ABSTRACT

We present the results of a spectroscopic analysis of extremely strong damped Lyα absorbers (ESDLAs; log N(HI)≥21.7) observed with the medium resolution spectrograph, X-shooter at the Very Large Telescope (VLT). Recent studies in the literature indicate that ESDLAS probe gas from within the star-forming disk of the associated galaxies and thus ESDLAS provide a unique opportunity to study the interstellar medium of galaxies at high redshift. We report column densities (N), equivalent widths (w), for Mg ii and Ca ii transitions), and the kinematic spread (Δv90) of species from neutral (namely O i, Ar i, Ni i, N i, and Na i), singly ionised (Mg ii, Ca ii, S ii, Ni ii, Mn ii, Ti ii, and P ii), and higher ionisation (C iv, Si iv, N v, and O v i) species. We estimate the dust-corrected metallicity measured using different singly ionised gas species such as P n, S n, Si n, N n, Mn n, and Cr n, and Zn ii. We find that, using the dust correction prescription, the measured metallicities are consistent for all mentioned species in all ESDLAs within 3−σ uncertainty. We further perform a quantitative comparison of column densities, equivalent widths, and kinematic spreads of ESDLAs with other samples that are associated with galaxies and detected in absorption along the line of sight towards high-redshift quasars (QSOs). We find that the distributions of the Ar i to H i column density ratio (N(Ar i)/N(H i)) in DLAs and ESDLAs are similar. We further report that ESDLAs do not show a strong deficiency of Ar i relative to other α-capture elements as is seen in DLAs. This supports the idea that the mentioned under-abundance of Ar i in DLAs is possibly caused by the presence of background UV photons that penetrate the low N(H i) clouds to ionise Ar i, but they cannot penetrate deep enough in the high N(H i) ESDLA environment. The w(Mg ii,Ca ii) distribution in ESDLAs is found to be similar to that of metal-rich C i-selected absorbers, but the velocity spread of their Mg ii profile is different. The dust content (measured by modelling the quasar extinction) and w(Ca ii,Na i) distributions are similar in ESDLAs and Ca ii-selected absorbers, yet we do not see any correlation between w(Ca ii,Na i) and dust content. The Δv90 velocity spread of singly ionised species in ESDLAs is statistically smaller than that of DLAs. For higher ionisation species (such as C iv and Si iv) that trace the warm ionised medium, Δv90 is similar in the two populations. This suggests that the ESDLAs sample a different H i region of their associated galaxy compared to the general DLA population. We further study the N(C i) distribution in high-redshift DLA and ESDLA sightlines, as C i is a good tracer of H2 gas. The N(C i)−N(H i) correlation is followed by all the clouds (ESDLAs and otherwise) having log N(H2)<22.

Key words. quasars: absorption lines - galaxies: high-redshift - galaxies: ISM

1. Introduction

Damped Lyα absorption systems (DLAs) correspond to a particular class of H i absorption systems, with a H i column density, log N(H i) (cm$^{-2}$) ≥ 20.3$^4$ (see e.g. Wolfe et al. 1999). These absorbers can be easily recognised through their damped Lyα absorption feature in the spectra of bright background sources such as quasars (QSOs) and γ-ray bursts (GRBs). Statistically, DLAs have been shown to dominate the neutral gas mass density in the high-redshift universe, providing the primary fuel for star formation (Wolfe et al. 2005, Prochaska et al. 2005). Noterdaeme et al. 2009, 2012, Zafar et al. 2013, Crighton et al. 2013, Sánchez-Ramírez et al. 2016). In some cases, DLAs are found to be associated with the halo and/or the circumgalactic medium (CGM) of galaxies at high redshift (z~2) (see e.g. Noterdaeme et al. 2012, Péroux et al. 2013, Fynbo et al. 2013, Péroux et al. 2018) as well as low redshifts (z<1) (see e.g. Rahmani et al. 2016, and references therein). Furthermore, an anticorrelation between the H i column density and the impact parameter of the host galaxy, ρ, is observed (see e.g. Pontzen et al. 2008, Noterdaeme et al. 2012, Rahmani & Schaye 2013, Krogaer et al. 2017).

Hence, it is expected that the highest end of the N(H i) distribution can preferentially probe the star-forming disk of the associated galaxies. Following this argument, Noterdaeme et al. (2014) studied ~100 extremely strong DLAs (or ESDLAs) defined as systems with H i column density, log N(H i) ≥ 21.7 at high redshift (z~2−4). Stacking the low resolution SDSS spectra led to the detection of Lyα emission within the SDSS fibres (i.e. within an impact parameter of ~8 kpc from the quasar sight line at the redshift of the DLAs, i.e. z~2.5). Additionally, numer-

$^*$ Based on observations performed with the Very Large Telescope of the European Southern Observatory under Prog. ID 095.A-0224(A) and 0101.A-0891(A) using the X-shooter spectrograph.

$^1$ In the following text, column densities, N, are given in cm$^{-2}$. 
ical simulations (e.g. Afik et al. 2013) show that the highest end of the H\textsc{i} column density distribution function is sensitive to the effects of stellar feedback and H$_2$ formation. Indeed, it is seen in high-z observations that ESDLAs have a significantly enhanced fraction of diffuse H$_2$ gas observed in comparison with regular DLAs (e.g. Noterdaeme et al. 2015, Balashev & Noterdaeme 2018).

This motivated a medium spectral resolution, wide wave- length range follow-up study of 11 ESDLAs using the X-shooter spectrograph at the Very Large Telescope (VLT, Paranal, Chile). These ESDLAs were identified using SDSS spectra (Noterdaeme et al. 2018). The analysis of one of these ESDLAs towards SDSS J1513+0352 (see Ranjan et al. 2018) led to the H$_2$ detection with the highest H$_2$ column density ever observed in QSO absorption line studies along with Ly$\alpha$ emission detected at a small impact parameter ($\rho = 1.4$ kpc) relative to the quasar line of sight.

The detailed analysis of the initial sample of 11 ESDLAs (along with ESDLAs taken from literature) is presented in Ranjan et al. 2020. The study notes that ESDLAs probe transitioning H$_2$-H$_2$ gas clouds with much higher frequency (~50% of the cases have H$_2$) as compared to the general DLA population, where only 5-10% of the systems are detected with H$_2$ (Petitjean et al. 2003, Ledoux et al. 2003, Noterdaeme et al. 2008, Balashev & Noterdaeme 2018). They also show that faint emission lines are detected in proximity to the absorbers which indicates that ESDLAs arise from the star-forming disk of their associated galaxy. Although, the direct study of the galaxy morphology is not possible due to the non-detection of the faint stellar continuum of these galaxies, hence, we need to probe alternative methods to understand the nature of ESDLAs and their associated galaxies. The galaxies associated with ESDLAs are detected independently of their intrinsic luminosity. In Ranjan et al. (2020), we focus primarily on the H$_2$ detection and the proximity of ESDLAs with their associated galaxy. In this paper, we intend to gain additional information about the physical and chemical properties of ESDLAs and the associated galaxies by studying the absorption lines of neutral (such as C\textsc{i} and Ar\textsc{i}), singly ionised (such as Mg\textsc{ii} and Ca\textsc{ii}), as well as highly ionised (such as C\textsc{iv}, Si\textsc{iv}, N\textsc{v}, and O\textsc{vi}) gas species. The comprehensive study probes features of gas in different ionisation states that are associated with the ESDLA host galaxy. We calculated the column density (and/or the equivalent width in specific cases) and quantified the gas kinematics (using $\Delta$$_{\text{FWHM}}$, defined as the velocity interval that contains 90% of the area under the apparent optical depth spectrum) of differently ionised species. We study the distribution of column density and velocity spread of gas species in different ionisation states and further compare them to other DLA sub-sets associated with galaxies such as the metal-rich C\textsc{i}-selected absorbers (see e.g. Ledoux et al. 2018, Zou et al. 2018, Noterdaeme et al. 2018), dust rich DLAs selected based on their Ca\textsc{ii} equivalent width (see e.g. Wild & Hewett 2005), Mg\textsc{ii}-selected strong absorbers (see e.g. Rao et al. 2005), and absorbers associated with outflowing gas clouds (see e.g. Fox et al. 2007, 2008). The comparison will help us to further understand the ESDLA gas clouds and their associated galaxies.

Details of the observations and data reduction are presented in Section 3. The analysis of the absorption lines is described in Section 4. The results of our study are presented in Section 5 and discussed in Section 6. In Section 7 we summarise our findings.

2. Observations and data reduction

Here, we use a sample of 11 ESDLAs observed with the VLT/X-shooter spectrograph. Spectra of 11 quasars from the first programme (ESO programme ID 095.A-0224(A)) were analysed in Ranjan et al. 2020 and Ranjan et al. 2018. The observations were carried out in service mode under good seeing conditions (typically 0.7-0.8') between April 2015 and July 2016 with the multiwavelength medium-resolution spectrograph X-shooter (Vernet et al. 2011) mounted at the Cassegrain focus of the Very Large Telescope (VLT-UT2) at Paranal, Chile. A two-step nodding mode with an offset of 4 arcsec between the two integrations was used. We reduced the data using the standard X-shooter pipeline (Modigliani et al. 2010) and combined individual exposures by weighting the measured flux in each pixel by the inverse of its variance to obtain the combined 2D and 1D spectra. The target spectra were obtained at medium spectral resolution, $R \sim 5000$-$10000$, depending on the arm of the spectrograph corresponding to the typical width of the instrument function, FWHM $\sim 30$ – $60$ km s$^{-1}$. We found that the resolution in most of the individual spectra are seeing-dominated. The detailed list of resolution for individual spectra can be found in Ranjan et al. (2020). For the absorption line analysis presented here, we have only used the combined 1D spectra of each arm of the X-shooter spectrograph. Further details about the observations and data reduction can be found in Ranjan et al. (2020). The long form QSO names (with precise RA, DEC information) with the QSO and the absorbers’ redshifts are given in Table. 2. Throughout this paper, we use a short notation for the quasar names, for example SDSS J223250.98+124225.29 is referred to as J2232+1242.

