ABSTRACT

Context. Recent Event Horizon Telescope observations of M 87* and Sgr A* strongly suggest the presence of a supermassive black hole at their respective cores. We use the semi-analytic radiatively inefficient accretion flows (RIAF) model to investigate the resulting images of the Joshi–Malafarina–Narayan (JMN-1) naked singularity and the Schwarzschild black hole.

Aims. We chose the JMN-1 naked singularity model and compared the synchrotron images with the Schwarzschild solution to search for any distinct features that can distinguish the two objects and to find an alternative to the solution with a black hole.

Methods. We performed general relativistic ray-tracing and radiative transfer simulations using the Brahma code to generate synchrotron-emission images using the thermal distribution function for emissivity and absorptivity. We investigated effects in the images by varying the inclination angle, the disk width, and the frequency.

Results. The shadow images simulated with the JMN-1 model closely resemble those generated by the Schwarzschild black hole. The disparities between the two images are very small. We conducted simulations using various plasma parameters, but the resulting images remained largely consistent for both scenarios. This similarity is evident in the horizontal cross-sectional brightness profiles of the two scenarios. Notably, the JMN-1 model exhibits a slightly higher intensity than the Schwarzschild black hole.

Conclusions. We conclude that JMN-1 is a viable substitute for the black hole scenario. This conclusion is not solely grounded in the fact that the two scenarios are indistinguishable from their respective shadow observations, but also in the consideration that JMN-1 emerges as an end state of a continual gravitational collapse. This paradigm not only allows for constraints on spacetime, but also provides a good probe for the nature of the central compact object.

Key words. accretion, accretion disks – black hole physics – radiative transfer

1. Introduction

In 1939, Oppenheimer, Snyder, and Datt (Oppenheimer & Snyder 1939) derived the first dynamical collapse solution for a spherically symmetric and homogeneous dust cloud. This was later known as OSD collapse. Their groundbreaking work demonstrated that a spherically symmetric and homogeneous dust collapse inevitably leads to the formation of a Schwarzschild black hole (BH). This result aligns with Birkhoff’s theorem, which states that the Schwarzschild spacetime represents the most general vacuum solution of Einstein’s equations. However, the OSD collapse model relies on several idealized assumptions, such as the homogeneous density of the collapsing star, the neglect of gas pressure, and no rotation, to simplify the complex Einstein equations (Joshi & Malafarina 2011). Although this model unveils the development of an event horizon during the collapse, which prevents the escape of matter, particles, or light to distant observers, it necessitates the exploration of more realistic scenarios that go beyond these idealistic assumptions. By considering the physical complexities and incorporating factors such as non-homogeneous density profiles and gas pressure, we can expand our understanding of gravitational collapse and its implications.

Large astrophysical bodies typically do not possess a homogeneous density profile throughout their structure. Instead, their density can vary, with a higher density at the core and decreasing values toward the surface. When more physically realistic scenarios are considered that introduce inhomogeneity into the matter distribution profile and account for nonzero pressures, the dynamical collapse can result in the formation of a strong-curvature singularity within the framework of general relativity (Joshi & Malafarina 2011; Joshi & Dwivedi 1993; Joshi et al. 2011; Janis et al. 1968; Mosani et al. 2020, 2021). The final states of these collapses depend on the initial conditions of the collapsing matter.

The general theory of relativity predicts that spacetime singularities necessarily form when sufficiently massive objects collapse under their own gravity. However, the simultaneous formation, or absence, of an event horizon is not enforced. A singularity that forms without an event horizon is known as a naked or cosmic singularity. Naked singularities are intriguing, horizonless compact objects characterized by ultrahigh density regions, where physical quantities diverge arbitrarily. This ultradense compact region can be described by models of various astrophysical compact objects, for instance, a BH,
a naked singularity (NS), or a boson star (Joshi & Malafarina 2011; Joshi & Dwivedi 1993; Joshi et al. 2011; Janis et al. 1968; Schunck & Mielke 2003). These compact objects have fascinating physical and geometrical properties, and it would be observationally significant to distinguish them.

