ABSTRACT

We study the star formation rate (SFR) vs. molecular gas mass (\(M_{\text{mol}}\)) scaling relation from hundreds to thousands of parsec in two strongly lensed galaxies at redshift \(z \sim 1\), the Cosmic Snake and AS21. We trace the SFR using extinction-corrected rest-frame UV observations with the Hubble Space Telescope (HST), and \(M_{\text{mol}}\) using detections of the CO(4–3) line with the Atacama Large Millimeter/submillimeter Array (ALMA). The similar angular resolutions of our HST and ALMA observations of 0.15–0.2′′ combined with magnifications reaching \(\mu > 20\) enable us to resolve structures in the galaxies of sizes lower than 100 pc. These resolutions are close to those of studies of nearby galaxies. This allows us to investigate for the first time the Kennicutt–Schmidt (KS) law \(\text{SFR} = \Sigma M_{\text{gas}}\) at different spatial scales, from galactic scales to \(\sim 100\) pc scales, in galaxies at \(z \sim 1\). At integrated scales we find that both galaxies satisfy the KS law defined by galaxies at redshifts between 1 and 2.5. We test the resolved KS (rKS) law in cells of sizes down to 200 pc in the two galaxies. We observe that this relationship generally holds in these \(z \sim 1\) galaxies, although its scatter increases significantly with decreasing spatial scales. We check the scale dependence of the spatial correlation between the surface densities of SFR and \(M_{\text{mol}}\) by focusing on apertures centred on individual star-forming regions and molecular clouds. We conclude that star-forming regions and molecular clouds become spatially de-correlated at \(\leq 1\) kpc in the Cosmic Snake, whereas they appear de-correlated at all spatial scales (from 400 pc to 6 kpc) in AS21.

Key words. galaxies: high-redshift – galaxies: structure – gravitational lensing: strong – stars: formation

1. Introduction

The star formation rate (SFR) and the total atomic (H I) and molecular (H_2) gas mass \(M_{\text{gas}}\) of galaxies are closely related. Hydrogen being the primary fuel for star formation, its mass content is expected to correlate with SFR. A study of the SFR–\(M_{\text{gas}}\) relation by Schmidt (1959) revealed a clear correlation between the volume densities of SFR and \(M_{\text{gas}}\), and in Schmidt (1963) it was recast as a power law relationship between surface densities \(\Sigma\): \(\Sigma \text{SFR} \propto \left(\Sigma M_{\text{gas}}\right)^n\). Kennicutt (1998) measured a power law index \(n\) of the relation of 1.4 ± 0.15 in local galaxies. H_2 is the gas phase in which the majority of star formation occurs, as it is the densest and coldest phase of the interstellar medium. A galaxy with a high H_2 mass \(M_{\text{mol}}\) content is thus expected to form stars more efficiently. Therefore, the SFR–\(M_{\text{mol}}\) relation, commonly called the molecular Kennicutt–Schmidt (KS) law, has been extensively studied. It has the form of a power law: \(\Sigma \text{SFR} \propto \left(\Sigma M_{\text{mol}}\right)^n\). Recent studies of the KS law report an index \(n\) of 1.03 ± 0.08 (e.g., de los Reyes & Kennicutt 2019).

The surface densities in the KS law are integrated quantities measured on the whole galaxy. With the increasing availability of high-resolution multiwavelength data for nearby galaxies, recent studies have been focusing on the investigation of the KS law at sub-galactic scales (Bigiel et al. 2008; Feldmann et al. 2011; Pessa et al. 2021; Leroy et al. 2013; Sun et al. 2023). A conclusion of these studies is that the resolved KS (rKS) law holds down to sub-kiloparsec spatial scales with a power law index of around 1–1.1, depending on the resolution. However, the scatter of the relation is expected to increase as the spatial scale decreases due to the statistical undersampling of the stellar IMF and to the time evolution of individual star-forming regions (e.g., Schruba et al. 2010; Kruizjes et al. 2018; Pessa et al. 2021).

The molecular gas-to-SFR ratio, also called the molecular depletion time \(\tau_{\text{dep}} = \Sigma M_{\text{mol}} / \Sigma \text{SFR}\), is the quantity that traces the time it would take for the molecular gas reservoir to be consumed assuming a constant SFR. If stars are formed in giant molecular clouds (GMCs) for many dynamical times, in other words if the star-forming process is in quasi-equilibrium at the scale of a single GMC, then the molecular gas and young stars are expected to correlate on small scales. On the contrary, if the star formation is a rapid cycle and GMCs are quickly destroyed by massive stars, then a decorrelation is expected at small scales between gas and young stars. In nearby galaxies, this is the phenomenon that has been clearly observed, and the
star-forming process is a rapid cycle at small scales (e.g., Schruba et al. 2010; Kruĳssen et al. 2019; Chevance et al. 2020; Kim et al. 2022).