We additionally use information about seven new ESDLAs observed with VLT X-shooter using similar observing conditions from Heliková et al. (2022) (initially discussed in Heliková et al. 2020). We further add information about five ESDLAs from literature, found towards the QSOs HE0027−1836 (from Noterdaeme et al. 2007), J0843+0221 (from Balashev et al. 2012), J113−0010 (from Noterdaeme et al. 2012), and J0230−0334 and Q0743+1421 (from Kulkarni et al. 2013). These ESDLAs form a part of the high-z ESDLA sample that meets the N(H\textsc{i}) criterion and were observed using medium and/or high resolution spectrographs.

3. Absorption-line analysis

We used multi-component Voigt-profile fitting to derive column densities from absorption features. The fitting was performed using VPFIT (Carswell & Webb 2014). The VPFIT website also provides a data file for the atomic parameters that was compiled primarily from Mortier 2005, but taking updated references from many other works in the literature (such as Petitjean & Aracil 2013, Abgrall & Kowal 2006, Salamonde et al. 2006, Ivanov et al. 2008, Hatliya et al. 2010, Berengut et al. 2011). We primarily used the atomic parameters from this data file for our fitting along with the others mentioned directly in the text.

The initial fit for C\textsc{i} and singly ionised species for the ESDLAs sample was reported in Ranjan et al. 2018 and Ranjan et al. 2020. We took advantage of the

\footnote{https://www.ast.cam.ac.uk/~rfc/vpfit}

\footnote{https://www.ast.cam.ac.uk/~rfc/vpfit}
wide wavelength range of X-shooter spectra to include many transition lines of Fe ii and Si ii, such as 'Si ii λ1193 ([Å]), 'Si ii λ1304', 'Si ii λ1526', 'Si ii λ1808', 'Fe ii λ1608', 'Fe ii λ1611', 'Fe ii λ2249', 'Fe ii λ2260', 'Fe ii λ2344', 'Fe ii λ2374', 'Fe ii λ2382', 'Fe ii λ2586', and 'Fe ii λ2600'. Using so many transitions with varying oscillator strengths is advantageous as it helps in resolving the highest number of low column density sub-components (in transitions with strong absorption) that can be identified separately given the spectral resolution. In addition, we can also constrain the column density for sub-components that appear saturated in transitions with a strong absorption signature by looking at the transitions with a weaker absorption signature. Hence, fitting a multi-component absorption model for all transitions mentioned above (in addition to other transitions from Cr ii, Zn ii, Mg i, Ni ii, and Ti ii) with their \( b \)-values and redshifts tied together helps us obtain a robust estimate on the total column density of the mentioned species for these ESDLAs. For Ca ii, we report the total column density as well rest-frame equivalent width (\( \lambda \)) for its two prominent transitions, 'Ca ii λ13934' and 'Ca ii λ13969'. The Mg ii profiles ('Mg ii λ2796' and 'Mg ii λ2803') are strongly saturated. Hence, we report only the rest-frame equivalent width (\( \lambda \)) for both the transitions. We applied a similar fitting approach for higher ionisation species, such as Si iv, C iv, and N v (i.e. tying the \( b \)-values and redshifts for multiple transitions of the mentioned ionisation), but the fitting was performed separately from that of the low-ionisation species. We found that the redshifts for individual components derived from fitting the higher ionisation lines (C iv, Si iv, and N v) are only slightly separated in velocity space (\( \lesssim 50 \text{ km s}^{-1} \)) from the components of the lower ionisation lines.

4. Results

In Ranjan et al. (2020), we studied only C i and singly ionised species (e.g. Fe ii, Zn ii, and Si ii) and the H i-H ii transition for 11 ESDLAs mentioned in Table II. The table shows basic information about the 11 ESDLAs from Ranjan et al. (2020) for reference that is used for this study. In continuation, we further searched for and analysed the following neutral gas species: Oxygen (O i), Argon (Ar i), Nitrogen (N i), Chlorine (Cl i), Sodium (Na i), singly ionised calcium (Ca ii), Sulphur (S ii), Magnesium (Mg ii), Phosphorous (P ii), Titanium (Ti ii), Manganese (Mn ii), Nickel (Ni ii), and four higher ionisation species – Carbon (C iv), Silicon (Si iv), Nitrogen (N v), and Oxygen (O vi). The results of our analysis (column density, rest-frame equivalent width, and \( \lambda \)) for estimates for 11 ESDLAs are provided in Table 4 and Table A.1. Table 4 also provides additional information about the seven ESDLAs studied in detail in Belkhova et al. (2022). We provide important details for each species in the following subsections.

In addition to these, we also use the relevant ESDLAs data from literature. We include the following: Noterdaeme et al. (2007), towards QSO HE0027–1836, with \( \log N(\text{Ar/Ar}) = 14.42 \pm 0.02 \), \( \log N(\text{H}) = 21.75 \pm 0.1 \), and \( \log N(\text{H}_2) = 17.3 \pm 0.07 \); Noterdaeme et al. (2012a), towards QSO J1135–0010, with \( \log N(\text{H}) = 22.1 \pm 0.05 \); Balshe et al. (2013), towards QSO J0843+0221, with \( \log N(\text{C/iv}) = 13.63 \pm 0.20 \), \( \log N(\text{H}) = 21.82 \pm 0.11 \), and \( \log N(\text{H}2) = 21.21 \pm 0.02 \); and Kulkarni et al. (2012), towards QSO J0230–0334, with \( \log N(\text{H}) = 21.74 \pm 0.1 \), \( \log N(\text{C/iv}) = 14.6 \pm 0.05 \), and \( \log N(\text{Si/iv}) = 13.89 \pm 0.04 \) as well as towards QSO Q0743+1421, with \( \log N(\text{H}) = 21.9 \pm 0.1 \), \( \log N(\text{C/iv}) = 14.41 \pm 0.07 \), and \( \log N(\text{Si/iv}) = 13.84 \pm 0.06 \).

4.1. Neutral Oxygen

Neutral oxygen absorption is present in all ESDLAs in our sample. We primarily used the 'O i λ1302' transition to estimate the O i column density. We also used the 'O i λ1303' line wherever possible, but with extreme caution as this transition is inside the Ly\( \alpha \) forest and can also be blended with H\( \alpha \) lines. Since our study is related to gas associated with galaxies, there is a chance that O i column densities are high and hence, most of the 'O i λ1302' lines are probably visibly or intrinsically saturated (a situation where the convolved absorption profile appears to be unsaturated, but the true unconvolved profile is saturated). Since our spectra are of medium resolution, the convolved absorption profile may appear unsaturated in many cases, when the true unconvolved profile is indeed saturated. In such cases, there is a degeneracy between the \( b \)-value and column density, and in the absence of additional information, the column density estimate might not be robust.

Therefore, we used the 'O i λ1302' profile taking component information (redshift and \( b \)-value) from other singly ionised species (such as Fe ii and Zn ii) to report a lower limit for the O i column density in all ESDLAs, except for the \( \lambda \text{abs} = 2.339 \) system towards QSO J2140–0321. We obtained a \( \log N(\text{O}) = 18.01 \pm 0.18 \) for this ESDLA. Noterdaeme et al. (2015b) have also published the results for this ESDLA using spectra obtained with the high resolution Ultraviolet and Visual Echelle (VLT-UVES, R = 480000) spectrograph. We further cross-checked our measured values for column densities with Noterdaeme et al. (2015b). Our estimates match with theirs (\( \log N(\text{O}) = 17.9 \pm 0.2 \)) within the measured uncertainties. However, we note that this robust estimate from single X-shooter spectra may not be representative of the sample. The column density estimates for O i are listed in Table A.1.

We also searched for the presence of absorption from the fine-structure transition of O i. In only one case, that is for ESDLA towards QSO J2140–0321, we are able to confirm the detection of O i absorption that is well separated from the Si ii λ1304 line and measure \( \log N(\text{O}) = 13.82 \pm 0.10 \). This is consistent with that measured by Noterdaeme et al. (2015a) using the UVES spectrum. There is a 2\sigma detection in the case of the ESDLA towards J1411+1228. For the ESDLA towards QSO J2232+1242, the 'O i λ1304 absorption is blended with the Si ii λ1304 line (\( \log N(\text{O}) = 13.46 \pm 0.19 \)). In the remaining cases, we do not have a clear detection at more than the 3\sigma level. The \( \log N(\text{O}) \) upper limits (\( \lambda \) level) estimated from the non-detection of the \( \lambda = 1304 \) line for all other ESDLAs are listed in Table A.1.
Table 1: Quasar name, redshift of the quasi (\(z_{QSO}\)), redshift of the ESDLAs (\(z_{abs}\)), column density (in logscale) of H\textsubscript{i} and H\textsubscript{2}, dust content measured in the ESDLAs (E(B-V)), metallicity relative to solar (in [M/H], where M represents the most depleted neutral gas species, \(\Delta v_{90}\), \(\Delta v_{90}(C\,iii)\), and column density (in logscale) of Si for ESDLAs.

**Notes.** \(\Delta v_{90}\) is derived from unsaturated transitions of singly ionised species, such as Ni\textsubscript{ii} and Zn\textsubscript{ii}. All data are taken from \textit{Kanjan et al. (2020)} and references therein, except for \(\Delta v_{90}(C\,iii)\) and N(Si\textsubscript{ii}), which is calculated in this work. \(^{(d)}\) Taking into account the effects of saturation and blends, we provide revised estimates of N(Si\textsubscript{ii}) here. See section \textit{E} for discussion.

