ABSTRACT

Aims. Soft γ-ray emission (100 keV – 10 MeV) has previously been detected in the hard state of several microquasars. In some sources, this emission was found to be highly polarized and was suggested to be emitted at the base of the jet. Until now, no γ-ray polarization had been found in any other state.

Methods. Using INTEGRAL/IBIS, we studied the soft γ-ray spectral and polarization properties of Swift J1727.8–1613 throughout its outburst.

Results. We detect a highly polarized spectral component in both the hard intermediate state and the early stages of the soft intermediate state above 210 keV. In the hard intermediate state, the polarization angle significantly deviates from the compact jet angle projected onto the sky, whereas in the soft intermediate state they are closely aligned. This constitutes the first detection of jet-aligned polarization in the soft γ-ray for a microquasar. We attribute this polarized spectral component to synchrotron emission from the jet, which indicates that some of the jet might persist into the softer states.

Key words. X-rays: binaries - Gamma rays: general - Polarization - stars: individual: Swift J1727.8-1613

1. Introduction

Black hole X-ray binaries (BHXBs) are compact binary systems that host a (candidate) black hole accreting matter from a companion star. They are commonly found to be sources of powerful jets and are therefore dubbed microquasars. Most BHXBs are transient sources seen to transit between various spectral states. In the (low) hard state (LHS), the 1–100 keV spectrum is phenomenologically described by a power-law with an exponential cutoff, interpreted as the thermal Comptonization of photons from an accretion disk by hot electrons. In the (high) soft state (HSS), the accretion disk emission becomes dominant below 10 keV and a weak power-law component may be present above 10 keV. Between these two states are the hard and soft intermediate states (respectively, the HIMS and SIMS; see, e.g., Belloni 2010; Remillard & McClintock 2006).

In several BHXBs, an additional component is sometimes seen above ~200 keV (e.g., Grove et al. 1998; Jourdain et al. 2012). It is usually brighter in the LHS and the HIMS (e.g., Rodriguez et al. 2015; Cangemi et al. 2023b, and references therein). This “hard tail” could originate from synchrotron emission at the base of the jet (Markoff et al. 2005) or from a hybrid corona of thermalized and non-thermalized electrons (Gierliński et al. 1999). Polarization above ~400 keV was first detected in the persistent microquasar Cyg X-1 by the Imager onboard the INTEGRAL Satellite (IBIS; Laurent et al. 2011) and INTEGRAL/IBIS Spectrometer (SPI; Jourdain et al. 2012). The source was later confirmed to be polarized in the LHS (Rodriguez et al. 2015), and in the HIMS with AstroSat/CZTI (Chattopadhyay et al. 2023). These three independent instruments gave compatible polarization angles (PAs) and polarization fractions (PFs) in their overlapping energy ranges (see Fig. 3 of Chattopadhyay et al. 2023). LHS polarization was also found in the transients MAXI J1348–630 and MAXI J1820+070 (Cangemi et al. 2023b, hereafter CRB23).

Swift J1727.8–1613 (J1727 hereafter) was discovered as a γ-ray burst by Swift in August 2023 (Page et al. 2023) and identified as a BHXB with follow-up observations from the Monitor of All-sky X-ray Image (MAXI) (Nakajima et al. 2023). The source was extremely bright at peak (up to 8 Crab in the 2–20 keV band), making it one of the brightest BHXBs ever detected. The source was intensely monitored from the radio to γ-rays and notably showed the presence of a hard tail in the LHS and HIMS (Cangemi et al. 2023a). The compact jet has been resolved in the radio, and its position angle was estimated to be −0.60 ± 0.07° (Wood et al. 2024).

This Letter is organized as follows: We describe the INTEGRAL observations and data reduction in Sect. 2, focusing on the calibration necessary for the most recent data. We then present the results of our phenomenological spectral study and polarization analysis in Sect. 3 and discuss our findings in Sect. 4.