Sub-kiloparsec studies are challenging at higher redshifts (z) because of the fine resolution needed. One can take advantage of strong gravitational lensing to probe a target galaxy behind massive galaxies or galaxy clusters at increased spatial resolutions and magnified luminosities (e.g., Richard et al. 2010; Jones et al. 2010; Bayliss et al. 2014; Livermore et al. 2015; Patrício et al. 2018). These background galaxies are often strongly stretched and sometimes show multiple images, so one needs to model the foreground mass distribution in order to reconstruct the shape of the target at a given redshift. This allows us to probe sub-kiloparsec sizes, and in the most strongly lensed regions even scales <100 pc. Using this methodology, in galaxies at z > 1 it is possible to resolve small-scale structures such as star-forming clumps (e.g., Cava et al. 2018; Messa et al. 2022; Claeyssens et al. 2023), giant molecular clouds (GMCs, e.g., Dessauges-Zavadsky et al. 2019, 2023), or to make other measurements at sub-kiloparsec scales, such as metallicity gradients (e.g., Patrício et al. 2019), kinematics (e.g., Girard et al. 2019), or radial profiles (e.g., Nagy et al. 2022).

In this paper we investigate the rKS law in two strongly lensed galaxies at z ∼ 1: the Cosmic Snake galaxy behind the galaxy cluster MACS J1206.2−0847, and A521-sys1, which we refer to as A521, behind the galaxy cluster Abell 0521. These two galaxies are typical main sequence (MS) star-forming galaxies at their redshifts, for which multiwavelength observations are available from, in particular, the Hubble Space Telescope (HST) in several filters, and the Atacama Large Millimeter/submillimeter Array (ALMA).

The paper is structured as follows. In Sect. 2 we present the HST and ALMA observations of the Cosmic Snake and A521 and their data reductions, as well as their gravitational lens modelling. In Sect. 3 we present the measurements of ΣSFR and ΣM_{mol} in both galaxies. In Sect. 4 we analyse and discuss the integrated and resolved KS laws in the Cosmic Snake and A521. Finally, we give our conclusions in Sect. 5.

Throughout this paper, we adopt the Lambda cold dark matter (ΛCDM) cosmology with H_0 = 70 km s^{-1} Mpc^{-1}, Ω_M = 0.3, and Ω_Λ = 0.7. We adopt the Salpeter (1955) initial mass function (IMF).

2. Observations and data reduction

2.1. Cosmic Snake and A521 galaxies

The Cosmic Snake and A521 are two strongly lensed galaxies located behind the galaxy clusters MACS J1206.2−0847 and Abell 0521, respectively. They have several multiple images that are magnified by factors of a few to hundreds. For both of these galaxies we can see an arc including several images of the source galaxy with significant stretching and amplification, as well as an isolated counter-image with almost no stretching and amplification of a few (see Figs. 1–3). These galaxies are representative of MS star-forming galaxies at z ∼ 1, with the Cosmic Snake having a stellar mass M_⋆ = (4.0 ± 0.5) × 10^{10} M_\odot and SFR = 30±10 M_\odot yr^{-1}, and A521 having M_⋆ = (7.4±1.2)×10^{10} M_\odot and SFR = 26±5 M_\odot yr^{-1}, as listed in Table 1. More detailed descriptions of these galaxies can be found in Patrício et al. (2018, 2019), Girard et al. (2019), Nagy et al. (2022), Messa et al. (2022), and Dessauges-Zavadsky et al. (2019, 2023).

Fig. 1. Rest-frame UV image with the F390W filter of HST of the Cosmic Snake galaxy’s arc. The red contours correspond to the ALMA CO(4−3) velocity integrated intensity in levels of 4σ, 5σ, 6σ, 7σ, 8σ, 10σ, and 12σ with an RMS noise of 0.020 Jy beam^{-1} km s^{-1}. The ALMA beam (0.22″ × 0.18″) is displayed in blue. The green crosses indicate bright foreground sources.

2.2. HST observations

We used the image of MACS J1206.2−0847 observed in F390W with WFC3/UVIS in the context of the Cluster Lensing And Supernova survey with Hubble (CLASH) as this filter corresponds to rest-frame ultraviolet (UV) wavelengths. The map we used has a point spread function (PSF) resolution of ~0.14′′ and

\[ \text{The data from CLASH are available at } \text{https://archive.stsci.edu/prepds/clash/} \]
ALMA beam -8°47’42”

was with a maximum baseline of 1 (project 2013.1.01330.S) in the extended C38-5 configuration of the Cosmic Snake and A521 were observed in band 6 in Cycle (Dessauges-Zavadsky et al. 2019). The isolated counter-images.

12 m array. The total on-source integration time was 52 z of .

ALMA in band 6 at 226 z of .

2.3. ALMA observations

The CO(4–3) emission of the Cosmic Snake was detected with ALMA at 226 GHz, corresponding to a redshift of $z = 1.03620$. The observations were acquired in Cycle 3 (project 2013.1.01330.S) in the extended C38-5 configuration with a maximum baseline of 1.6 km and 38 antennas of the 12 m array. The total on-source integration time was 52.3 min (Dessauges-Zavadsky et al. 2019). The isolated counter-images of the Cosmic Snake and A521 were observed in band 6 in Cycle 4 (project 2016.1.00643.S) in the C40-6 configuration with a maximum baseline of 3.1 km and 41 antennas of the 12 m array. For the isolated counter-image of the Cosmic Snake, the total on-source time was 51.8 min. For A521, it was 89.0 min. The CO(4–3) line in A521 was detected at 225.66 GHz, which corresponds to a redshift of $z = 1.04356$ (Dessauges-Zavadsky et al. 2023). The spectral resolution was set to 7.8125 MHz for all three observations.