4.2. Neutral Argon

Neutral argon is difficult to probe in high-z clouds especially because the twin transitions - ‘Ar\textsubscript{i} λ1066’ and ‘Ar\textsubscript{i} λ1048’ are located within the Ly\textalpha\ forest. We fitted these transitions together taking any possible contamination from intervening Ly\textalpha\ absorption into account and using the same component structure as other low ionisation species such as Fe\textsubscript{ii} and Zn\textsubscript{ii}. We estimated the column density of Ar\textsubscript{i} in four of our ESDLAs, towards the QSOs J0017+1307, J2232+1242, J2246+1328, and J2322+0033. For the ESDLA towards QSO J1411+1229, we could only fit the ‘Ar\textsubscript{i}λ1066’ line and hence, we consider this detection as tentative.
Due to efficient charge exchange reactions between Cl\textsubscript{i} and H\textsubscript{2} (see for e.g. Jura 1975), chlorine is predominantly neutral in the presence of H\textsubscript{2}. Balashev et al. (2013) also noted a strong association of neutral chlorine with H\textsubscript{2} gas in high-z absorbers. Kanjan et al. (2020) found diffuse H\textsubscript{2} signatures in their rest-frame Lyman-Werner (L-W) band absorption in about ~50% of the ESDLAs. Although, the Ly\alpha forest at high redshift is dense enough to create strong blends with the L-W band and create confusion. In addition, there are cases (such as the ESDLA towards QSO J0025+1145), where the L-W band signatures are washed away due to the presence of a Lyman-limit system. Hence, tracers such as C\textsubscript{i} and Cl\textsubscript{i} can be used as indirect evidence for the presence of H\textsubscript{2} gas. Thus, we would like to study the presence of Cl\textsubscript{i} in our sample.

We primarily looked for Cl\textsubscript{i} transitions at \( \lambda = 1347 \) and \( \lambda = 1363 \) (atomic data taken from Scheckman et al. 1993) and the transitions at \( \lambda = 1335, \lambda = 1379, \) and \( \lambda = 1389 \) (atomic data taken from Welty et al. 2020, and references therein). Other Cl\textsubscript{i} transitions located in the Ly\alpha forest (such as Cl\textsubscript{i} transitions at \( \lambda = 1088, \lambda = 1188, \) and \( \lambda = 1084 \), reported in Oliveira & Hebard 2008, and references therein) have a high probability of being blended with other absorption lines. We note the non-detection of ‘’Cl\textsubscript{i}1363’’ in all our spectra. We also note that the transition ‘’Cl\textsubscript{i}1335’’ is heavily blended with the saturated ‘’C\textscript{ii}1334’’ and ‘’C\textsubscript{iii}1335’’ transitions. Using the other three transitions (at \( \lambda = 1347, \lambda = 1379, \) and \( \lambda = 1389 \)), we fitted the Cl\textsubscript{i} lines with the component structure (redshift and b-value) tied with C\textsubscript{i}, as neutral carbon is also found in the presence of H\textsubscript{2} gas. We note that for two ESDLAs towards QSO J0025+1145 and J1513+0352, the Cl\textsubscript{i} \( \lambda = 1347 \) profile has contamination from other absorbers in proximity. For ESDLAs towards QSO J1513+0352, the other two Cl\textsubscript{i} transitions are clear and the contamination near \( \lambda = 1347 \) is identified. Hence, we get a robust estimate on N(C\textsubscript{i}). For ESDLAs towards QSO J0025+1145, the other transitions are also contaminated and the N(C\textsubscript{i}) is highly uncertain. We report the N(C\textsubscript{i}) lower limit from the \( \lambda = 1347 \) transition and the upper limit from the \( \lambda = 1389 \) transition. We also report the robust measurement of N(C\textsubscript{i}) in ESDLA towards QSO J2140−0321 by combining our medium resolution X-shooter spectra and high-resolution UVES spectra (initially studied in Noterdaeme et al. 2015a). All measurements and upper limits are reported in Table.

We detected Cl\textsubscript{i} in all systems where H\textsubscript{2} was previously detected. In the new ESDLA sample studied in Telhova et al. (2022), they detected H\textsubscript{2} towards J2205+1021 and J2359+1354. We note that Cl\textsubscript{i} is not detected in these systems. Although, the N(H\textsubscript{2}) in these two systems are much lower than the other ESDLAs with conformed Cl\textsubscript{i} detection. Since N(H\textsubscript{2})-N(C\textsubscript{i}) are correlated, the non-detection could just indicate the the Cl\textsubscript{i} detection limit with an X-shooter wavelength range and resolution. The detection of H\textsubscript{2} towards J0025+1145 was declared as tentative in Kanjan et al. (2020) despite a high inferred column density. The reason being the presence of a Lyman-limit system towards QSO J0025+1145 which implies that we could detect only \( \lambda = 1145 \) transition. We also report the robust measurement of N(C\textsubscript{i}) in ESDLA towards QSO J2140−0321 by combining our medium resolution X-shooter spectra and high-resolution UVES spectra (initially studied in Noterdaeme et al. 2015a). All measurements and upper limits are reported in Table.

### 4.3. Neutral Chlorine

Nitrogen is produced in different stages of hydrogen and helium burning shells in stars. There is large uncertainty in the contribution of nitrogen production from different stages in various types of stars such as low, intermediate, or massive stars (see Meynet & Maeder 2002). The study of nitrogen abundance in neutral gas clouds gives important insight into resolving this uncertainty (see e.g. Petitjean et al. 2008). Hence, we looked for neutral Nitrogen (N\textsubscript{i}) in our ESDLA sample as well. We note that N\textsubscript{i} is another challenging species to detect as its transitions fall within the Ly\alpha forest. However, due to multiple transitions (centred around rest frame \( \lambda = 1134 \) and \( \lambda = 1200 \)), we were able to detect neutral Nitrogen in ESDLAs. In our sample, we report the detection of neutral nitrogen in four ESDLAs towards QSOs J0017+1307, J1411+1229, J2140−0321, and J2232+1242. For the rest of the ESDLAs, the N\textsubscript{i} profile was either too weak or heavily contaminated with forest lines to be detected robustly in our medium resolution study. The measured column densities and 3\( \sigma \) upper limits are reported in Table.

---

Fig. 1: Distributions of the column density ratio, \( N(\text{Ar}^\text{i})/N(\text{H}^\text{i}) \), in ESDLAs (blue curves, this work) and the general DLA population (red curves, Zafar et al. 2014). The histogram and cumulative distributions from the two samples are compared in the top and bottom panels, respectively.
4.5. Mg II

The Mg II absorption signature has been a common feature of gas associated with galaxies both in the local (see e.g. Bergeron & Bouissé [1991], Steidel & Sargent [1992], Ettre et al. [2018]) and distant (see e.g. Bouche et al. [2018], Rao et al. [2018], Bouche et al. [2017]) universe. We detect Mg II absorption in all of our ESDLAs. We note that Mg II is quite abundant in strong H i absorbers (DLAs). The primary transitions, ’Mg ii λ2796’ and ’Mg ii λ2803’, are strongly saturated in most DLAs. Hence we report the equivalent width of the mentioned Mg II transitions as previously done in the literature (see e.g. Zou et al. [2018], Matejek et al. [2013]). We compare our distribution of ’Mg ii λ2796’ equivalent widths in ESDLAs (median - 2.1Å) with that of other high-z absorption selected samples associated with galaxies, such as the DLA population (taken from Mg ii-selected absorbers studied in Matejek et al. [2013], median - 1.72Å), the C i-selected high metallicity absorber sample (see, Zou et al. [2018], median - 2.89Å), and the Ca ii-selected dusty absorber sample (see, Wild & Hewett [2005]).

Fig. 4 shows the distributions of w(Mg ii λ2796) in the above-mentioned samples. The K-S test reveals that the Mg ii equivalent width distribution of ESDLAs, ESDLAs are indistinguishable from that of the Mg ii-selected DLA population (p-value=0.35). ESDLAs also tend to have w(Mg ii λ2796) similar to the Ca ii-selected sample as testified by the medians of the samples. The K-S test of ESDLAs with the Ca ii sample (p-value=0.37) also indicates that the sample distributions are indistinguishable. We performed a K-S test with the C i-selected sample as well and found that the samples are consistent with being drawn from the same parent population (p-value=0.13). In addition, we show the different samples mentioned above in N(H i) – w(Mg ii λ2796) plane in Fig. 4. We note that the N(H i) for ESDLAs and w(Mg ii λ2796) for the Matejek et al. [2013] sample are restricted by their respective selection technique. Although, we note that the w(Mg ii λ2796) for the sample of ESDLAs is quite varied and no significant relation can be drawn between the two quantities shown in the figure.

In addition to the Mg ii equivalent width, we also report the velocity spread of Mg ii absorption using Δv (Mg ii λ2796) similar to Zou et al. [2018] in Table 4. In their paper, Zou et al. [2018] define Δv as the velocity separation between the two extreme pixels where the optical depth τ < 0.1. We note that the velocity spread of ESDLAs is different (K-S test p-value=0.02) and statistically smaller (median=150 km s^{-1}) than that of the C i-selected absorbers (median=390 km s^{-1}) 6.

4.6. Na i and Ca ii

With an ionisation potential of 5.1 eV, neutral Sodium (Na i) serves as a tracer for cold neutral gas (see Crawford [1992]). We did not find any significant trace of Na i in our sample. The stronger transitions on Na i lie in the far end of the X-shooter near-infrared (NIR) arm (rest wavelengths 5891Å and 5897Å), where the signal-to-noise ratio (S/N) is very poor in our observations. Hence, we note that the non-detection in our observations is not necessarily an indication of a low abundance of Na i. In Table A.1, we report the 3σ upper limit on the column density

---

6 The velocity spread of ’Mg ii λ2796’ in C i-selected absorbers was obtained with private communication from the authors of Zou et al. [2018].
of Na I in our sample.

A Ca II absorption signature has been associated with dusty DLAs at high redshift (see e.g. Wild et al. 2006; Nestor et al. 2008). We found signatures of Ca II absorption in seven ESDLAs. For weak transitions, we calculated the equivalent width (\(w\)) of the absorption profile. In cases where the spectra have a low S/N, we checked whether the value for the equivalent width is greater than a 3 \(\sigma\) uncertainty and we report it as detection if this is true. If not, we used the Voigt profile model to estimate a 3\(\sigma\) upper limit on the column density. The NIR spectrum has significant sky residuals hindering a robust estimate of the equivalent width of some transitions such as 'Ca II 3934' and 'Ca II 3969'.

For systems towards QSO J1513+0352 and J2246+1328, the respective transitions, 'Ca II 3934' and 'Ca II 3969', are contaminated. Hence, we declare them to be tentative in our list. In Table A.1, we report the column density of Ca II in our sample. Additionally, in Table A.2, we report the equivalent width of the 'Ca II 3934' transition as this has been previously used in the literature.