The cosmic censorship conjecture (CCC) proposed by Penrose (Penrose 1965) posits that strong horizonless singularities are prohibited. However, several research studies have revealed the potential formation of naked singularities during continuous gravitational collapses of inhomogeneous matter clouds. In a seminal work, Joshi, Malafarina, and Narayan (JMN; Joshi et al. 2011) demonstrated that nonzero tangential pressure can prevent the formation of trapped surfaces around the high-density core of a collapsing matter cloud, leading to the emergence of a central NS in extended comoving time. This NS, occurring in physically realistic astrophysical scenarios, holds significant observational consequences. It gives rise to captivating phenomena such as distorted shadows, intense gravitational lensing, and orbital precession of nearby stars (Vagnozzi et al. 2023; Sahu et al. 2012; Bambhaniya et al. 2022a).

On the other hand, black holes have astonishing features as well. As its distinct signature, a black hole possesses an event horizon, which is a one-way membrane in spacetime through which things can fall in, but not escape, and even light cannot escape. Almost every galaxy is thought to have a supermassive black hole at its core (Kormendy & Ho 2013). There is no conclusive proof at this time for the existence of an event horizon, however. The Event Horizon Telescope (EHT) captured the first shadow image in 2019 in the galaxy M 87 (Event Horizon Telescope Collaboration 2019), and more recently, in the center of our own galaxy, Sgr A* (Event Horizon Telescope Collaboration 2022a). While these results are indeed exciting, they should be interpreted with caution. For instance, Mizuno et al. (2018) and Röder et al. (2023) performed general relativistic magnetohydrodynamics (GRMHD) simulations of a dilated BH and compared it with the Kerr BH. They concluded that it is difficult to distinguish them based on the shadow images alone. Additionally, many other such works indicated the presence of such “mimickers”. Therefore, the shadow images of M 87* and the Milky Way galactic centers observed by the EHT do not confirm the existence of an event horizon and hence a supermassive black hole (SBMH). Other compact objects can also cast similar shadows. The shadows cast by compact objects such as black holes, naked singularities, gravastars, and wormholes have been extensively studied in Gralla et al. (2019), Vagnozzi & Visinelli (2019), Bambhaniya et al. (2021, 2022b), Gyulchev et al. (2019), Amaturotov et al. (2015), Ohgami & Sakai (2015); Stuchlík & Schée (2019); Sakai et al. (2014), Solanki et al. (2022); Younsi et al. (2023).

It is generally thought that the shadows arise due to the presence of a photon sphere. Recently, however, Joshi et al. (2020) have introduced a new spherically symmetric NS solution of the Einstein field equation that lacks a photon sphere, but still casts a shadow. The general criteria for a shadow to occur in the absence of a photon sphere are then determined for null and time-like naked singularities, where both types of singularities satisfy all the energy conditions (Dey et al. 2021). Moreover, another model of a NS that was proposed in 1968 by Janis–Newman–Winicour (JNW) can cast a shadow similar to that of a Schwarzschild black hole (Gyulchev et al. 2020; Sau et al. 2020). The JNW NS is a minimally coupled massless scalar field solution of the Einstein field equations. Sau et al. (2020) showed that as the scalar field charge $q$ increases, the radius of the photon sphere $r_{ph}$ increases while the shadow radius decreases.

Shaiikh et al. (2019) investigated the shadows of JMN-1 NS spacetimes and compared the results to the shadow of a Schwarzschild black hole. For the range of the characteristic parameter $0 < M_0 < 2/3$, there is no photon sphere, and hence no shadow is formed in JMN-1 NS, but an intriguing, full moon image is formed. However, JMN-1 can cast a shadow for $2/3 < M_0 < 1$, similar to that of a Schwarzschild black hole.