The data reduction was performed using the standard automated reduction procedure from the pipeline of the Common Astronomy Software Application (CASA) package (McMullin et al. 2007). Briggs weighting was used to image the CO(4–3) emission with a robust factor of 0.5. Using the clean routine in CASA interactively on all channels until convergence, the final synthesised beam size obtained for the Cosmic Snake galaxy was 0.22″×0.18″ with a position angle of 85° for the arc, and 0.21″×0.18″ with an angle of 49° for the isolated counter-image. For A521 the final synthesised beam size was 0.19″×0.16″ at –74°. The adopted pixel scale for the CO(4–3) data cube is 0.04″ for the Cosmic Snake arc and 0.03″ for the Cosmic Snake isolated counter-image and A521. The achieved root mean square (RMS) values are 0.29 mJy beam$^{-1}$, 0.42 mJy beam$^{-1}$, and 0.20 mJy beam$^{-1}$, per 7.8125 MHz channel, for the Cosmic Snake arc, the Cosmic Snake isolated counter-image, and A521, respectively. The CO(4–3) moment-zero maps were obtained using the immoments routine from CASA by integrating the flux over the total velocity range where CO(4–3) emission was detected.

Notes. The redshift values for both galaxies were derived from the CO(4–3) emission line observed with ALMA. The values of $M_\star$ and SFR of the Cosmic Snake are from Cava et al. (2018), and those of A521 from Nagy et al. (2022). ΣSFR and $\Sigma M_{mol}$ for both galaxies are derived in this paper in Sect. 4.1.

3. Methodology

3.1. Gravitational lens model

The gravitational lens models used for the Cosmic Snake and A521 galaxies are constrained by multiple images found in HST observations. Lenstool (Jullo et al. 2007) was used to compute the lens models for the positions in the image plane of the Cosmic Snake and A521 galaxies are constrained by multiple images found in HST observations. Lenstool (Jullo et al. 2007) was used to compute and optimise the models. The RMS accuracies of the lens models for the positions of the objects in the image plane of the Cosmic Snake and A521 galaxies are 0.15″ and 0.08″, respectively. More details on the gravitational lens models used for the Cosmic Snake and A521 can be found in Cava et al. (2018) for the Cosmic Snake, and in Richard et al. (2010) and Messa et al. (2022) for A521.

3.2. Convolution

Since we compared quantities derived from ALMA and HST fluxes in small regions of the galaxies, we ensured that our HST images with the PSF of HST. Then we convolved the HST images with the synthesised beam of the ALMA observations, and the ALMA images with the PSF of HST.

3.3. Determination of physical quantities

3.3.1. Molecular gas mass

We used the CO(4–3) line detected with ALMA as the tracer of $M_{mol}$. First, we converted the velocity-integrated flux of the CO(4–3) line ($S_{\text{CO(4–3)}}$) into luminosity ($L_{\text{CO(4–3)}}$) using this equation from Solomon et al. (1997)

$$L_{\text{CO(4–3)}} = 3.25 \times 10^8 S_{\text{CO(4–3)}} \Delta V \nu_{\text{obs}} D_L^2 (1+z)^{-1} \text{K km s}^{-1} \text{pc}^2,$$
with $S_{\text{CO}}\Delta V$ in Jy km s$^{-1}$, and where $\nu_{\text{obs}}$ is the observed frequency in GHz, and $D_L$ the luminosity distance of the source in Mpc. The luminosity is then converted into $M_{\text{mol}}$ (Dessauges-Zavadsky et al. 2019):

$$M_{\text{mol}} = \frac{\alpha_{\text{CO}}}{M_\odot} \frac{L'_{\text{CO}(4-3)}/0.33}{(\text{K km s}^{-1} \text{ pc}^2)} M_\odot,$$

where we used the CO luminosity correction factor $r_{4,1} = L'_{\text{CO}(4-3)}/L'_{\text{CO}(1-0)} = 0.33$, which was extrapolated from $r_{1.2}$ and $r_{2,1}$ measured in the Cosmic Snake (Dessauges-Zavadsky et al. 2019) and $z \sim 1.5$ BzK galaxies (Daddi et al. 2015), respectively. We assumed the Milky Way CO-to-H$_2$ conversion factor $\alpha_{\text{CO}} = 4.36 M_\odot (\text{K km s}^{-1} \text{ pc}^2)^{-1}$ since both in the Cosmic Snake and A521 $\alpha_{\text{CO}}$ was found to be close to the Milky Way value from the virialised mass of detected GMCs (Dessauges-Zavadsky et al. 2019, 2023).

The CO(2–1) line was also detected with the Plateau de Bure Interferometer (PdBI) for the Cosmic Snake (Dessauges-Zavadsky et al. 2019), and with the Institut de radioastronomie millimétrique (IRAM) 30 m single dish antenna for A521 (Dessauges-Zavadsky et al. 2023). In both cases, the total molecular gas content traced by the CO(2–1) emission was identical to that traced by CO(4–3). We therefore conclude that using the CO(4–3) line to trace the molecular gas mass is reliable.