Fig. 4 shows the distribution of \(w\) (Ca II 3934) (left) and E(B-V) (right) for ESDLAs in our sample, CI-selected absorbers from Zou et al. (2018), and the Ca II-selected sample from Wild & Hewett (2008). The E(B-V) for ESDLAs were obtained from Ranjan et al. (2020). K-S tests between ESDLAs and CI-selected absorbers for \(w\) (Ca II 3934) (p-value=0.79) and E(B-V) (p-value=0.18) and with the Ca II-selected absorber sample, with a p-value=0.31 for \(w\) (Ca II 3934) and a p-value=0.41 for E(B-V) indicate that the dust content and Ca II abundance for all three samples are indistinguishable.

4.7. Si II, Ni II, Mn II, Ti II, and P II

In this subsection, we further report the detection of five other singly ionised species, Si II, Ni II, Mn II, Ti II, and P II in our sample. These low ionisation species are commonly detected in DLAs. For all five species, the redshift and \(b\)-values are tied to other low ionisation species such as Fe II and Si II. We note that Ni II is detected in all ESDLAs, and Mn II is also detected in all ESDLAs, except towards QSO J1513+0352. For this ESDLA, the two Mn II transitions, \(\lambda = 1162\) and \(\lambda = 1199\), are contaminated by the Ly\(\alpha\) forest. The remaining three Mn II transitions, \(\lambda = 2576, \lambda = 2594,\) and \(\lambda = 2606\), are strongly blended with the sky residuals in the VIS arm spectra of X-shooter.

Single ionised sulphur (S II) is a good tracer of gas phase metallicity (similar to Zn II) as sulphur is hardly depleted onto dust. However, the relevant S II transitions, \(\lambda = 1250, \lambda = 1253,\) and \(\lambda = 1259\), are often contaminated by the Ly\(\alpha\) forest lines. Due to this, the robust measurement of the column density is not possible in all cases. For six of our ESDLAs, the S II profiles were free of Ly\(\alpha\) contamination. Out of these, the non-blended profile of one system was saturated (towards QSO J0025+1145) and hence we could only estimate the lower limit on N(S II). For another ESDLA system, towards QSO J1258+1212, we found one slightly blended transition, 'S II 11250', and using that line, we give a tentative estimate on the column density. For the remaining four ESDLAs, towards QSOs J2140−0321, J2232+1242, J2246+1328, and J2322+0033, we obtained a robust estimate on the column density. All the estimations are given in Table A.1.

We further looked for the Ti II transitions at \(\lambda = 3384, \lambda = 3242, \lambda = 3230, \lambda = 3073, \lambda = 3067,\) and \(\lambda = 1910\). For all ESDLAs rest frames in our study, all mentioned transitions (except \(\lambda = 1910\)) lie in the NIR arm region of the X-shooter spectrograph (with the exception of the ESDLAs towards QSO J2246+1328 for which the \(\lambda = 3073\) and \(\lambda = 3067\) transitions also lie in VIS arm region). There is strong contamination from sky lines in the NIR region. In addition, the spectra in the NIR region have significantly lower S/Ns and they are more strongly blended with the sky lines relative to the VIS and UVB band. Using different combinations of the above-mentioned transitions, we obtained a robust estimate of the Ti II column density. For systems where none of the NIR lines can be used for the fit, we report a tentative value for the lower limit using the \(\lambda = 1910\) transition. The column density estimates and limits for Ti II are reported in Table A.1.

For most ESDLAs, the P II transitions, \(\lambda = 961, \lambda = 963\) and \(\lambda = 1152\), are strongly contaminated by the Ly\(\alpha\) forest and \(\lambda = 1301\) and \(\lambda = 1532\) are often weak and not detected. We used a combination of multiple transitions mentioned above to obtain a robust column density estimate of P II in ESDLAs towards QSO J1411+1229, J2140−0321, J2232+1242, and J2246+1328. In the appendix, the metal line plots (see section 4.8) for all ESDLAs show the relevant transitions used for fitting S II, Ni II, Mn II, Ti II, and P II.

4.8. Dealing with saturation effects for Si II

Absorption lines from Si II are frequently detected in high-z DLAs and they are a good tracer of neutral H I gas. While Si II has a detectable absorption spread over a wide range of rest wavelengths, only a few transitions are outside the Lyman-\(\alpha\) forest. For estimating the total column density of Si II, we tied the \(b\)-value and redshift of individual Si II, components to Fe II and fitted the observed absorption lines in the spectra with a combination of many Si II transitions with a varying oscillator strength, with namely \(\lambda = 989, 1020, 1190, 1193, 1260, 1304, 1526, 1808,\) and 2335 taking care of possible blending. The total Si II column densities from this analysis are listed in Table II. However, for some systems, such as ESDLAs toward QSO J0025+1145, J1349+0448, J2140−0321, and J2232+1242, it seems that the absorption profiles of most Si II transitions are saturated. In these cases, in Table II, we give the allowed range for the Si II column density by getting a conservative upper limit on N(Si II) using the line at \(\lambda = 2335\) with the weakest oscillator strength.

4.9. Warm and hot gas tracers

In addition to cold gas, a DLA line of sight also reveals ionised warm gas (\(T \sim 10^4\) K, traced by Si IV and C IV) and hot gas (traced by N V and O VI), residing in the warm and hot ionised medium as well as the halo of the associated galaxy. Fox et al. (2017) searched for warm and hot gas signatures in DLAs using VLT/UVES data. We searched for the same thing in our medium resolution ESDLAs sample.

All the ESDLAs in our sample show absorption lines of warm gas tracers (Si IV and C IV). We performed a multi-component Voigt profile fitting by simultaneously tying the \(b\)-value and redshift of all detected warm and hot gas species. Contrary to the plethora of lines for singly ionised species.
such as Fe ii, there are fewer detected lines for warm gas species. Hence, we have to be careful when dealing with intrinsic saturation (see section 4.1 for details). To deal with this issue, we created a mock Voigt absorption profile models for the transitions with a relatively lower oscillator strength – 'C iv\(\lambda 1550' and 'Si iv\(\lambda 1402'. To create this mock, we needed to estimate a certain minimal \(b\)-value for the fitting. The \(b\)-value is dependant on the thermal properties of the transition \(b_{\text{thermal}} = \sqrt{2kT/m}\), where \(k\) is Boltzmann’s constant, \(T\) is temperature of the gas, and \(m\) is atomic mass) as well as the turbulence in the medium. Since we do not have any way to distinguish between the two, for a conservative lower limit, we assumed that the gas is non-turbulent and hence, the lower limit on \(b\)-value was obtained just from the thermal component. Taking \(T\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\sim\si...
is detected in all DLAs (including ESDLAs). Hence, the warm gas signature seen in ESDLAs can be from a mixed contribution from both the CGM and the ISM of the associated galaxy.

Due to the Lyα forest confusion, we could not estimate the column density of any hot gas tracer (N v and O vi transitions) in our sample, except towards QSO J1349+0448, in which we detected the ‘N v,1238’ transition (fixing the position and b-value from C iv). However, we declare this detection as tentative (with log N(N v)∼14.16) as the second transition of the doublet (‘N v,1124’) is contaminated by the Lyα forest. We do show the normalised spectra of N v and O vi transitions for some other ESDLA systems (see section 4.4), yet they are heavily contaminated with the Lyα forest lines.

5. Discussion

5.1. Comparing dust-corrected abundances

In absorption line literature, the metallicity of the neutral gas in a system is given as the ratio of the column density of the least dust depleted element, X, to the total hydrogen column density. Volatile elements, such as Zinc or Sulphur, are commonly used in the literature (see e.g. Kulkarni & Fall 2002), since they are usually accessible in the spectrum and their lines are unsaturated. We note that Zn ii was detected in all ESDLAs in our sample and we used Zn (assuming N(Zn)=N(Zn ii) in neutral gas clouds) to calculate the metallicity of ESDLAs in

---

8 We note that the uncertainty in N(Zn ii) along QSO J2246+1328 was reported incorrectly in Paper I, leading to relatively large errors in metallicity and depletion measurements. The revised value for the Zn ii column density along J2246+1328 is log N(Zn ii)=12.52±0.1. We further revised the value of metallicity as [Zn/H]c=−1.84±0.1 and the depletion as [Fe/Zn]c=−0.14±0.13.

---
5.2. Neutral Argon in ESDLAs

The first ionisation potential of Argon (15.76 eV) is higher than the H\(\text{I}\) ionisation threshold (13.6 eV) and hence, Argon largely should remain neutral in H\(\text{I}\) clouds. However, Soha & Jenkins (1998) showed that the photo-ionisation to recombination rates of Ar\(\text{i}\) is one order of magnitude higher than H\(\text{I}\), indicating that Ar\(\text{i}\) is quite sensitive to high energy ionising photons. Hence, in the presence of UV-background photons, Ar\(\text{i}\) might become deficient relative to other \(\alpha\)-capture elements, such as Silicon and Sulphur. Indeed, Jenkins (2014) show that Ar\(\text{i}\) is deficient in diffuse H\(\text{I}\) gas in the Milky Way. Zafar et al. (2014) note a similar deficiency in their sample of DLAs observed at high redshift \(z < 2.0\) and \(z_{\text{abs}} < 4.2\). They conclude that, given the typical DLA metallicity, the deficiency is caused by extragalactic UV photons that ionise neutral Argon in the absence of H\(\text{I}\) self-shielding and that such a deficiency should not exist in the presence of high-N(H\(\text{I}\)) gas clouds originating from within the associated galaxy. Since ESDLAs are high-N(H\(\text{I}\)) gas clouds with a similar metallicity as DLAs that likely reside within their associated galaxy, our sample is ideal to test this conclusion. Following up on the work of Zafar et al. (2014) (and references therein), we plotted Fig. 7 showing the ratio of Ar\(\text{i}\) over Si\(\text{ii}\) relative to solar ([Ar/Si]), as a function of the H\(\text{I}\) column density.

