage of the aforementioned sample shall be achieved by the *AdvACT* survey, for which frequency maps over $\sim 18\,000$ sq. deg of the sky were recently publicly released ([Naess et al. 2020](#)).