### 3.3.2. Star formation rate

We used the HST rest-frame UV observations with the F390W filter to compute SFR using Eq. (1) of Kennicutt (1998):

$$\text{SFR} = 1.4 \times 10^{-28} L_\nu (\text{ergs s}^{-1} \text{ Hz}^{-1}),$$

where $L_\nu$ is the UV luminosity. Furthermore, we applied an extinction correction on the SFR, as in Calzetti (2001), as the UV continuum may be significantly affected by extinction

$$f_\nu(\lambda) = f_\nu(\lambda) 10^{0.4(E(B-V))},$$

with the obscuration curve for the stellar continuum $k_\nu(\lambda) = 1.17(-2.156 + 1.509/\lambda - 0.198/\lambda^2 + 0.011/\lambda^3) + 1.78$ given by Calzetti et al. (2000), where $\lambda$ is the rest-frame wavelength in $\mu$m. The colour excess $E(B-V)$ was computed in Nagy et al. (2022), in radial bins and in the isolated counter-images of the galaxies, by performing spectral energy distribution (SED) fitting on multiple HST bands. The values of $E(B-V)$ obtained from SED fits are in agreement with the value estimated from the Balmer decrement by Messa et al. (2022).

### 4. Analysis and discussion

#### 4.1. Integrated Kennicutt–Schmidt law

We measured the integrated $\Sigma M_{\text{mol}}$ and SFR on the isolated counter-image to the north-east of the arc for the Cosmic Snake, and on the counter-image to the east for A521. These counter-images show the entire galaxy for both galaxies, unlike the arcs where only a fraction of the galaxy is imaged. To compute $\Sigma M_{\text{mol}}$ and SFR we used the following method. We integrated both the CO(4–3) emission and the UV flux inside the half-light radius measured in the $F160W$ band (Nagy et al. 2022), and then we converted them into the corresponding physical quantities $M_{\text{mol}}$ (using Eqs. (1) and (2)) and SFR (using Eq. (3)), by correcting the SFR for extinction using $E(B-V)$ computed in the same counter-images. To obtain $\Sigma M_{\text{mol}}$ and SFR we then divided by the respective half-light surfaces of the galaxies in the image plane. As the fluxes and the surfaces were both measured in the image plane, there is no need to correct for gravitational lensing if we assume a uniform amplification over the integration area. This is a fair assumption because the magnification varies only by ~0.3 and ~0.5 over the counter-images of the Cosmic Snake and A521, respectively.
The uncertainty on $\Sigma_{M_{mol}}(\Delta(\Sigma_{M_{mol}}))$ was computed following

$$\Delta(\Sigma_{M_{mol}}) = \frac{\Sigma_{M_{mol}}(\sigma_{\text{RMS}})}{\sqrt{N_{\text{pix, tot}}/N_{\text{pix, beam}}}},$$

(5)

where $\Sigma_{M_{mol}}(\sigma_{\text{RMS}})$ is the root mean square noise ($\sigma_{\text{RMS}}$) around the galaxy converted into $\Sigma_{M_{mol}}$ units, $N_{\text{pix, tot}}$ is the total number of pixels inside the integration area, and $N_{\text{pix, beam}}$ is the number of pixels in the beam. The uncertainty on $\Sigma_{\text{SFR}}(\Delta(\Sigma_{\text{SFR}}))$ was computed following

$$\Delta(\Sigma_{\text{SFR}}) = \sqrt{\left(\frac{\Sigma_{\text{SFR}}(\sigma_{\text{RMS}})}{\sqrt{N_{\text{pix, tot}}/N_{\text{pix, beam}}}}\right)^2 + (\Sigma_{\text{SFR}}(\sigma_{\text{phot}}))^2},$$

(6)

where $\Sigma_{\text{SFR}}(\sigma_{\text{RMS}})$ is the root mean square noise ($\sigma_{\text{RMS}}$) around the galaxy converted into $\Sigma_{\text{SFR}}$, and $\Sigma_{\text{SFR}}(\sigma_{\text{phot}})$ is the photometric error converted into $\Sigma_{\text{SFR}}$. We add the magnification uncertainties in quadrature, although they are negligible in comparison to other sources of uncertainties.

We find for the Cosmic Snake $\Sigma_{\text{SFR}} = 1.5 \pm 0.1 M_{\odot} \text{yr}^{-1} \text{kpc}^{-2}$ and $\Sigma_{M_{mol}} = 570 \pm 60 M_{\odot} \text{pc}^{-2}$. For A521 we have $\Sigma_{\text{SFR}} = 1.8 \pm 0.1 M_{\odot} \text{yr}^{-1} \text{kpc}^{-2}$ and $\Sigma_{M_{mol}} = 430 \pm 50 M_{\odot} \text{pc}^{-2}$. We show in Fig. 4 the Cosmic Snake and A521 in the (integrated) KS diagram ($\Sigma_{\text{SFR}} − \Sigma_{\text{M_{mol}}}$), along with a compilations of 25 galaxies from Genzel et al. (2010; $z = 1−2.5$), 73 galaxies from Tacconi et al. (2013; $z = 1−2.4$), and 4 galaxies from Freundlich et al. (2013; $z \sim 1.2$). These galaxies are all MS star-forming galaxies (SFGs). We also plot the slope from de los Reyes & Kennicutt (2019) for local spiral galaxies, as well as the slope obtained for stacks of MS SFGs by Wang et al. (2022) at $z = 0.4−3.6$. The Cosmic Snake and A521 are clearly within the distribution of $z \gtrsim 1$ galaxies.