Zafar et al. (2014) combined modelling with observations to exclude the possibility that Ar\(\text{i}\) is deficient due to dust depletion or nucleosynthesis and they conclude that the deficiency is due to ionizing photons originating from the extragalactic background at that redshift. Their photo-ionisation models are for gas with solar abundance ratios, low density \(n_{\text{HI}}=0.1\) atoms cm\(^{-3}\)), and Haardt & Madau (HM) extragalactic background radiation (see Haardt & Madau (2012) at \(z = 2.5\). We performed photo-ionisation modelling using the spectral synthesis code CLOUDY (as described by Ferland et al. (2017); Shaw et al. (2008; Shaw & Ferland 2020) using these parameters. We show the models in Fig. 7 as green dots. Zafar et al. (2014) also have a separate set of models with similar parameters and twice the radiation intensity to include the effects of high energy ionising photons. For our analysis, instead of doubling the radiation intensity which would not be physical, we lowered the density of our cloud models (to \(n_{\text{HI}}=0.01\) atoms cm\(^{-3}\)) instead (shown in the figure with purple dots). The lowering of the density is a better assumption also because, if the ESDLAs are made up of multiple gas clouds, we are unsure about the mean particle density in the clouds, even if we know the total column density. We performed additional modelling with an updated background radiation field (from Khaire & Srianand (2019)). We assumed a plane parallel gas cloud under constant pressure irradiated from both sides. The gas cloud extends up to a given N(H\(\text{I}\)). The radiation field consists of cosmic microwave background (CMB) and Khaire and Srianand (see Khaire & Srianand (2013) metagalactic radiation at \(z = 2.5\) along with diffuse radiation due to its star formation. This is similar to the photo-dissociation region (PDR) modelling used to interpret observations of high-\(z\) DLAs in the literature (see e.g. Shaw et al. (2016; Rawlings et al. (2018)). We used the updated parameters relative to Zafar et al. (2014) to verify that we obtained consistent results. For the new models, we used solar abundance ratios and log(N(H\(\text{I}\))) ranging from 20 to 22.5. We used a metallicity of [Zn/H]\~{}1.3 (average ESDLA metallicity) and a density ranging from \(n_{\text{HI}}=0.1\) to \(n_{\text{HI}}=100\) cm\(^{-3}\). Models with \(n_{\text{HI}} \geq 1\) do not show any under-abundance in the range of N(H\(\text{I}\)) mentioned. Hence, we do not show these systems in the plot for clarity. We do, however, show the series of models with \(n_{\text{HI}}=0.1\) (as cyan dots), which seems to be similar to Zafar et al. (2014) for the high N(H\(\text{I}\)) regime.

Comparing observations with modelling, we note that for a robust N(Ar\(\text{i}\)) measurement, neutral Argon is almost as abundant as singly ionised Silicon in ESDLAs and hence, consistent with photoionisation models, there is no pronounced under-abundance of Ar\(\text{i}\) compared to Si\(\text{ii}\). Two other ESDL systems with tentative Ar\(\text{i}\) detections, towards QSOs J0024−0725 and J1411+1229, show an under-abundance in Ar\(\text{i}\) (compared to Si\(\text{ii}\)). For these systems, the column density was estimated using only one transition due to strong Ly\(\alpha\) forest blends in the other Ar\(\text{i}\) transition. Hence, we expect these column density estimates to be quite uncertain. Since, we have no way to robustly quantify the uncertainty (hence the measurements are shown as open stars in the figure), we refrained from interpreting the trend arising from these tentative detections.

Our ESDL sample result indicates that the Argon-Silicon column density ratio seems to be increasing as predicted by the photoionisation models at high column densities. The average [Ar/Si] in ESDLAs is -0.21±0.1 and that of the photoionisation models is \(~0.05\) for \(n_{\text{HI}}=0.1\) cm\(^{-3}\) and \(~0.11\) for \(n_{\text{HI}}=100\) cm\(^{-3}\). We conclude that the mean deficiency of Argon as compared to Silicon (other \(\alpha\)-capture element) as seen by Zafar et al. (2014) in DLAs is non-existent in ESDLAs (within a 2\(\sigma\) uncertainty). There is a residual deficiency of ~0.2 dex in the Argon-Silicon column density ratio in ESDLAs, but as shown by photoionisation models, this can be attributed to low metallicity and/or a number density of the clouds. We conclude that Ar\(\text{i}\) is likely ionised in low N(H\(\text{I}\)) (DLAs). This ionisation is likely driven by UV-background photons which cannot penetrate high N(H\(\text{I}\)) self-shielding ESDLAs. Hence, the under-abundance of Ar\(\text{i}\) relative to Si\(\text{ii}\) is not seen in ESDLAs.

5.3. Neutral Chlorine in H\(_2\) bearing gas

Neutral chlorine (Cl\(\text{i}\)) is an important tracer of molecular hydrogen as both are connected by charge-exchange reactions. So the production of neutral chlorine (Cl\(\text{i}\)) is very efficient in the presence of molecular gas (see e.g. Jura (1974). It has been shown in the Milky Way sightlines that there is a direct correlation between N(H\(\text{II}\)) and N(Cl\(\text{i}\)) (see e.g. Jura (1974; Sonnenstiel et al. (2006; Mooney et al. (2012) (See Figure 8). Using the data points from the literature, Wallstrom et al. (2019) give a relation between N(H\(\text{II}\)) and N(Cl\(\text{i}\)), holding for up to two orders of magnitude \((18 < \log(N(H_{\text{II}})) < 20)\), as given below:

\[
\log[N(Cl)]= \left(0.79 \pm 0.06 \right) \times \left[ \log(N(H_{\text{II}})) \right] - \left(2.13 \pm 1.15 \right) \quad \text{(1)}
\]

This correlation has also been shown to be true for other H\(_2\) bearing high-\(z\) DLAs (see e.g. Balashev et al. (2015). The high-\(z\) observations available in Balashev et al. (2015) are limited to log(N(H\(_2\)))<20.2. In our sample, we have an ESDL system towards QSO J1513+0352 with the highest log N(H\(_2\)) (=21.3±0.01) amongst QSO-DLAs. Even for such a high N(H\(_2\)), the neutral chlorine measured in this study follows the above-mentioned relation between N(Cl\(\text{i}\)) and N(H\(_2\)). The other two N(Cl\(\text{i}\)) measurements in ESDLAs towards QSO J0025+1145 and J2140−0321 also show consistency with the relation. Further, Noterdaeme et al. (2017) also reported another DLA (towards QSO J0000+0048) with log N(H\(_2\))=20.43±0.02
and log N(Cl) = 14.6±0.3. Studies of C1-selected metal-rich DLAs (see e.g. Zou et al. 2018; Noterdaeme et al. 2010) report a system towards QSO J0917+0154 with a high log N(Hi)=20.11±0.06 with no significant detection of neutral chlorine (as discussed in a private conversation with the authors of Zou et al. 2018). Balashev et al. (2016) reported an ESDLA towards QSO J0843+0221 with log N(Hi)=21.21±0.02 and log N(Cl)=13.21±0.18. We found that the system, J0843+0221, slightly deviates from the N(Cl)−N(Hi) relation. The environment of the associated GRB-DLAs (gas probed from the host galaxy associated with a γ-ray burst) have also been shown to be similar to ESDLAs (see Ranjan et al. 2020). In GRB-DLA studies, Heiniz et al. (2019) reported a GRB-DLA (towards QSO 181020A) with log N(Hi) = 20.4±0.04. We report the neutral chlorine in this GRB-DLA to be log N(Cl) = 14.6±0.3 (information received from private conversation with the authors of Heiniz et al. 2019). Fig. 8 shows all the above discussed data points along with the mentioned N(Cl)−N(Hi) relation as a straight line. We conclude that the N(Hi)−N(Cl) relation remains consistent up to another two orders of magnitude, log(N(Hi))<22 for all high-z H2 bearing clouds.

5.4. Mg II in different DLA sub-samples

Strong Mg II absorption (w(Mg II λ2796)> 1Å) is seen in ESDLAs similar to C1-selected absorbers. Such strong Mg II absorption (high w(Mg II)>1.0Å) signatures have been linked with starburst related feedback processes in low mass galactic halos (see Prochier et al. 2019). Although further studies such as Bouche et al. (2012) note that strong Mg II absorption might not always represent strong star-formation activity, Zou et al. (2018) further conjecture that strong Mg II absorption in their sample along with a large velocity spread might be a consequence of either an interaction or star-formation activity in the associated galaxy. To continue this discussion further, we compared the N(Hi), metallicity, velocity spread, Δv(Mg II λ2796), and equivalent width, w(Mg II λ2796), for Mg II-selected DLAs from Matejek et al. (2013), C1-selected absorbers from Zou et al. (2018), and ESDLAs from this work. We attempted to understand different properties of these sub-samples that are shown to be associated with galaxies by comparing their corresponding Mg II profiles.

To explore these, Fig. 8 shows the plots between N(Hi), metallicity (log Z), Δv(Mg II λ2796), and w(Mg II λ2796). We found that ESDLAs metallicity strongly correlates with Δv(Mg II λ2796, Pearson correlation coefficient, r=0.79) and w(Mg II λ2796, r=0.91). We also see a correlation between N(Hi) of C1-selected DLAs and Δv(Mg II λ2796, r=0.58). We note that while both C1-selected absorbers and ESDLAs have a high Mg II equivalent width (compared with general DLAs), the associated kinematics of Mg II indicate that these two sets may be sampling different populations of galaxies.