The rotating black holes or naked singularities describe the observational data for Sgr A* much better than the static solutions. For rotating spacetimes, the shadow is slightly asymmetric along the spin axis, which will be smaller in diameter than in the Schwarzschild case. The inclusion of spin in the black holes and naked singularities will give the prolate contour shape of the shadow (Bambhaniya et al. 2021), although for some parameter space that includes spin and scalar field charge, naked singularities will give an arc-shaped shadow (Solanki et al. 2022). However, for simplicity, we restricted ourselves to static spherically symmetric metrics here, that is, we neglected the effect of spin. The reason for this choice is twofold. First, the effect of spin on the shadow radius is small for the case of a Kerr BH (see, e.g., Vagnozzi et al. 2023). Second, and perhaps most importantly, there is currently no clear consensus on the spin and inclination angle of Sgr A*.

The EHT images are in principle consistent with high spin and low inclination angle, but they are far from being inconsistent with low spin and high inclination angle (Event Horizon Telescope Collaboration 2022a,b). To be precise, however, this is strictly speaking only true for the Kerr metric, which was assumed to derive these results. Independent works based on radio, infrared, and X-ray emission as well as millimeter VLBI, excluded extremal spin ($1 - a_*/1 < 1$), but were unable to place strong constraints otherwise (Broderick et al. 2009, 2011; Kato et al. 2010). Estimates based on semi-analytical models, magnetohydrodynamics simulations, or flare emissions have reported constraints across a wide range of spin values (Huang et al. 2012; Shcherbakov et al. 2012). One of the most recent dynamical estimates of the Sgr A* spin was reported in Fragione & Loeb (2020), based on the impact on the orbits of the S stars of frame-dragging precession, which would tend to erase the orbital planes in which the S stars formed and are found today: Observations of the alignment of the orbital planes of the S stars today require the spin of Sgr A* to be very low, $a_* \lesssim 0.1$ (see also Fragione & Loeb 2022). Some of these estimates rely on an assumed metric, although it is worth pointing out that the result of Fragione & Loeb (2020) does not. Constraints on the inclination angle are even more uncertain. The inconsistency for different estimates of the Sgr A* spin prompts us to choose a conservative approach in which we neglect the effect of spin, while taking the very recent estimate of Fragione & Loeb (2020) as an indication that the spin may be low: for $a_* \lesssim 0.1$. Additionally, the effect of spin on the shadow radius is negligible at all inclination angles. Moreover, we lack a complete rotating solution of JMN-1 naked singularity so far. Therefore, we restricted ourselves to static spherically symmetric metrics here.

We used a semi-analytic RIAF model to investigate the resulting images of JMN-1 and the Schwarzschild black hole surrounded by accretion flows. Motivated by RIAF, we integrated the system of geodesics and its radiative transfer equation to compute the theoretically observed intensity.

The paper is organized as follows. In Sect. 2, we briefly introduce the JMN-1 model. We describe the semi-analytic RIAF model in Sect. 3. In Sect. 4, we describe the ray-tracing
formalism and the initial conditions we used to generate accretion images. In Sect. 5, we summarize our results. Finally, the discussion and conclusion are given in Sect. 6.

2. JMN-1 naked singularity

We briefly review the solution that was proposed in the literature for the JMN-1 NS. The spacetime metric for a static and spherically symmetric object in the generalized form can be written as

\[ ds^2 = -g_{tt}(r)dt^2 + g_{rr}(r)dr^2 + g_{\theta\theta}(r)d\theta^2 + g_{\phi\phi}(r)d\phi^2, \]  

where \( g_{ij} \) are the metric tensor components, all of which are only functions of \( r \). The JMN-1 naked singularity can be formed as an end state of gravitational collapse with zero radial pressure and nonzero tangential pressures. These equilibrium configurations of the collapsing fluid within the general theory of relativity were extensively studied in Joshi et al. (2011). The JMN-1 naked singularity spacetime is described by the following metric tensor components:

\[ g_{tt}^{\text{JMN-1}} = (1 - M_0) \left( \frac{r}{R_b} \right)^{M_0/(1 - M_0)}, \]  
\[ g_{rr}^{\text{JMN-1}} = (1 - M_0)^{-1}, \]  
\[ g_{\theta\theta}^{\text{JMN-1}} = r^2, \]  
\[ g_{\phi\phi}^{\text{JMN-1}} = r^2 \sin^2 \theta, \]

where \( M_0 \) and \( R_b \) are positive constants. Here, \( R_b \) represents the radius of the distributed matter around the central singularity, and \( M_0 \) should be within the range \( 0 < M_0 < 1 \). The JMN-1 spacetime contains a curvature singularity at \( r = 0 \). The stress-energy tensor of the JMN-1 spacetime gives the energy density \( \rho \) and pressures \( p \) as

\[ \rho = \frac{M_0}{r^2}, \quad p_r = 0, \quad p_\theta = \frac{M_0}{4(1 - M_0)} \rho. \]