Furthermore, the compilation of $z \gtrsim 1$ galaxies globally satisfies the KS relation with a slope of $1.13 \pm 0.09$ (Wang et al. 2022), and thus higher than $z = 0$ galaxies. This steeper slope implies, for a given $\Sigma_{\text{M_{mol}}}$, a higher $\Sigma_{\text{SFR}}$ in distant galaxies than in the nearby ones. This might indicate that $z \gtrsim 1$ galaxies have higher star formation efficiencies. This is indeed the case since the study of the integrated star formation efficiencies (SFE = $M_{\text{mol}}$/SFR) of MS galaxies shows a mild increase in SFE with redshift (Tacconi et al. 2018; Dessauges-Zavadsky et al. 2020; Wang et al. 2022).
The algorithm takes into account the uncertainties on the x and y values of the datapoints.

The results for the rKS relation in the Cosmic Snake and A521 are displayed in Figs. 5 and 6, respectively; each panel corresponds to a different bin size. We display with orange squares the $\Sigma M_{\text{mol}}$ values corresponding to the means in six $x$-axis bins with and equal number of datapoints. By performing a linear regression on all datapoints using the Levenberg–Marquardt algorithm\(^2\) and least squares statistic in the Cosmic Snake for scales $\leq 1600$ pc, we obtain slopes of $n_{1600} = 0.9 \pm 0.1$, $n_{800} = 1.0 \pm 0.3$, and $n_{1.6} = 1.1 \pm 0.4$. Uncertainties in the slope measurements increase with spatial scale due to the decrease in the number of datapoints. For the Cosmic Snake, the overall slope of the distribution for the bin sizes $\leq 1600$ pc is similar to the slope reported for local galaxies. For larger scales ($>1600$ pc) the number of boxes is too low for a reliable fit. For A521, no overall slope can be inferred at any bin size. The horizontal alignment of the binned means in Fig. 6 can be due to a lack of correlation in the data, as the binned means of a random distribution of points has the same horizontal alignment. We investigate below the differences between the two galaxies and, in particular, in the context of nearby samples from the literature.

In order to determine what is driving the difference in the distribution of datapoints between the two galaxies, we investigated the galactocentric effect, and used a colour-coding depending on the galactocentric distance of each box. For the smaller scales of 200 pc and 400 pc we clearly see a segregation with the galactocentric distance in the Cosmic Snake galaxy. The Cosmic Snake has steep radial profiles of $\Sigma SFR$ and $\Sigma M_{\text{mol}}$ (Nagy et al. 2022), so seeing a correlation between the galactocentric distance and the positions of the datapoints in the rKS diagram is not surprising. In A521, no segregation with the galactocentric distance is seen. This is in line with the shallow radial profiles of $\Sigma SFR$ and $\Sigma M_{\text{mol}}$ in A521, and hence no significant difference in the rKS diagram between regions closer to the centre and regions in the outskirts is seen.

Pessa et al. (2021) measured the rKS in 18 star-forming galaxies from the Physics at High Angular resolution in Nearby GalaxieS (PHANGS\(^3\)) survey, at scales of 100 pc, 500 pc, and 400 pc.

2 The algorithm takes into account the uncertainties on the x and y values of the datapoints.

3 https://phangs.stsci.edu/
1 kpc. They reported slopes\(^4\) of \(n_{100 \text{pc}} = 1.06 \pm 0.01\), \(n_{500 \text{pc}} = 1.06 \pm 0.02\), and \(n_{1 \text{kpc}} = 1.03 \pm 0.02\), respectively, concluding that no evidence of systematic dependence on spatial scale is shown by the slopes. The slopes of local galaxies match those of the Cosmic Snake within the error bars, although our measurements have much bigger uncertainties due to sparser sampling.

Moreover, in both galaxies, and specifically in A521, we lack dynamical range in \(\Sigma \text{SFR} \) and \(\Sigma \text{M}_{\text{mol}}\), especially for small values, to consistently constrain the rKS slope in \(z \sim 1\) galaxies. \(\Sigma \text{SFR}\) spans ~3.5 orders of magnitude in the Cosmic Snake and ~2.5 in A521, compared to ~5 in the sample of 18 galaxies from Pessa et al. (2021), and \(\Sigma \text{M}_{\text{mol}}\) spans ~2 orders of magnitude in the Cosmic Snake and in A521, compared to ~3 in Pessa et al. (2021). Higher sensitivity observations could allow us to refine the estimation of the slope in the Cosmic Snake or to estimate the slope in A521. It is important to note, however, that the lack of dynamical range in A521 is not only due to a poor S/N as the Cosmic Snake has a S/N comparable to that of A521, but a much better dynamical range.