Fig. 7: Ratio of neutral argon ArI to SiII column density (relative to solar), [Ar/SiII], plotted as a function of the H I column density. Red stars indicate measurements for ESDLAs from this work, with empty stars indicating tentative detections of ArI and down arrows representing upper limits. Blue squares are measurements for DLAs from Zafar et al. (2019). The green dots represent a series of photoionisation models run by Zafar et al. (2018) for gas with a solar abundance ratio, low density (nH=0.1 atoms cm$^{-3}$), and Haardt & Madau (HM) extragalactic background radiation (see Haardt & Madau 2012) at z = 2.5. The purple dots also represent similar models, but with a lower density (nH=0.01 atoms cm$^{-3}$). The cyan points are a series of photoionisation models from this work with an updated Khaire & Srianand extragalactic background radiation field (see Khaire & Srianand 2014) and the cosmic microwave background (CMB) at redshift, z = 2.5, solar abundance ratios, logN(HI) ranging from 20 to 22.5, a metallicity of [Zn/H]<0.05 solar (average ESDLA metallicity), and a density, nH=0.1 cm$^{-3}$. The photoionisation model results were obtained using CLOUDY.
We note that while C1-selected DLAs were targeted to have a high C1 content and were found to have a high metallicity and ESDLAs to be of high N(H1) by definition, they do indeed probe low N(H1) and low metallicity gas consecutively. Although, the absence of metal-rich high N(H1) gas might just represent the limitation of our selection criteria. Metal- and dust-rich systems will be missed in the optical colour-excess selection based criteria (see Richards et al. 2002) for observing QSOs as used by SDSS. Future surveys such as DESI that implement a more robust selection combining optical and NIR colours (see Yèche et al. 2020) might help understand whether such systems were just missed in our observations or are indeed rarer to find.

In kinematics-metallicity space, we show that ESDLAs and C1-selected absorbers are clearly distinct entities, while their w(Mg ii λ2796) distribution is similar. The C1-selected sample shows high kinematical extension (measured as a Δv value for their ‘Mg ii λ2796’ absorption profile) with all but four (out of 17) systems having ‘Mg ii λ2796’ Δv > 300 km s\(^{-1}\). Fig. 13 plots the Δv against the equivalent width (w) of ‘Mg ii λ2796’ line. We can see that in comparison to C1-selected absorbers, ESDLAs have a relatively lower kinematical extension (only six out of 18 systems have Δv > 300 km s\(^{-1}\)). In addition to having a high Δv value, Zou et al. (2018) also show that some of their DLAs have subsystems in which the Mg ii and C1 absorption profiles are separated by more than ≈200 km s\(^{-1}\), termed as gas with disturbed kinematics in their work. In this work, Mg ii and C1 profiles (see Ranjan et al. 2018, 2020) in ESDLAs do not show such disturbed Kinematics as opposed to what is seen in C1-selected clouds. This is representative of different origins for the ESDLA gas clouds compared to C1-selected absorbers.

As discussed in literature, the connection of strong Mg ii absorbers (w(Mg ii λ2796) > 1 Å) with star-formation activity is rather ambiguous. In addition, the current observations using X-shooter and other high-resolution ground-based spectrographs do not detect the galaxy stellar continuum in any of the samples discussed above. While emission lines have been detected in ESDLAs that indicate a modest instantaneous star-formation rate (see Ranjan et al. 2020), they are not enough to form a general consensus about the galaxy morphology. Rafeelski et al. (2010) note that the star-formation rate (SFR) deficiency in DLAs are a consequence of poor conversion efficiency of H1 to H2 in low metallicity environments. While we do note that ESDLAs are metal-poor compared to C1-selected absorbers, the presence of H2 is high in ESDLAs (more than half of the ESDLAs have confirmed diffuse H2 detection), similar to the C1-selected sample. Although, ESDLAs are dust-poor (A\(_v\) ≈ 0.1) and due to our limited line of sight study, there is no way to confirm as to how much of this diffuse H2 gas indeed cools down to form fully molecular regions that can further form stars. Using the analysis above, we conclude that, while C1-selected absorbers and ESDLAs indeed probe different environments, no strong conclusion can be drawn by this about the nature of star formation in their associated galaxy.

---

9 We note that the Δv mentioned here is measured for saturated or intrinsically saturated lines for both C1-selected absorbers and ESDLAs and hence cannot be compared with the standard Δ\(\omega_0\) measurements of unsaturated lines (as shown in Ledoux et al. 2006).

5.5. Trend of Ca ii with dust

The presence of calcium (as Ca ii) in high-z DLAs and sub-DLAs have been linked to dusty gas systems from within the halo of their associated galaxy. Calcium gets depleted onto dust and hence, the Ca ii column density does not necessarily scale linearly with dust. The ionisation potential of Ca ii is 11.87 eV and is lower than H1 (13.6 eV) and hence, Ca ii is not the main ionisation state of calcium in H1 gas. Nestor et al. (2008) indicated that the systems with w(Ca ii)>0.25Å should be DLAs. We note that, among robust detections, all our ESDLAs fulfil this criterion except the ESDLA towards QSO J1513+0352. We note that this is the only ESDLA in our sample with Ly\(\alpha\) emission detected in proximity as well as the presence of higher rotational levels of H2 (see Ranjan et al. 2018), indicating a possibly enhanced radiation environment as compared to other ESDLAs. Such enhanced radiation might ionise Ca ii significantly to show the observed under-abundance. However, further investigation of the effects of radiation on Ca ii requires detailed modelling and is beyond the scope of discussion for this article.

Studies in the literature (such as Zych et al. 2009) also suggest that absorbers with w(Ca ii λ3934)>0.7Å should probe diffuse H2 gas clouds from within their associated galactic disks. However, Ca ii is easily depleted onto dust and hence, it does not simply correlate with N(H2) in diffuse gas clouds with a moderate dust content (0.2<\(A_v\)<1). The ESDLAs toward QSOs J0025+1145, J1411+1229, and J2359+1354 fulfill this criterion. We found traces of H2 in ESDLAs towards QSO J0025+1145 (with \(A_v\)=0.51) in Ranjan et al. (2020) and J2359+1354 (with \(A_v\)=0.29) (Felikova et al. 2020). In J0025+1145, we also found \([\text{O} \text{iii}]\lambda5007\) and H-\(\alpha\) emission in very close proximity (\(\rho =1.9\pm 0.1\) kpc) to the absorber line of sight, indicating that the gas originates from within the star-forming disk of the associated galaxy. However, we did not find a significant trace of H2 in the ESDLA system towards QSO J1411+1229. Since the survival of H2 is associated with dust, the extremely low dust content (\(A_v\)=0.09) as compared to the other two cases can be the reason for the absence of H2.

In the local universe, Nestor et al. (2008) initially showed that w(Ca ii λ3934) might not increase linearly with N(H1). However, later studies from the local universe (such as Murca et al. 2018 and references therein) indicate an increasing trend of N(H1) and E(B-V) with increasing w(Ca ii λ3934). Yet the trend disappears once saturation effects become significant (at N(H1)= 5\times 10^{20} \text{cm}^{-2} and E(B-V) ~ 0.08 \text{mag}). At high-z, Wild & Hewett (2008) were the first to search the SDSS catalogue for Ca ii-bearing absorbers and they reported a trend of increasing dust content with an equivalent width of Ca ii. Although they also mention that ~40% of the Ca ii absorbers would be missed due to the optical selection criteria of SDSS. Nestor et al. (2008) further noted that no trend was found between the Ca ii equivalent width and metallicity or degree of depletion. They also noted that the strength of Ca ii lines is determined by a combination of particle density, background UV photons, and the dust content of the gas clouds. Zou et al. (2018) also state that the relation between w(Ca ii λ3934) and dust reddening E(B-V) is ambiguous for high-z observations.

Given that our ESDLAs sample metal- and dust-poor environments that are, as of yet, often H2 bearing (at least for 50% of the cases), we intend to check whether we see any
Fig. 9: Comparison between properties of Mg ii profiles in different samples. Top left panel: log N(Hi) [atoms cm$^{-2}$] vs. metallicity (log Z=[X/H]). Top right panel: $\Delta v$(Mg ii $\lambda$2796) [km s$^{-1}$] vs. metallicity (log Z). Bottom left panel: Equivalent width $w$(Mg ii $\lambda$2796) [Å] vs. log N(Hi) [atoms cm$^{-2}$]. Bottom right panel: Equivalent width $w$(Mg ii $\lambda$2796) [Å] vs. metallicity (log Z) for ESDLAs (green pentagons, this work), C i-selected absorbers (blue points, from Zou et al. 2018), and the Mg ii-selected DLAs (red circles, from Matejek et al. 2013).

A similar trend as mentioned above. Fig. 11 shows the plot of $w$(Ca ii $\lambda$3934) versus E(B-V) for ESDLAs in our sample, the C i-selected absorbers from Zou et al. (2018), and the Ca ii-selected sample from Wild & Hewett (2005). The figure shows that $w$(Ca ii $\lambda$3934) does not correlate with E(B-V) globally or even in the individual high-z samples. Hence, we cannot conclude that there is any strong trend of $w$(Ca ii $\lambda$3934) with dust extinction in high-z absorbers. We note that this lack of a trend cannot be necessarily attributed to a low dust content (E(B-V) ≲ 0.3) in QSO absorber samples. The correlation between $w$(Ca ii $\lambda$3934) and E(B-V) is seen in previous studies for samples with E(B-V)<0.08 and $w$(Ca ii $\lambda$3934)<0.35. However, for all high-z absorbers seen here, there seems to be no significant correlation between $w$(Ca ii $\lambda$3934) and E(B-V). We also checked for correlation in sub-samples with E(B-V)<0.08 and $w$(Ca ii $\lambda$3934)<0.35 and found no significant correlation to report. Probing dustier sightlines (E(B-V) ≳ 0.3), which might be possible in future deeper surveys such as DESI (see Yéche et al. 2020) and WEAVE-QSO (see Pieri et al. 2016), will help understand
stand if there is any strong trend of \( w(\text{Ca} \, \text{II} 3934) \) with dust in absorbers with \( E(B-V) \geq 0.3 \).

5.6. Kinematics

ESDLAs provide a unique opportunity to study the nature of gas, not only from within the star-forming disk of an associated faint galaxy (see Ranjan et al. 2020), but also study the warm and hot medium associated with it. Since ESDLAs do probe gas from within the galactic disk, they are likely to probe warm and hot gas both from within the disk (see discussion in Section. 4.9) and the outskirts of the associated galaxy. Warm gas is likely to have relatively disturbed kinematics as compared to their neutral gas counterparts. (Fox et al. 2017) showed that the mean \( \Delta v_{90}(\text{C} \, \text{iv}) \) is approximately twice that of the mean \( \Delta v_{90}(\text{neutral}) \). In our ESDLA sample, we make a similar comparison of the standard \( \Delta v_{90} \) measurements of singly ionised unsaturated lines (taken from Majetek et al. 2013) and shown in Table. 10 with the \( \Delta v_{90} \) of unsaturated \( \text{C} \, \text{iv} \) profiles.