Article number, page 1 of 7
2. Data reduction and analysis

The journal of the INTEGRAL observations of J1727 is reported in Table A.1. We used data from IBIS (Ubertini et al. 2003) and from the Joint European Monitor for X-rays (JEM-X; Lund et al. 2003). IBIS consists of two detector planes, the IBIS Soft Gamma Ray Imager (ISGRI; Lebrun et al. 2003), sensitive in the 30–500 keV range, and the PixelImaging Imaging Caesium Iodide Telescope (PIcSfT; Labanti et al. 2003), sensitive in the 150 keV–10 MeV range. These detectors can either be used independently or together as a “Compton telescope,” which allows the 200 keV–10 MeV polarization to be probed (Sect. 2.2).

2.1. JEM-X and ISGRI data reduction

ISGRI products were extracted with the INTEGRAL Off-line Scientific Analysis (OSA) software v11.2, following standard reduction processes1. For observations after 2020, the ISGRI calibration is (currently) not up to date. We thus created homecorrected ancillary response files using recent ISGRI spectra of the Crab that were adjusted to match the corresponding SPI spectra. The correction is particularly important in the 30–100 keV band, where ISGRI suffers most from CdTe aging. Fluxes were obtained for the 30–50, 50–100, and 100–200 keV ranges from individual pointings, the ~1700 s long “Science Windows” (ScWs). We first stacked all ScWs from the same satellite revolution to obtain source spectra. We added a systematic error of 3% to each spectral channel as recommended in the User Manual.

To better constrain the continuum, we added the 5–20 keV spectra from JEM-X unit 1, applying the same revolution-based stacking as for ISGRI. We included 3% systematic errors on the spectra that we obtained with the procedure described by CRB232).

2.2. Compton mode and polarization

Photons with energy ≥ 200 keV can be Compton-scattered by ISGRI and absorbed by PICsIT. The energy of the incident radiation can then be deduced from the energy deposited in both layers of IBIS (see Forot et al. 2007; Forot et al. 2008). It is also possible to reconstruct the azimuthal scattering angle, , from the interaction points on both detectors, such that the PA of the incident radiation can be reconstructed.

Polarization measurements of the Crab between 250 and 450 keV are found to be compatible with independent SPI measurements when applying these corrections (Bouchet et al. 2024). This allowed us to explore the polarization in the 210–300 keV range with INTEGRAL (IBIS) for the first time. Appendix B gives a brief overview of the principles of polarization measurements and the estimates of significances and upper limits.

3. Results

3.1. State classification and spectral evolution

Figure 1 shows the light curves of the entire outburst of J1727 with data from IBIS/ISGRI (20–200 keV), the 338 MHz VLA Low-band Ionsphere and Transient Experiment (VLITE; Peters et al. 2023), and the RATAN-600 radio telescope at 11.2 GHz (extracted from Ingram et al. 2023), as well as the corresponding hardness intensity diagram obtained with the MAXI data. We used the spectral state classification and dates of transitions reported from the analysis of the Neutron Star Interior Composition Explorer (NICER) data (Draghis et al. 2023; Bollemeijer et al. 2023a,b). The source first rises in the LHS (revs. 2678 and 2680; see Table A.1) and starts transiting to the HIMS around MJD 60185 (rev. 2681). The INTEGRAL light curves decrease rather smoothly until MJD ~ 60221 (rev. 2694), at which point we see the occurrence of ~150–200 mJy 11.5 GHz radio flares (MJDs ~60205 and 60221), which occurred around the time of the transition to the SIMS. The source had small re-brightenings at high energies around MJDs 60226–60229 (revs. 2695 and 2696) before experiencing a bright radio flare (MJD 60230) that preceded its global decrease.