The JMN-1 naked singularity is a nonvacuum solution of the Einstein field equations that satisfies all energy conditions.
where \( I \) is the Lorentz-invariant intensity and is related to the specific intensity via \( I = I_0/\nu^3 = I_0/\nu_0^3 \), where the subscript 0 denotes quantities in the local rest frame. \( \tau_\nu \) is defined as the optical depth. \( \chi \) and \( \eta \) are the invariant absorption coefficient and emission coefficient at frequency \( \nu \). These coefficients are defined by the specific emissivity and absorptivity. For this work, we used the thermal electron distribution function (eDF; Pandya et al. 2016).

The number density and temperature of electrons can be written as a hybrid combination of radial and exponential functions given by

\[
\begin{align*}
\rho_{\text{th}} &= n_{\text{e,th}} e^{-\tau_{\text{e,th}}} \nu^{-2/3} \eta \chi, \\
T_{\text{th}} &= T_{\text{e,th}} r^{-\beta},
\end{align*}
\]

where \( z = r \cos \theta \) and \( h \) is the disk width. \( n_{\text{e,th}} \) and \( T_{\text{e,th}} \) are the respective normalization parameters. The magnetic field strength of the toroidal field is then given by

\[
B^2 = \frac{1}{8\pi} \frac{m_p c^2}{6 r} |\epsilon_r|,
\]

where \( \epsilon_r = GM/c^2 \), and \( m_p \) is the mass of proton.

We modeled the four-velocity of the plasma accreted onto the central compact object by following Younsi et al. (2023). The four-velocity can be written as

\[
u' = (u', u', 0, \Omega u'),
\]

where \( (\Omega) \) is the angular velocity. The radial component of the four-velocity can be written in parameterized form,

\[
u' = -\eta_r \left( \frac{r}{R_{\text{ISCO}}} \right)^{-\eta_t},
\]

where \( \eta_t = 0.1 \) and \( \eta_r = 1.5 \) are the free parameters. We kept their values fixed for the current analyses.

Because no stable circular orbits are possible beyond the innermost stable circular orbit (ISCO) radius \( (R_{\text{ISCO}}) \), the particles will plunge with the constant energy \( (E_{\text{ISCO}}) \) and the constant angular momentum \( (L_{\text{ISCO}}) \) acquired at the ISCO radius. In this way, we can model the motion of particles for \( r < R_{\text{ISCO}} \).

Fig. 2. Cross-sectional horizontal intensity for the model images of Fig. 1 with varied inclination angles (\( \theta_{\text{obs}} \)).

We immediately see that the comoving time required by a photon to reach the boundary is \( t_b = \frac{2R_b}{\sqrt{2 - 3M_b}} < +\infty \). It follows that there are future directed null geodesics in the spacetime that reach the boundary of the cloud, and which in the past terminated at the singularity, thus showing this to be a naked singularity.

### 3. Radiative transfer

In this section, we describe the prescription for the semi-analytic radiative inefficient accretion flows (RIAF) model. We closely follow Pu & Broderick (2018) for some basic definitions of the parameters. The covariant form of general relativistic radiative transfer is expressed as

\[
\frac{dI}{dr} = -I + \frac{\eta}{\chi},
\]

where \( I \) is the Lorentz-invariant intensity and is related to the specific intensity via \( I = I_0/\nu^3 = I_0/\nu_0^3 \), where the subscript 0 denotes quantities in the local rest frame. \( r \) is defined as the optical depth. \( \chi \) and \( \eta \) are the invariant absorption coefficient and emission coefficient at frequency \( \nu \). These coefficients are defined by the specific emissivity and absorptivity. For this work, we used the thermal electron distribution function (eDF; Pandya et al. 2016).