We see that the mean \( \Delta v_{90}(\text{C} \, \text{iv}) (=260 \, \text{km s}^{-1}) \) is – 3 times the mean \( \Delta v_{90}(\text{neutral})(=80 \, \text{km s}^{-1}) \) for unsaturated lines indicating less disturbed \( \text{H} \, \text{i} \) gas in ESDLAs compared to DLAs. Fig. 12 shows the distribution of kinematics (\( \Delta v_{90} \)) of unsaturated \( \text{C} \, \text{iv} \) and neutral gas. We show that the distribution has a large spread, but the \( \Delta v_{90} \) of \( \text{C} \, \text{iv} \) gas is larger than neutral gas for all the absorbers. We also note that this is especially evident for ESDLAs as the neutral gas is much less disturbed. While the distribution of \( \Delta v_{90} \) of neutral gas in ESDLAs is quite similar for DLAs and ESDLAs (as evident in Figures. 8 and 12), the \( \Delta v_{90} \) of neutral gas in ESDLAs is smaller than that of DLAs. Figure 12 further shows that the \( \Delta v_{90} \) of \( \text{C} \, \text{iv} \) profiles is always more than double than that of \( \Delta v_{90} \) of neutral gas in ESDLAs, while the same is not true for DLAs. In DLAs, the \( \Delta v_{90} \) of neutral gas can be higher in many cases. In addition, the average metallicity of the DLAs of Fox et al. (2017) is -1.68 \pm 0.08, which is also lower than that of the ESDLAs (-1.30 \pm 0.05). Hence, this trend in \( \Delta v_{90} \) of neutral gas cannot be attributed to the standard \( \Delta v_{90} \)-metallicity relation. Using the above argument, we conclude that while the \( \Delta v_{90} \) of \( \text{C} \, \text{iv} \) in DLAs and ESDLAs are not distinguishable, \( \text{H} \, \text{i} \) gas is statistically less disturbed for ESDLAs (with a relatively smaller \( \Delta v_{90} \)) and hence, indicative of different origins of the \( \text{H} \, \text{i} \) in gas in DLAs and ESDLAs.

6. Summary

We study a sample of extremely strong damped Ly\( \alpha \) absorber systems (ESDLAs) observed in medium and higher spectral resolution spectra towards quasars. In Ranjan et al. (2020), we reported the column density and kinematics of \( \text{H} \, \text{i} \) gas, diffuse \( \text{H} \, \text{ii} \) and some associated species in addition to reporting the emission signatures from nearby star-forming regions. The impact parameter of these absorbers relative to the centroid of the emission indicates that ESDLAs originate from the star-forming disk of their associated galaxies. In this paper, we extend our analysis towards the multi-phase nature of ESDLAs. We measured the column density and equivalent width and kinematics (\( \Delta v_{90} \)) of low ionisation species (such as \( \text{O} \, \text{i}, \text{Ar} \, \text{i}, \text{C} \, \text{i}, \text{N} \, \text{i}, \text{Na} \, \text{i}, \text{Mg} \, \text{ii}, \text{Ca} \, \text{ii}, \text{Si} \, \text{i}, \text{Ni} \, \text{i}, \text{Mn} \, \text{i}, \text{Ti} \, \text{i}, \text{and} \text{P} \, \text{i} \)). We found tracers of all of these species in different systems, except for \( \text{Na} \, \text{i} \). We also looked for signatures of warm and hot gas tracers (\( \text{C} \, \text{iv}, \text{Si} \, \text{iv}, \text{N} \, \text{v}, \text{and} \text{O} \, \text{vi} \)) associated with these ESDLAs and identified all these species in addition to reporting the emission signatures from nearby star-forming regions.
ESDLAs and DLAs have the same column density distribution. CII with the MgII gas associated with galaxies. Specifically, we compare our species with other absorber samples, which are known to probe from Matejek et al. (2018). The presence of O IV in ESDLAs cannot be ruled out.

We further compare the distribution of column densities, equivalent widths, and kinematics of the above-mentioned species with other absorber samples, which are known to probe gas associated with galaxies. Specifically, we compare our ESDLAs with the MgII-selected DLA population (studied by Matejek et al. 2018), dusty gas clouds probing Ca II H-K absorption bands (studied by Wild & Hewett 2005), metal-rich CII-selected absorbers (studied by Zou et al. 2018), and C IV absorption (studied in the DLA sample by Fox et al. 2018). ESDLAs and DLAs have the same column density distribution for their warm gas tracers, C IV and Si IV. The robust estimate of NV and O VI column densities are not possible in our medium resolution study due to the contamination by Lyα forest absorption lines.

We estimate dust-corrected metallicity measured using different neutral gas species such as P II, S II, Si II, Mn II, and Cr II and compare it with the standard Zn II-based measurements, which is common in DLA literature. We find that, after applying dust correction as prescribed by De Cia et al. (2016), the measured metallicities are consistent for all mentioned species in all ESDLAs within a 3-σ uncertainty.

By comparing the neutral Argon (Ar I) in ESDLAs and DLAs, we conclude that the distribution of [Ar/H] in DLAs is similar to our sample of ESDLAs. We also note that the under-abundance of Ar I compared to α-elements as found in DLAs (see Zafar et al. 2013) do not extend to our ESDLA sub-sample. Zafar et al. (2013) claim that as opposed to dust depletion, or nucleosynthesis effects, the mentioned under-abundance is caused by background UV photons ionising the Ar I in DLAs. They also conclude that, in the presence of self-shielding high N(HI) gas, Ar I should be able to survive. As our sample has high N(HI), we tested this hypothesis. Comparing our observations and with updated CLOUDY photo-ionisation models, we conclude that ESDLAs do not show any under-abundance of Ar I relative to another α-capture element, Silicon relative to the photoionisation models. Hence, the ionisation seen in DLAs is likely driven by UV-background photons that cannot penetrate the high N(HI) in ESDLAs. We further note that a residual under-abundance of Ar I relative to Si II of ~0.2 dex in ESDLAs can be attributed to the low metallicity of ESDLAs.

Compared to the MgII-selected DLA population, we detect a large equivalent width, w(MgII λ2796), for some ESDLAs similar to some metal-rich CII-selected absorbers. Although, we note that ESDLAs and CII-selected samples can have a rather different velocity spread (Δv) of 'MgII λ2796'. In the combined sample of MgII-selected DLAS, ESDLAs, and CII-selected absorbers, we find a correlation between metallicity and velocity spread. The dust extinction, E(B-V), and w(Ca II λ3934) distribution in ESDLAs is quite similar to that of CII and Ca II-selected absorbers.

We study the relationship between N(H2) and N(CI), previously studied in the literature (see e.g. Balashev et al. 2015). By extending studies in literature (with ESDLAs and other translucent clouds with log(N(HI)) > 20), we note that the N(CI)-N(H2) correlation shown in the literature is consistent even for high N(H2) translucent clouds (up to log(N(HI)) < 22). We conclude that the H2 production seems as favourable in clouds with a low metallicity and high N(HI) environments (such as ESDLAs) as they are in metal-rich, relatively lower N(HI) environments (such as CII-selected systems studied by Zou et al. 2018, and reference therein). Additionally, we report a strong Ca II presence (w(Ca II) > 0.3 Å) in most of our ESDLAs. By comparing the dust extinction measurement with the Ca II measurement, we also conclude that w(Ca II λ3934) does not correlate with the dust content in different high-α absorbers. Although, the dust content in all absorbers discussed above is rather limited (E(B-V) ≤ 0.3). We note that this might be indicative of the SDSS optical colour-excess selection technique (see Richards et al. 2002) being biased towards dust-poor absorbers. Future large-sky surveys such as DESI that use a more robust selection technique combining optical colour with NIR band colour from the Wide-field Infrared Survey Explorer (WISE) (see e.g. Yèche et al. 2010) will likely probe dustier (A_V ~ 1), possibly metal-rich, high N(H2) gas environments towards QSOs. These samples could be then be used for robust comparison between high N(H2) metal-rich systems and ESDLAs.

The column density and kinematics of C IV and Si IV associated with ESDLAs are similar to those found in DLAs. This is expected as both DLA and ESDLA sightlines will sample warm gas in the CGM and the warm neutral medium associated with their host galaxy despite sampling different H I regions. Interestingly, the Δv90 of a warm ionised medium (traced by unsaturated C IV lines) is always more than double that of H I gas (traced by an unsaturated, singly ionised species such as Fe II and Zn II) in ESDLAs. This trend is not often seen in DLAs. We also show that the Δv90 of the H I region in DLAs are higher than in ESDLAs, despite having a lower average metallicity.

Fig. 12: Comparison between Δv90 estimates of warm gas (C IV) (from this work) and neutral gas as obtained from unsaturated transitions of singly ionised species such as Zn II and Fe II in different ESDLAs (taken from Ranjan et al. 2020) and DLAs (taken from Fox et al. 2017). The dashed black and green lines indicate Δv90(C IV) = Δv90(neutral) and Δv90(C IV) = 2Δv90(neutral), respectively.
metallicity as compared to ESDLAs. This indicates that the H$_1$ regions sampled by DLAs might be different from the H$_1$ regions sampled by ESDLAs.

ESDLAs provide a unique way to study gas within a metal-poor, general galaxy population at a high redshift and hence, warrant follow-up studies of their physical properties and kinematics. We believe that future studies of ESDLAs in higher spectral resolution ($R\sim40000$) will help model the physical conditions for each individual ESDLA. In addition, the NIR-optical-based QSO selection technique in large sky surveys such as WEAVE-QSO and DESI will help identify if dustier (A$_V\sim1$) ESDLA environments also exist.