We performed a phenomenological analysis of the 5–15 keV and 35–500 keV JEM-X unit 1 and ISGRI spectra on a revolution-by-revolution basis with simple models of the XSpec software (Arnaud 1996): a power-law (POWERLAW, hereafter PL) and a cutoff power-law (CUTOFFPL, hereafter CPL) for the continuum. A normalization constant (frozen to 1 for IBIS) was included to account, in particular, for the differences in IBIS and JEM-X exposure times, as well as for imperfections in source reconstruction due to its large brightness. The best model was retained on the basis of the value of the fit, and, when similarly good fits were obtained with various combinations, we retained the one with the JEM-X normalization constant closest to 1. We then combined spectra that were close in time and spectral behavior to obtain a better statistical significance. Some fits have larger values, which can be due to the source becoming fainter at the end of the outburst and thus the relative background increasing (due to the other sources in this crowded field), which may produce the residuals at higher energies. The values are nevertheless acceptable for our phenomenological analysis. An overview of the state-based stacked observations is given in Table A.1. Observations 1–5 and 7 were fitted with a CPL, covering the spectra up to ~100 keV, and an additional PL for Obs. 1–4, covering the excess above ~100 keV. Observations 6 and 8 are best described with a single PL. A Gaussian line (GAUS) representing the Fe + line was added for Obs. 2–5 (see Fig. 2, left), and an accretion disk (diskbb) fixed at an inner disk temperature of 1 keV was added for Obs. 6–8 (see Fig. 2, right). The results of these phenomenological fits and their statistical significance are reported in Table 1.

3.2. Polarization properties

Figure 3 shows the temporal evolution of the PF and PA of our grouped observations in the 210–250 keV and 250–300 keV ranges. All polarimetric values along with their S/Ns can be found in Table C.1. All errors are given for a 68% confidence interval. No polarization is detected in Obs. 1. The exposure time is shorter than for the next combined observation, but the much higher flux still allows us to put satisfying upper limits of 19% (respectively 25%) in the 210–250 keV bands (respectively 250–300 keV) for this LHS observation. We detect polarized signals in all HIMS observations with PF ≥ PF and a rather stable and similar PA in the two energy ranges in Obs. 2 to 4 (around ~45°). The 210–250 keV (respectively 250–300 keV) PF increases up to ±8% (respectively ±17%) in Obs. 4. Significant evolution is visible in Obs. 5, where PA = −30 ± 7° with a decrease in PF. A more detailed view of the energy dependence is shown in Appendix C.

Fig. 1: Evolution of J1727 outburst. Left: Hardness intensity diagrams from the MAXI/GSC data. Data points closest in time to INTEGRAL observations are highlighted as crosses for those with no polarization, and as black (respectively red) squares for those with a PA misaligned (respectively aligned) with the jet angle. Right: INTEGRAL/ISGRI ScW-based and radio (VLITE and RATAN) light curves of J1727. In both plots the numbers show the locations of our grouped observations.

Table 1: Parameters from 5–500 keV spectral fits for the observation groups defined in Fig. 1.

4. Discussion

4.1. Hard-tail origin

Our spectral analysis of J1727 confirms the presence of a ≥100 keV hard tail (Cangemi et al. 2023a) persisting throughout the whole HIMS (Table 1) in addition to a CPL, interpreted as thermal Comptonization, dominating below 100 keV. At the transition to the SIMS (Obs. 6), the CPL is replaced by a PL extending out to about 400 keV (Fig. 2, left). Observation 7 can be fitted with a CPL, but the cutoff energy is above ~250 keV and not well constrained, meaning it could be modeled by a simple PL like Obs. 6 and 8 if we had access to better data at higher energies. The presence of a hard tail on top of Comptonization and the persistence of a ≥100 keV PL emission during softer states is similar to the behavior of Cyg X-1 (McConnell et al. 2002), MAXI J1348–630, and MAXI J1535–571 (CRB23). The CPL components seems to disappear (quasi-)simultaneously with a radio flare (Fig. 1), which might indicate that (part of) the Comptonizing plasma is ejected (see, e.g., Rodriguez et al. 2003, 2008, for similar behavior in XTE J1550–564 and GRS 1915+105).