The number density and temperature of electrons can be written as a hybrid combination of radial and exponential functions given by

\[
\begin{align*}
\rho_{\text{th}} &= n_{\text{e,th}} e^{-\tau_{\text{e,th}}} \nu^{-2/3} \eta \chi, \\
T_{\text{th}} &= T_{\text{e,th}} r^{-\beta},
\end{align*}
\]

where \( z = r \cos \theta \) and \( h \) is the disk width. \( n_{\text{e,th}} \) and \( T_{\text{e,th}} \) are the respective normalization parameters. The magnetic field strength of the toroidal field is then given by

\[
B^2 = \frac{1}{8\pi} \frac{m_p c^2}{6 r} |\epsilon_r|,
\]

where \( \epsilon_r = GM/c^2 \), and \( m_p \) is the mass of proton.

We modeled the four-velocity of the plasma accreted onto the central compact object by following Younsi et al. (2023). The four-velocity can be written as

\[
u' = (u', u', 0, \Omega u'),
\]

where \( (\Omega) \) is the angular velocity. The radial component of the four-velocity can be written in parameterized form,

\[
u' = -\eta_r \left( \frac{r}{R_{\text{ISCO}}} \right)^{-\eta_t},
\]

where \( \eta_t = 0.1 \) and \( \eta_r = 1.5 \) are the free parameters. We kept their values fixed for the current analyses.

Because no stable circular orbits are possible beyond the innermost stable circular orbit (ISCO) radius \( (R_{\text{ISCO}}) \), the particles will plunge with the constant energy \( (E_{\text{ISCO}}) \) and the constant angular momentum \( (L_{\text{ISCO}}) \) acquired at the ISCO radius. In this way, we can model the motion of particles for \( r < R_{\text{ISCO}} \).

Fig. 2. Cross-sectional horizontal intensity for the model images of Fig. 1 with varied inclination angles (\( \theta_{\text{obs}} \)).

We immediately see that the comoving time required by a photon to reach the boundary is \( t_b = \frac{2R_b}{\sqrt{2 - 3M_b}} < +\infty \). It follows that there are future directed null geodesics in the spacetime that reach the boundary of the cloud, and which in the past terminated at the singularity, thus showing this to be a naked singularity.
4. Ray-tracing formalism

In order to calculate the shadow image of a BH or a naked singularity, the geodesic equations in the considered background spacetime must first be solved. To this end, we used the Brahma code (in prep.). We briefly describe the approach for ray-traced images of the models described in Sect. 3. We solve a system of six differential equations ($\dot{t}, \dot{r}, \dot{\theta}, \dot{\phi}, \dot{p}_r, \dot{p}_\theta$).

**Geodesic equations of motion.** For a given metric $g_{\alpha \beta}$, the Lagrangian and the Hamiltonian can be written as

\begin{align}
2L &= g_{\alpha \beta} \dot{x}^\alpha \dot{x}^\beta, \\
2H &= g^{\alpha \beta} p_\alpha p_\beta,
\end{align}

where an overdot denotes differentiation with respect to the affine parameter, $\lambda$. The corresponding equations of motion are given by

\begin{align}
\dot{x}^\alpha &= \frac{\partial H}{\partial p_\alpha}, \\
\dot{p}_\alpha &= -\frac{\partial L}{\partial x^\alpha}.
\end{align}

From the Lagrangian, the covariant four-momenta of a geodesic may be written as

\[ p_\alpha = \frac{\partial L}{\partial \dot{x}^\alpha}. \quad (21) \]

Using the conservation of energy and angular momentum, this can be broken down to write $p_t = -E$ and $p_\phi = L$, where $E$ is the total energy of the particle, and $L$ is the angular momentum in the direction of $\phi$. To solve the system of an ordinary differential equation (ODE), initial conditions are required. Different authors have assumed different initial conditions based on the type of work and ODEs that were to be solved. In Brahma, we used the formalism described in Younsi et al. (2016). The observer is placed far away from the compact object ($r_{\text{obs}} = 10^3 M$), where the spacetime is assumed to be flat (asymptotic flatness).