Appendix A.1: Details on abundance and kinematics of neutral gas ions and other fine structure transitions

Appendix A.2: Absorption line figures
Table A.1: Column density (in logscale) of low ionisation gas species, \(N(\text{Ni})\), \(N(\text{O}^+)\), \(N(\text{Ca}^{+})\), \(N(\text{S}^{+})\), \(N(\text{Na}^{+})\), \(w(\text{Ca}^{+}\lambda 3969)\), \(w(\text{Mg}^{+}\lambda 2803)\), \(N(\text{P}^{+})\), \(N(\text{Ti}^{+})\), \(N(\text{Mn}^{+})\), \(N(\text{Ni}^{+})\), and equivalent width (w) measurement of "\(\text{Ca}^{+}\lambda 3934\)" and "\(\text{Mg}^{+}\lambda 2803\)" for the ESDLA sample.

**Notes.** Symbol ‘B’ means that all the transition lines for that species are blended and hence the column density cannot be estimated.
Fig. A.1: Different ionisation metal lines (O\textsc{i}, Mg\textsc{ii}, Fe\textsc{ii}, Si\textsc{ii}, Ar\textsc{i}, N\textsc{i}, Ca\textsc{ii}, Mn\textsc{ii}, Ni\textsc{ii}, Si\textsc{iv}, and C\textsc{iv}) associated with the $z_{\text{abs}} = 2.326$ ESDLA system towards QSO SDSS J0017+1307. The normalised X-shooter spectrum is shown in grey, the continuum is shown as a dashed green line, with the total best-fit multi-component Voigt profile over-plotted in red. The highlighted part of the spectrum (in black) shows the data that were used to constrain the fit. The residuals are shown above each line in areas used for the fit in units of the standard deviation ($\pm 2\sigma$) from the error spectrum. In some of the plots where there is contamination either from the Ly$\alpha$ forest or from other transitions from different absorber systems, apart from the total modelled profile in red, the modelled profile for the labelled transition is also shown as a dashed blue line. Short vertical marks (or ticks) in black show the location of the different velocity components. The position of blends with the Ly$\alpha$ forest and other absorption systems unrelated to the ESDLA are shown with cyan ticks. There is a velocity shift between the UVB and the VIS arm spectra for some systems (see Ranjan et al. 2020, for more details). The velocity shifted positions, if any, are indicated with magenta ticks. The sub-component redshifts and $b$-values of neutral and singly ionised gas species, such as Ar\textsc{i}, N\textsc{i}, and Ca\textsc{ii}, are tied together. The sub-component redshifts and $b$-values for Si\textsc{iv} and C\textsc{iv} profiles are also tied together. The saturated absorption profiles for O\textsc{i} and Mg\textsc{ii} are shown for reference. The subplot with Fe\textsc{ii} is taken from Ranjan et al. 2020 and is shown here just for reference.
Fig. A.2: Different ionisation metal lines (O i, Mg ii, Cl i, Fe ii, Si ii, S ii, Ni ii, Mn ii, Ti ii, Ca ii, Si iv, and C iv) associated with the \( z_{\text{abs}} = 2.304 \) ESDL LA system towards QSO SDSS J0025+1145. The legends as well as the assumption on sub-component redshifts and \( b \)-values are the same as in Fig. A.1.
Fig. A.3: Different ionisation metal lines (Mg II, O I, Fe II, Si II, Mn II, Ni II, Ti II, Si IV, and C IV) associated with the $z_{\text{abs}} = 2.323$ ESDLAs system towards QSO SDSS J1143+1420. The legends as well as the assumption on sub-component redshifts and $b$-values are the same as in Fig. A.1.
Fig. A.4: Different ionisation metal lines (Mg II, O I, Fe II, Si II, S II, Mn II, Ni II, P II, Ti II, C IV, Si IV, and N V) associated with the $z_{\text{abs}} = 2.444$ ESDL A system towards QSO SDSS J1258+1212. We note that N V transitions are heavily contaminated with the Ly$\alpha$ forest and hence we could not find any robust solution for the column density tied with C IV. Hence, we only show the spectrum of “N V $\lambda 1238$” here without the fit. The legends as well as the assumption on sub-component redshifts and $b$-values are the same as in Fig. A.1.
Fig. A.5: Different ionisation metal lines (Mg\textsc{ii}, O\textsc{i}, Fe\textsc{ii}, Si\textsc{ii}, Mn\textsc{ii}, Ni\textsc{ii}, Si\textsc{iv}, C\textsc{iv}, and N\textsc{v}) associated with the $z_{\text{abs}} = 2.482$ ESDLA system towards QSO SDSS J1349+0448. The sub-component redshifts and $b$-values of C\textsc{iv} and N\textsc{v} are also tied together. 'N\textsc{v}$\lambda 1242' is contaminated and hence the transition was not used for fitting. The Si\textsc{iv} profiles are strongly blended and we could not find any robust solution for the column density tied with C\textsc{iv}. Here, we just show the unfitted spectrum for reference. The cyan tick in the 'Si\textsc{ii}$\lambda 1526$' subplot represents a blend with an Mg\textsc{ii} absorption system at $z_{\text{abs}} = 0.8998$. The legends as well as the assumption on sub-component redshifts and $b$-values are the same as in Fig. A.1.
Fig. A.6: Different ionisation metal lines (Mg ii, Fe ii, Si ii, Ar i, N i, O i, O i∗, P ii, Mn ii, Ni ii, C iv, and Si iv) associated with the $z_{\text{abs}} = 2.545$ ESDL A system towards QSO SDSS J1411+1229. The subplot with 'Ar iλ1048' shows the mock Ar i profile on top of the spectrum, heavily contaminated with the Ly$\alpha$ forest and it was not used for fitting. The legends as well as the assumption on sub-component redshifts and $b$-values are the same as in Fig. A.1.
Fig. A.7: Different ionisation metal lines (O\textsubscript{I}, Mg\textsubscript{II}, Fe\textsubscript{II}, Si\textsubscript{II}, Ni\textsubscript{II}, Ca\textsubscript{II}, C\textsubscript{IV}, Si\textsubscript{IV}, and N\textsubscript{V}) associated with the $z_{\text{abs}} = 2.464$ ESDLA system towards QSO SDSS J1513+0352. The N\textsubscript{V} transitions are heavily contaminated with the Ly\alpha forest and hence we could not find any robust solution for the column density tied with C\textsubscript{IV}. Hence, we only show the N\textsubscript{V} absorption profiles here without the fit. The legends as well as the assumption on sub-component redshifts and $b$-values are the same as in Fig. A.1.
Fig. A.8: Fit to C\textsubscript{i} and Cl\textsubscript{i} lines associated with the $z_{\text{abs}} = 2.464$ ESDL system towards QSO SDSS J1513+0352. The plot with neutral Chlorine ('Cl\textsubscript{i} $\lambda$1347' transition) includes velocity components from two other absorption systems, $z_{\text{abs}} = 2.339$ (Si\textsubscript{iv} absorber) and $z_{\text{abs}} = 2.006$ (C\textsubscript{iv} absorber), fitted together. The total C\textsubscript{i} column density ($\log N($C\textsubscript{i}$) = 15.2\pm0.8$, $\log N($C\textsubscript{i}$^\prime) = 15.0\pm0.8$ and $\log N($C\textsubscript{i}$^{\prime\prime}) = 14.6\pm0.7$) with a multi-component fit is consistent with the single component fit result reported in Kanjan et al. (2018).
Fig. A.9: Different ionisation metal lines (Mg ii, Fe ii, Si ii, N i, O i, O i*, S ii, Mn ii, P ii, Ni ii, Ca ii, C iv, and Si iv) associated with the $z_{\text{abs}} = 2.339$ ESDLA system towards QSO SDSS J2140−0321. The plots showing 'O i $\lambda 1302$' and 'O i* $\lambda 1304$' include additional components from 'Si ii $\lambda 1304$' transition. The legends as well as the assumption on sub-component redshifts and $b$-values are the same as in Fig. A.1.

Fig. A.10: Fit to CII and ClI lines associated with the z_{abs} = 2.339 ESDL system towards QSO SDSS J2140−0321. The total CII column density (logN(CII) = 13.18±0.04) with a multi-component fit is ~0.3 dex smaller that the single component fit result reported in Ranjan et al. (2020).
Fig. A.11: Different ionisation metal lines (Mg II, Fe II, Ar I, O I, O I*, N I, Si II, and Mn II) associated with the $z_{\text{abs}} = 2.230$ ESDLA system towards QSO SDSS J2232+1242. The plots show 'O I $\lambda 1302$' and 'O I* $\lambda 1304$'. The subplots showing 'Ar I $\lambda 1066$' and 'N I $\lambda 1134$' transitions have contamination from the Ly$\alpha$ forest that were included while fitting. The legends as well as the assumption on sub-component redshifts and $b$-values are the same as in Fig. A.1.
Fig. A.12: Different ionisation metal lines (Ni II, P II, Ti II, C IV, and Si IV) associated with the $z_{\text{abs}} = 2.230$ ESDL A system towards QSO SDSS J2232+1242. The legends as well as the assumption on sub-component redshifts and $b$-values are the same as in Fig. A.1.
Fig. A.13: Different ionisation metal lines (Mg\textsc{ii}, Fe\textsc{ii}, Si\textsc{ii}, Ar\textsc{i}, O\textsc{i}, Ca\textsc{ii}, S\textsc{ii}, Mn\textsc{ii}, Ni\textsc{ii}, P\textsc{ii}, Si\textsc{iv}, and C\textsc{iv}) associated with the $z_{\text{abs}} = 2.215$ ESDLA system towards QSO SDSS J2246+1328. The plots with neutral Argon (Ar\textsc{i}) includes components from the Ly$\alpha$ forest (H\textsc{i}) lines. The legends as well as the assumption on sub-component redshifts and $b$-values are the same as in Fig. A.1.
Fig. A.14: Different ionisation metal lines (Mg II, Fe II, Si II, O I, Ar I, S II, Mn II, Ni II, C IV, and Si IV) associated with the $z_{\text{abs}} = 2.477$ ESDL A system towards QSO SDSS J2322+0033. The legends as well as the assumption on sub-component redshifts and $b$-values are the same as in Fig. A.1.