The polarization properties of J1727 are different in both states. The PA in the HIMS is stable with time and energy (Figs. 3 and C.1), whereas the PF increases with energy and varies with time. The polarization properties change in Obs. 5, with a significant evolution of the PA and a decrease in the PF. While the misalignment of the PA with the radio jet may call into question the association of the hard tail with the radio jet, similar discrepancies are also seen in, for example, Cyg X-1 (Laurent et al. 2011). The level of the PF in all HIMS observations is compatible with the maximum PF expected from synchrotron radiation in an ideal case (~75% for a $\Gamma \approx 2.1$ PL; Bjornsson & Blumenthal 1982), and it is challenging to reconcile PF values above 40% with another emission mechanism.

The difference in position angle between the jet and polarization in the HIMS was discussed by Russell & Shahbaz...
The detection of a polarized signal near the probable transition toward the SIMS with a large PF, 210–250 keV (the signal is too weak at higher energies for a meaningful measure), is new and unexpected. In this band, the PA is aligned with the compact jet axis resolved in the radio. The quasi-simultaneous occurrence of a radio flare (∼200 mJy at 11.2 GHz), probably associated with a discrete ejection of material, suggests an association of the polarized high-energy PL component with the jet. The 62% PF we measure is also compatible with the maximum expected polarization (80%) from synchrotron emission with a $\Gamma = 2.7$ PL. This favors the jet as the source of the SIMS PL emission, as proposed by Jourdain et al. (2014) for Cyg X-1. We also note that for synchrotron emission, the magnetic field interacting with the electrons has to be distributed orthogonally to the jet axis, and the inclination of the jet (i.e., the angle between the jet axis and the line of sight) will likely affect the PF. According to Laing (1980), an inclination angle of at least ∼60° is required to achieve this level of polarization for a randomly distributed magnetic field in a slab orthogonal to the jet. Blazars dominated by synchrotron emission in the X-ray were observed to be polarized at a few percent (Middei et al. 2023) and up to 30% (Kouchner et al. 2024) despite their intrinsically low inclination.

4.2. Simple phenomenological model

To explain the evolution of polarization, we used a phenomenological two-population toy model on top of the usual inverse Compton emission. This approach is compatible with both hypotheses of Russell & Shahbaz (2014) and aims to provide a simplified framework for our discussion: population 1 interacts with...
a perpendicular magnetic field, producing synchrotron emission with PA\textsubscript{1} parallel to the jet; and population 2 produces synchrotron emission polarized at a shifted angle PA\textsubscript{2} compared to population 1 because of a different electron pitch angle. This simplistic representation is also motivated by the persistence of radio emission throughout the whole outburst (Fig. 1), which may indicate the persistence of some kind of jet.

We can compute different polarized emissions with different PAs, PFs (assumed constant with energy for simplicity), and energy flux distributions \(f_1 = F_1/F_{\text{tot}}\) added together. From the angle distribution of the emitted photons (Eq. B.1), we deduce the resulting polarization parameters as a function of energy,

\[
\text{PA}(E) = \frac{1}{2} \arctan \left( \frac{\sum_i f_i(E) \text{PF}_i \sin(2\text{PA}_i)}{\sum_i f_i(E) \text{PF}_i \cos(2\text{PA}_i)} \right)
\]

and

\[
\text{PF}(E) = \frac{\sum_i f_i(E) \text{PF}_i \cos(2\text{PA}_i)}{\cos(2\text{PA}(E))}.
\]