We plot the combined rKS of the Cosmic Snake and A521 in Fig. 7 in order to increase the dynamical range of \(\Sigma \text{SFR} \) and \(\Sigma \text{M}_{\text{mol}}\). The slopes of the stacks \((n^{\text{Stack}})\) are \(n^{\text{Stack}}_{100 \text{pc}} = 0.88 \pm 0.04\), \(n^{\text{Stack}}_{400 \text{pc}} = 0.76 \pm 0.05\), \(n^{\text{Stack}}_{800 \text{pc}} = 0.79 \pm 0.07\), and \(n^{\text{Stack}}_{1 \text{kpc}} = 0.8 \pm 0.1\). These slopes are shallower than the slopes of the Cosmic Snake galaxy alone, and also than the slopes obtained by Pessa et al. (2021). The reason is that A521 has a high density of points below the rKS line from Pessa et al. (2021), as illustrated by the contours in Fig. 6. One possible reason that these points have such a low SFR may be that the extinction is underestimated, and specifically where the molecular gas density is high. It may also be due to the SFR tracer we use (rest-frame UV), which tracks star-forming regions with ages ~100 Myr. For a long continuous star formation history (SFH), the estimated SFR by Eq. (3) would be accurate. However, in the case of a more bursty star formation with a constant SFH over a shorter time frame of ~10 Myr, Eq. (3) underestimates the real SFR.

For each set of datapoints at a given bin size, we compute the scatter in dex (\(\sigma\)) as the standard deviation of the datapoints around the rKS power law fits from Pessa et al. (2021) at the closest reported spatial scale (100 pc, 500 pc, or 1 kpc). We use this method instead of computing the scatter around the best-fitting power law, as in Pessa et al. (2021), due to the uncertainty of the fit for the Cosmic Snake, and the meaningless fit if performed for A521. The values are reported in Table 2. Although the number of datapoints per grid binning size and the global shape of their distribution is notably different between the Cosmic Snake and A521, their respective scatters are similar at bin sizes up to 800 pc. The scatter of the two galaxies is also similar to the stack of the two at those scales. At 1600 pc the scatter of the Cosmic Snake decreases significantly, whereas that of A521 stays constant up to 3200 pc, then it decreases as well. The scatter decrease with increasing spatial scale is consistent with the results from Bigiel et al. (2008), Schruba et al. (2010), and Leroy et al. (2013). As a comparison, Pessa et al. (2021) reported scatters for the rKS law of \(\sigma_{100 \text{pc}} = 0.41\), \(\sigma_{500 \text{pc}} = 0.33\), and \(\sigma_{1 \text{kpc}} = 0.27\). They argued that the decrease
in scatter at increasing spatial scales is due to the averaging out of small-scale variations.

### 4.3. Scale dependence of the \( \Sigma \text{SFR} - \Sigma M_{\text{mol}} \) spatial correlation

We investigate the scale dependence of the spatial correlation between \( \Sigma \text{SFR} \) and \( \Sigma M_{\text{mol}} \) in the Cosmic Snake and A521. As in Schruba et al. (2010), we do this by considering \( \tau_{\text{dep}} = \Sigma M_{\text{mol}} / \Sigma \text{SFR} \). The value of \( \tau_{\text{dep}} \) is computed for apertures centred on CO and rest-frame UV peaks. The peaks were identified in the arcs of both galaxies, using the CO(4–3) emission from ALMA by Dessauges-Zavadsky et al. (2019) for the Cosmic Snake and by Dessauges-Zavadsky et al. (2023) for A521, and the rest-frame UV emission from HST by Cava et al. (2018) for the Cosmic Snake and Messa et al. (2022) for A521. The CO peaks trace the GMCs, and the rest-frame UV peaks trace the star-forming regions. We then project the locations of the peaks in the source plane, and we centre apertures of different sizes on those positions. We use circular apertures with diameters of 200, 400, 800, 1200, and 1400 pc for the Cosmic Snake, and 400, 800, 1600, 3200, and 6400 pc for A521. These apertures are then lensed into the image plane, and we measure fluxes within each of them. As in Sect. 4.2, we apply a 4.4σ RMS detection threshold to each individual channel of the ALMA datacubes for both the Cosmic Snake and A521, and a 4.0σ detection threshold in the case of co-spatial emission detections in two adjacent channels for the Cosmic Snake and 3.6σ for A521. Again, as the HST rest-frame UV emission is always detected where we also detect CO; we do not apply any detection threshold to the HST maps. We only consider apertures that are larger than the matched PSF in the image plane. We compute an average \( \tau_{\text{dep}} \) for each set of apertures of a given size and centred on a given type of peak (CO or UV). The uncertainty of a given average \( \tau_{\text{dep}} \) measurement (\( \Delta \tau_{\text{dep}} \)) is computed as

\[
\Delta \tau_{\text{dep}} = \frac{\text{std}(\tau_{\text{dep}})}{\sqrt{N_{\text{peaks}}}}
\]

where \( \text{std}(\tau_{\text{dep}}) \) is the standard deviation of all the \( \tau_{\text{dep}} \) used to compute the average, and \( N_{\text{peaks}} \) is the number of peaks.

The molecular gas depletion times for apertures of different sizes are given in Fig. 8, showing separately the results for the apertures centred on CO peaks (blue points) and rest-frame UV peaks (red points). The value of \( \tau_{\text{dep}} \) varies strongly with the spatial scale (aperture size) and the type of emission targeted (CO or UV). From apertures larger than \(~1\) kpc in the Cosmic Snake and \(~6\) kpc in A521, the depletion times around CO peaks and those around rest-frame UV peaks converge towards a common value.