5. Results

We used the formalism described in Sect. 4 to trace the photons along geodesics and solved for the observed intensity. In principle, the model consists of various parameters that can be
Intensity
second, and third columns represent 1, and the third row represents the image di-
the Schwarzschild BH, the second row corresponds to the JMN-
The first row in Fig. 1 corresponds to the Schwarzschild BH, the second row corresponds to the JMN-1 model, and the corresponding horizontal cross section is shown in Fig. 4. The profiles for both spacetimes are again similar here, with JMN-1 having a slightly higher intensity for $h = 0.1$.

- **Frequency.** Currently, the EHT operates at 230 GHz, and there are plans for including other frequency bands as part of EHT and neEHT. We therefore also performed simulations for different frequencies, and the results are plotted in Fig. 5 for 84 GHz, 230 GHz, and 345 GHz. No significant changes are observed for the two spacetimes relative to each other when the observed frequency is changed. As the frequency is increased, however, the emission becomes thinner, which agrees with previous results. The horizontal cross-sectional intensity as plotted in Fig. 6 retains a similar profile as in previous cases for different values of the disk width and inclination angle.

### 6. Conclusion and discussion

We have modeled radiative inefficient accretion flows around the JMN-1 cosmic singularity and calculated the resulting shadow images. Because JMN-1 causes a shadow of the same size as the Schwarzschild BH, it is worthwhile to investigate various effects from the change in spacetime on the accretion flows and the resulting images. We first defined the geodesic equations for both photons and particles. We then defined our semi-analytic RIAF model in Sect. 3. Thereafter, we solved the system geodesic equations with the ray-tracing formalism as described in Sect. 4 simultaneously with the radiative transfer equation to calculate the observed intensity. In order to compare the JMN-1 naked singularity with the Schwarzschild BH, we carried out simulations to generate images for various values of the parameters: for the inclination angle ($\theta_{\text{obs}}$), the disk width ($h$), and the observed frequency ($\nu_{\text{obs}}$). The results from the simulations are presented in Sect. 5.

The visual representations of the Schwarzschild BH and JMN-1 model exhibit striking similarities. Subtle differences lie in the slightly heightened intensities observed for the JMN-1 model. Even though we varied several parameters associated with the accretion disk, the overall characteristics of the disk remained relatively unchanged. This reflects the results of previous studies (Shaikh et al. 2019; Shaikh & Joshi 2019). The results we obtained here contribute to an expanded understanding of a realistic model for the accretion disk, which is astrophysically relevant in particular in the context of AGNs. Following the fact that JMN-1 emerges as the end state of gravitational collapse and acts as galactic spacetime, this opens up an intriguing avenue in the study of AGNs in which the central engine powering the galaxy is a visible cosmic singularity. This analysis concludes that if horizon-scale observations of the central supermassive compact object produce a shadow-like structure, it is impossible to distinguish between a BH and a naked singularity, and by extension, this is valid for the recent studies of M 87* and Sgr A*.

However, many other paths can be pursued further in order to test and investigate the robustness of the model. For example, we can generate synthetic VLBI observations from the ray-traced images presented in this paper to directly compare our results to observational data.

- For instance, Shaikh et al. (2019) have considered a spheri-
cally accreting system and studied the corresponding shadow images. Bondi accretion flow was also used to study the shadow and spectral properties in MHD simulations. This treatment can also be applied to our model to study the spec-
tra, which can then be used to study specific sources such as Sgr A*. The spectral signatures will be studied in an accompanying paper.

- We only studied the horizon-scale accretion-flow images of the models, and in GRMHD simulations, black holes produce highly energetic jets that were variously observed. Studies of jets and accretion flows in GRMHD simulations (Kocherlakota et al. 2023) will help us to conclude whether the Universe contains horizonless objects.

Using the models described in this work, it will be possible to unveil the true nature of the objects in M 87* and Sgr A*. From the studies so far, it would appear that naked singularities present a possible alternative to the standard picture of a black hole within the framework of nonmodified general relativity.