During Obs. 1 (LHS with PF < 25\%), the radio flux at 338 MHz is lower by a factor of at least 5 compared to the next few observations in the HIMS (see Fig. 1, right). The hard X-ray flux, on the other hand, is much higher, especially below 100 keV. We can interpret this as the weakly polarized Comptonized medium being dominant up to 300 keV in the LHS \(f_{\text{comptimized}} \approx 1\), \(PF_{\text{comptimized}} \leq 20\%\), at which time the polarized synchrotron emission from the jet is low. Chattopadhyay et al. (2023) reached the same conclusion regarding the pure hard state of Cyg X-1 \(\Gamma < 1.78\), for which they find a PF upper limit of 7\% in the 100–380 keV energy range. Unfortunately, our spectral fit has a low emission from the jet is low. Chattopadhyay et al. (2023) reached the 200–1000 keV energy range. In the hypothesis of synchrotron emission, the magnetic field with which the electrons interact should be orthogonal to the jet axis, similarly to the radio synchrotron emission. We also find a misaligned but stable PA in the HIMS, with a PF increasing with energy, hinting at a different electron population related to the hard tail seen above 200 keV.

We conclude that the medium producing the soft \(\gamma\)-rays evolves during the outburst, and that the PL observed in the SIMS could originate in part from synchrotron emission, similar to the hard tail seen in the HIMS.

5. Conclusion

For the very first time, a soft \(\gamma\)-ray polarized signal was found in a BHXB with a PA aligned within a few degrees with the black hole jet axis. This emission coincides with a radio flare and was most likely seen during the transition to the SIMS. The high PF is compatible with optically thin synchrotron emission, and other emission mechanisms should only marginally contribute to the overall flux. In the hypothesis of synchrotron emission, the magnetic field with which the electrons interact should be orthogonal to the jet axis, similarly to the radio synchrotron emission. We also find a misaligned but stable PA in the HIMS, with a PF increasing with energy, hinting at a different electron population related to the hard tail seen above 200 keV.

We conclude that the medium producing the soft \(\gamma\)-rays evolves during the outburst, and that the PL observed in the SIMS could originate in part from synchrotron emission, similar to the hard tail seen in the HIMS.

Based on measurements done with the onboard $^{22}$Na calibration source (half-life of 2.6 yrs) during the first years of the mission. We then corrected the offset with the 511 keV internal background line of the satellite itself for each ScW used in our analysis.

We determine the probability of a detection based on a probability density function $p(a, \phi)$ (see, e.g., Forot et al. 2007), which we first integrate over $\phi$ while assuming that the source is unpolarized ($a_{\text{mes}} = 0$). We then compute the probability for observations of this unpolarized source yielding a modulation, $a$, which is greater than the modulation we measure, $a_{\text{mes}}$, by integrating the probability density function from $a_{\text{mes}}$ to $a_{100}$. The resulting probability is

$$p_{\text{unpolarized}} = e^{-k^2 a_{\text{mes}}} - e^{-k^2 a_{100}}, \quad (B.2)$$

where $k^2 = N p_c^2 / (2 \sigma_c^2)$, with $N_p$ the number of angle bins, $c$ the count-rate, and $\sigma_c$ the standard deviation of $c$.

Following CRB23 we consider here that polarization is detected when the S/N in the source of the energy range considered is above $5 \sqrt{N_p}$, and when the unpolarized probability is less than 1%. In the cases where we have a good enough signal-to-noise ratio but an insufficient $p_{\text{unpolarized}}$, we can reverse (Eq. B.2) and divide it by $a_{100}$ to estimate the upper limit of PF,

$$\text{PF}_{\text{up}} = \sqrt{-\ln(p + \exp(-k^2 a_{100}^2 / a_{100}^2)) / k^2 a_{100}^2}, \quad (B.3)$$

Here $p$ is the probability that the true PF is in fact higher than $\text{PF}_{\text{up}}$. We used $p = 1\%$ to match our detection criteria.

Appendix C: Polarization evolution with energy

Despite the variations of PF, we combined Obs. 2 to 4 to look at the energy dependence of the polarization (Fig. C.1). The PF increases with energy from 25% to about 60% at 300 keV and stays between 60 and 80% for higher energies. The PA shows a good stability with energy around a mean value of $-46.0 \pm 3.9^\circ$, suggesting that the polarization in these energy ranges has the same origin.