The overall behaviour of the molecular gas depletion time curves, commonly known as the tuning fork diagram, resembles that reported in the literature for local galaxies (e.g., Schruba et al. 2010; Kruijssen et al. 2019; Chevance et al. 2020; Kim et al. 2022). However, the uncertainties are much larger for the \( z \sim 1 \) galaxies because of the lack of statistics as the number of detected clumps is about ten times lower than in a typical local galaxy. The \( \tau_{\text{dep}} \) convergence seems to happen at slightly larger...
The differences might be due to the difference in tracer; the local studies used Hα as the tracer of star-forming regions, but we used rest-frame UV emission which traces, on average, older star cluster complexes. As a result, the UV clumps that we detect are on average older (∼100 Myr) than the Hα clumps (10 Myr) detected in nearby galaxies. This may imply that the dynamical drift is more significant because UV-bright star-forming regions have moved further away from their parent clouds for a given drift velocity.

The drift of young stars from their parent molecular clouds might be faster in z ∼ 1 galaxies than in local galaxies. This is expected because of the larger gas fraction of high-redshift galaxies, and also because of their higher compactness. Cloud-cloud collisions are enhanced and the gas is more dissipative, while the newly formed stars are collisionless, and decouple faster from the gas. However, as argued in Schruba et al. (2010) and Chevance et al. (2020), the dynamical drift alone, at least in nearby galaxies, is not significant enough to be the cause of such large separations between GMCs and star-forming regions.

Unless the stellar feedback is not strong enough, after 100 Myr the GMC parents of the UV clumps should already be destroyed if their lifetime is comparable to local GMCs (10–30 Myr; Kruĳssen et al. 2019; Chevance et al. 2020), explaining the lack of correspondence between the CO and UV peaks. Resolved Hα observations are needed to check how significantly the difference in tracers impacts the observed results.

The star-forming regions detected in our high-redshift galaxies might not have been born in the GMCs that we observe, but in other undetected clouds. In other words, there is no correspondence between the GMCs and the star-forming regions that we detect. In the Cosmic Snake and A521, small apertures only contain few a points, and the majority are of the kind the aperture is centred on (CO or UV). Apertures of increasing sizes will include more peaks of both kinds, so the ratio of the CO peaks to the UV peaks will converge towards 1. Therefore, the scale dependence of τ_{dep} would actually trace the number of CO and UV peaks inside each aperture.

An explanation of the increasing scatter at smaller spatial scales seen in the rKS plots (Figs. 5–7) and discussed in Sect. 4.2 may be found in the divergence at small scales of the molecular gas depletion time curves. At large scales (>1 kpc in the Cosmic Snake and >6 kpc in A521), any aperture chosen results in proportional fluxes of molecular gas and SFR tracers, even when focusing specifically at either star-forming regions or GMCs. This means that at these large scales, a randomly selected aperture will likely have a ΣSFR and a ΣM_{mol} that satisfy the rKS relation, and consequently the scatter of the relation for a sample of randomly selected apertures larger than 1 kpc (Cosmic Snake) or 6 kpc (A521) will be low, which is what we observe (Table 2). However, as apertures get smaller, there is much larger scatter because individual star-forming regions are at different stages of time evolution, and thus have different CO-to-UV ratios. Focusing for example on a GMC results in a large τ_{dep} because the flux from the tracer of SFR is missed, and τ_{dep} is dominated by the numerator ΣM_{mol} (and vice versa). This is the reason for...
the divergence at small spatial scales seen in Fig. 8. However, when using a random gridding with a small bin size, as in the $\Sigma \text{SFR} - \Sigma \text{M}_{\text{mol}}$ plots, the boxes happen to be sometimes between a CO peak and a rest-UV peak, resulting in a datapoint that satisfies the rKS relation, but sometimes they also fall right on a given peak, which yields a datapoint with either a high $\Sigma \text{SFR}$ and a low $\Sigma \text{M}_{\text{mol}}$, or the opposite. This is the cause of the large scatter seen at small scales in the rKS diagrams. As a result, the majority of the datapoints do not satisfy the rKS law at small scales, but the entire cloud of datapoints is centred on it, and even the slope is close to the value obtained for scales $>1$ kpc (in the case of the Cosmic Snake). If the rKS law were valid at small scales, any randomly selected aperture would fall on the slope of the relation, within the scatter observed for the largest scales.

5. Conclusions

We analysed the KS law in the Cosmic Snake and A521, two strongly lensed galaxies at $z \sim 1$, at galactic integrated scales down to sub-kiloparsec scales. We used the rest-frame UV emission from HST to trace SFR and the CO(4–3) emission line detected with ALMA to trace $\text{M}_{\text{mol}}$. In addition to several multiple images with magnifications of $\mu > 20$ that are significantly stretched and where only a fraction of the galaxy is visible, the two galaxies show an isolated counter-image with over-all uniform magnifications of 4.3 and 3 for the Cosmic Snake and A521, respectively. In these counter-images, the entirety of the galaxies is visible, and thus we used them to compute integrated values of SFR and $\text{M}_{\text{mol}}$. We found $\Sigma \text{SFR} = 1.5 \pm 0.1 \text{M}_\odot \text{yr}^{-1} \text{kpc}^{-2}$ and $\Sigma \text{M}_{\text{mol}} = 570 \pm 60 \text{M}_\odot \text{pc}^{-2}$ in the Cosmic Snake, and $\Sigma \text{SFR} = 1.8 \pm 0.1 \text{M}_\odot \text{yr}^{-1} \text{kpc}^{-2}$ and $\Sigma \text{M}_{\text{mol}} = 430 \pm 50 \text{M}_\odot \text{pc}^{-2}$ in A521. The two galaxies satisfy the integrated KS relation derived at $z = 1-2.5$ (Genzel et al. 2010; Tacconi et al. 2013; Freundlich et al. 2013; Wang et al. 2022).

To study the rKS law by taking advantage of the strong gravitational lensing in the Cosmic Snake and A521, we defined six different grids in the source plane of each galaxy. We then lensed those grids in the image plane, and computed $\Sigma \text{M}_{\text{mol}}$ and $\Sigma \text{SFR}$ inside each box. The grids that we used had sizes of 200 pc, 400 pc, 800 pc, 1600 pc, 2800 pc, and 3200 pc for the Cosmic Snake, and 200 pc, 400 pc, 800 pc, 1600 pc, 3200 pc, and 6400 pc for A521.

We derived the following results from the analysis of the rKS law in the Cosmic Snake and A521:
- We were able to perform a linear regression on the measurements in the Cosmic Snake for scales $\leq 1600$ pc, obtaining slopes of $n_{200 \text{pc}}^{\text{CS}} = 1.00 \pm 0.08$, $n_{400 \text{pc}}^{\text{CS}} = 0.9 \pm 0.1$, $n_{800 \text{pc}}^{\text{CS}} = 1.0 \pm 0.3$, and $n_{1600 \text{pc}}^{\text{CS}} = 1.1 \pm 0.4$. These slopes are similar to those typically found in local galaxies. For A521 no overall slope could be inferred at any scale. We measured slopes for the combined rKS of the Cosmic Snake and A521 of $n_{200 \text{pc}}^{\text{Stack}} = 0.88 \pm 0.04$, $n_{400 \text{pc}}^{\text{Stack}} = 0.76 \pm 0.05$, $n_{800 \text{pc}}^{\text{Stack}} = 0.79 \pm 0.07$, and $n_{1600 \text{pc}}^{\text{Stack}} = 0.8 \pm 0.1$.
- To consistently constrain the rKS slopes in the analysed $z \sim 1$ galaxies, we lack dynamical range in both $\Sigma \text{M}_{\text{mol}}$ and $\Sigma \text{SFR}$. In the study of 18 PHANGS galaxies from Pessa et al. (2021), the two quantities span at least one more order of magnitude than our study.
- We see a clear spatial segregation in the distribution of the datapoints in the rKS diagram of the Cosmic Snake. Points close to the galactic centre tend to have higher $\Sigma \text{M}_{\text{mol}}$ and $\Sigma \text{SFR}$, whereas measurements in the outskirts show lower values. No such segregation is observed in A521. These observations match the results from Nagy et al. (2022) showing that the Cosmic Snake has much steeper radial profiles than A521, in $\Sigma \text{M}_{\text{mol}}$ and $\Sigma \text{SFR}$ in particular.
- The scatter of the datapoints in the Cosmic Snake and A521 is very similar at small scales up to 800 pc. The scatter of the galaxies decreases at higher scales of 1600 pc for the Cosmic Snake and 6400 pc for A521. The decrease in scatter with increasing bin sizes is similar to what is observed in $z = 0$ galaxies, and is due to the averaging out of small-scale variations.

We measured the average $\tau_{\text{dep}}$ inside apertures of different diameters centred on either rest-frame UV or CO(4–3) emission peaks in the Cosmic Snake and A521. In both galaxies we observe the same overall behaviour as in local galaxies; that is, the $\tau_{\text{dep}}$ values measured using small apertures are clearly different whether the apertures are centred on rest-frame UV peaks or on CO(4–3) peaks, and they converge towards a common value at large enough spatial scales. In nearby galaxies, the convergence typically happens in apertures of diameters of 500 pc – 1 kpc. In the Cosmic Snake the $\tau_{\text{dep}}$ measurements converge at higher but comparable apertures of size $\geq 1$ kpc, whereas in A521 it happens in much larger apertures of $\sim 6$ kpc.

We conclude that the increasing scatter in the rKS diagrams in small bin sizes is partly explained by the divergence observed between $\tau_{\text{dep}}$ measured when focusing on rest-frame UV peaks and CO(4–3) peaks at small scales. By taking values of $\Sigma \text{SFR}$ and $\Sigma \text{M}_{\text{mol}}$ from randomly selected boxes of small sizes, the corresponding datapoint may satisfy the rKS law, but may also be significantly off if the aperture happens to capture only one kind of peak. In boxes larger than the size for which the $\tau_{\text{dep}}$ values converge, any datapoint will tend to fall on the rKS, and hence the smaller scatter. In the Cosmic Snake and A521, the scales at which $\tau_{\text{dep}}$ converges are the scales at which the scatter of those galaxies in the rKS diagram decreases.
